
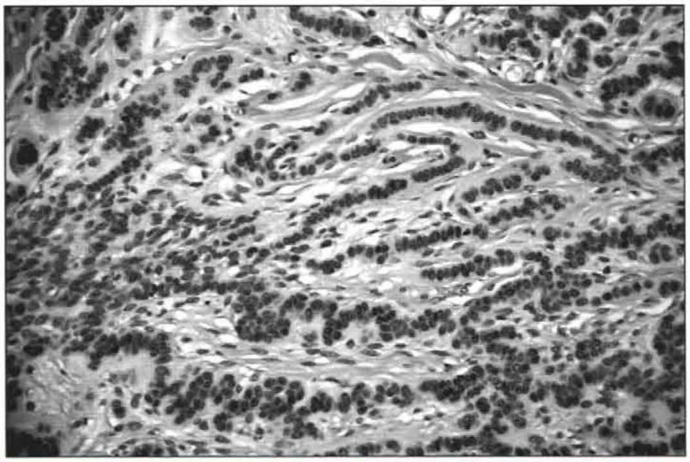

Figure 5.133 Trichoblastoma. Long ribbons of pale epithelial cells extend into the dermis.

outer root-sheath cells. Each tumor follicle is surrounded by a thick, homogeneous basal lamina resembling the vitreous sheath of the normal follicle. The epithelial cells in the *isthmic tricholemmoma* are arranged as islands and radiating cords that may intersect or be associated with the epidermis. The tumor cells show central trichilemmal keratinization.

Trichoblastoma is *a benign tumor derived from the primitive hair germ of embryonic follicular development.* There are ribbon, trabecular, granular, and spindle cell trichoblastomas. In dogs, these tumors were formerly classified as basal cell tumors.

- The **ribbon trichoblastoma** is a dermal to subcutaneous tumor formed by long, narrow, branching cords of pale eosinophilic epithelial cells (Fig. 5.133) that may join or radiate from a large central aggregate (medusoid pattern). A mucinous stroma is frequently associated with the medusoid pattern. Cell borders are indistinct. Nuclei of tumors arranged in cords often palisade perpendicular to the long axis of the cord. Mitotic figures may be numerous. Abundant collagen that may appear hyalinized accompanies the tumor cells.
- **Trabecular trichoblastomas** occur in the dermis and consist of multiple lobules of pale eosinophilic epithelial cells with scant poorly demarcated cytoplasm and euchromatic nuclei. The cells at the periphery of the lobules palisade while centrally located cells have more abundant cytoplasm.
- **Granular trichoblastoma** tumor cells have large numbers of intracytoplasmic eosinophilic granules and eccentrically placed nuclei.
- **Spindle cell trichoblastomas** are most often seen in cats and consist of trabeculae and lobules of elongated, streaming, basaloid epithelial cells within a fibrous stroma. Tumor cells have scant cytoplasm, oval nuclei with inconspicuous nucleoli, and rare mitoses. Melanin may be present in the tumor cells and accompanying melanophages.

Pilomatricoma (*pilomatrixoma, epithelioma of Malherbe, necrotizing and calcifying epithelioma*), macroscopically resembles trichoepithelioma (Fig. 5.134A) but is often more heavily mineralized and consists of fewer, larger cysts than does trichoepithelioma. Pilomatricomas are believed to be derived from primitive hair

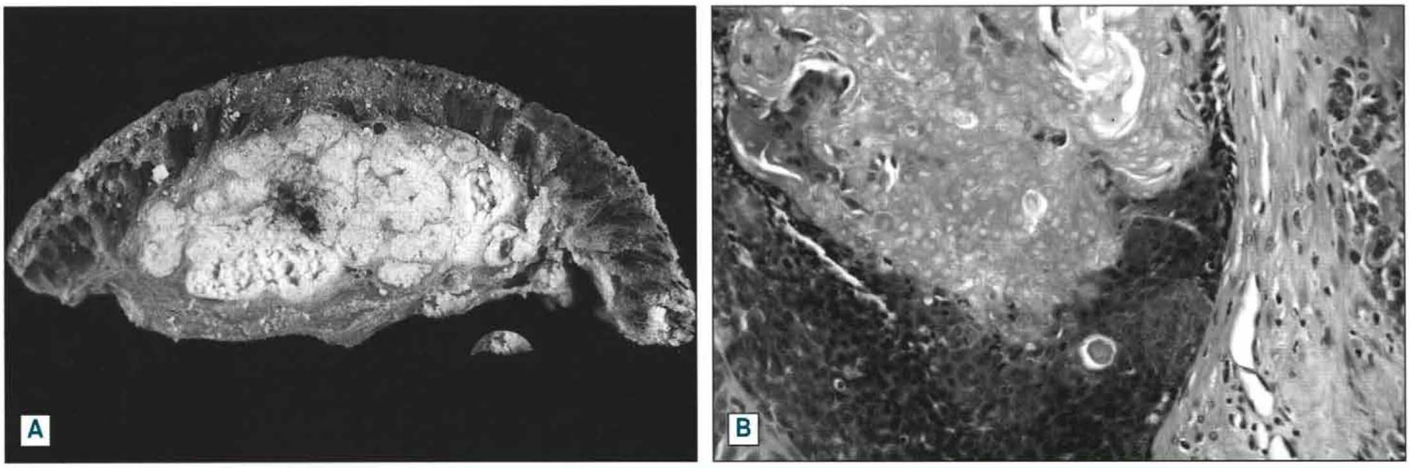

Figure 5.134 Pilomatricoma in a dog. **A.** Multilobulated, mineralized, and well-demarcated keratinizing dermal tumor. **B.** Multiple lobules of basal cells with abrupt keratinization. Note shadow cells in the center of the lobules.

matrix and thus show incomplete differentiation towards hair cortex. *The typical microscopic morphology is of one or more large, thick-walled cysts partially filled with so-called shadow or ghost cells* (Fig. 5.134B) *typical of matrical differentiation.* These cells are flattened eosinophilic epithelial cells with a central empty halo in place of the lysed nucleus. The cyst wall is composed of multiple layers of basal cells, showing a sudden zonal degeneration to form the central laminations of shadow cells. Mitoses may be present. Mineralization of shadow cells is very common, and cyst rupture results in the pyogranulomatous inflammation that is very typical of these tumors. Foci of necrosis within the tumor are frequently seen, and mineralization or even ossification within the stroma occurs occasionally.

Pilomatricomas are almost always single and benign. They occur most often on the back, neck and tail. One report indicates that Miniature Poodles and Kerry Blue Terriers develop these tumors more frequently than other breeds. The very few reports of behaviorally malignant tumors describe tumors with greater mitotic activity and nuclear pleomorphism; however, some of these tumors were not readily distinguished at initial presentation from benign tumors and the diagnosis of malignancy was made in retrospect after documented metastasis. Metastases to the regional lymph nodes, lung and bone have been documented.

Tumors arising from sebaceous or modified sebaceous glands

Sebaceous glands give rise to *sebaceous gland hyperplasia, sebaceous adenoma, sebaceous epithelioma, and sebaceous carcinoma.* **Modified sebaceous glands** include the Meibomian glands of the eyelid, which give rise to *Meibomian gland adenomas, epitheliomas, and carcinomas* that are histologically identical to the corresponding sebaceous gland lesion and will not be described separately. The **hepatoid (perianal) glands** are also modified sebaceous glands that give rise to hepatoid gland adenomas, epitheliomas, and carcinomas. *Epitheliomas are considered to be lesions intermediate between an adenoma and carcinoma.*

Sebaceous gland hyperplasia is seen as single or multiple, raised, multilobulated masses within the superficial dermis below focally hyperplastic, hyperkeratotic epidermis. Many are ulcerated by continued tumor growth or by trauma. Most are less than 1 cm in diameter and are most frequently submitted with clinical diagnoses of "multiple papillomas." Histologically, each tumor consists of rather symmetrical hyperplasia of a single sebaceous gland clustered about a keratinized sebaceous duct. In some specimens, more than one gland is involved. The sebaceous cells (sebocytes) are fully mature and the peripheral rim of basal (reserve) cell population is inconspicuous. Surrounding dermis and adnexa are compressed. The hyperplasia is multiple in about 40% of affected dogs.

Sebaceous adenoma is *comprised primarily of mature sebaceous cells, but differs from hyperplasia in that there are more basal (reserve) cells than in hyperplasia, and the lobular proliferation is greater, less symmetrical, and not necessarily related to a single sebaceous duct.* The lesion compresses adjacent structures. Melanin within tumor cells, and stromal melanocytes and melanophages may be present and cause the tumor to be grossly pigmented. **Sebaceous ductal adenomas** are similar tumors but are comprised primarily of large numbers of haphazardly arranged ducts with intervening clusters of sebocytes and reserve cells.

Sebaceous epithelioma *is a term used by some to refer to sebaceous gland tumors of low-grade malignancy.* These tumors have mostly basaloid reserve cells with numerous mitoses and only scattered single or small clusters of well-differentiated sebocytes. Horn cysts suggesting ductal differentiation may be present (Fig. 5.135). Melanocytes and melanophages may be present within the intervening stroma and the basaloid cells may contain melanin also.

Sebaceous carcinomas are occasionally encountered in dogs and rarely in cats. *Sebaceous carcinomas are locally infiltrative, solitary, poorly circumscribed tumors made up of pleomorphic cells that show some evidence of sebaceous differentiation.* The sebaceous carcinoma lacks complete or orderly sebaceous cell maturation, and distinct reserve cell populations are not present. Lobule formation is often present but is not prominent. Mitotic figures, anisocytosis, anisokaryosis and hyperchromasia are present as the cytologic counterparts of malignancy. The prognosis following wide surgical excision seems to be good, although no large series has been published. Differentiation from liposarcomas and balloon cell melanomas may be difficult.

Perianal gland adenomas (*hepatoid gland tumor, circumanal gland tumor*) are common in intact, aged male dogs. They occur occasionally in females and rarely in castrated males. They have not

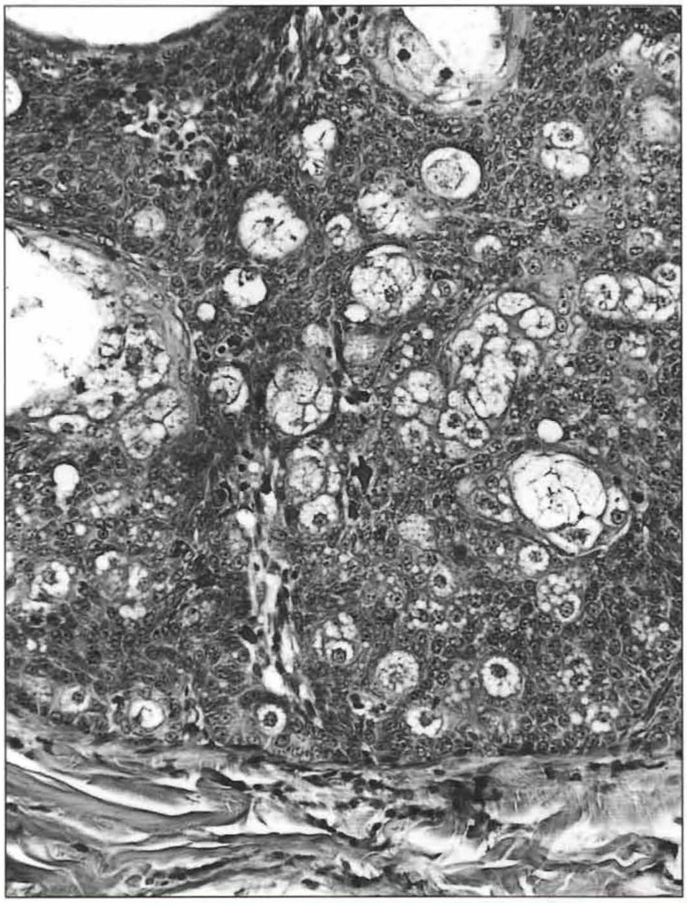

Figure 5.135 Sebaceous epithelioma in a dog.

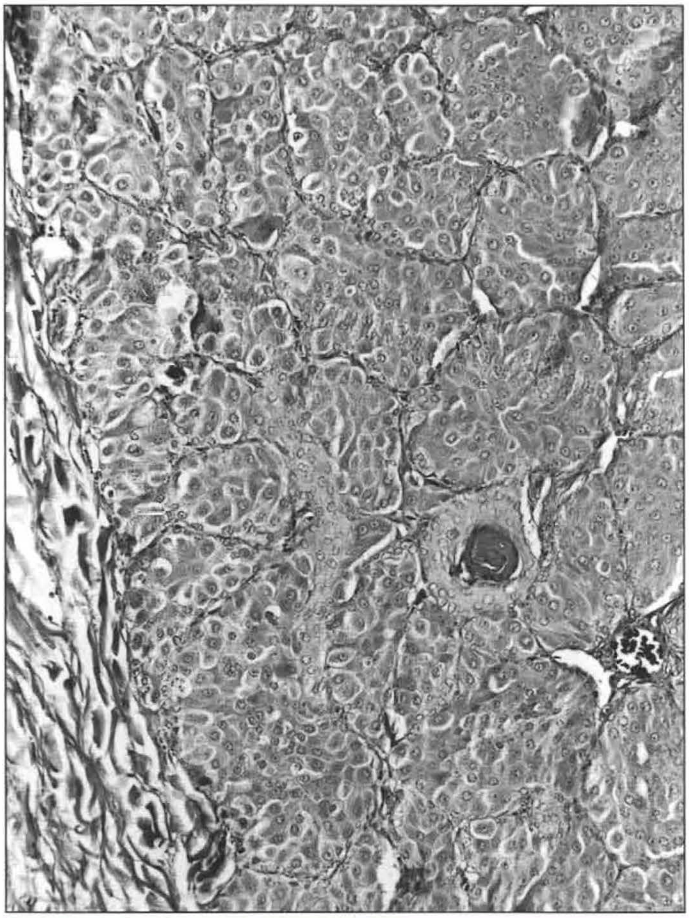

Figure 5.136 Perianal gland adenoma. Lobular arrangement of hepatoid cells and foci of squamous metaplasia.

been reported in other domestic species. *Most perianal gland tumors are called adenomas, even though the lobular development is so uniform that the tumor is more likely to be hormone-dependent hyperplasia.* The strong predilection for intact male dogs and the regression of about 95% of these tumors following castration also points to hyperplasia rather than true neoplasia. Nonetheless, "perianal adenoma" seems firmly entrenched and the difference in terminology is of no practical importance. The tumor growths most commonly occur in the perianal area, but about 10% occur in sites of ectopic perianal gland tissue such as tail, flank, back, prepuce and even chin. Of these, the ventral skin of the tail is the most frequent location.

The *gross appearance* of perianal gland adenomas is of one or more raised rubbery masses that may grow to 10 cm or more in diameter. Ulceration and secondary infection are common, and can serve to confuse the diagnosis. The typical tumor consists of multiple tan lobules separated by a delicate but definite collagenous stroma. *The histologic lesion is similar to normal perianal gland.* Well-differentiated tumors consist of islands, cords, and lobules of polygonal cells with abundant, finely vacuolated eosinophilic cytoplasm and a central, small, round, vesicular nucleus. The cells resemble hepatocytes and these tumors are sometimes called "hepatoid gland" tumors (Fig. 5.136). At the periphery of each lobule is a rim of basal reserve cells, and in some tumors these cells may predominate over the fully differentiated hepatoid cells. Mitotic activity of reserve cell, necrosis, hemorrhage, secondary inflammation, squamous metaplasia and squamous pearl formation (ductal differentiation) are common and are no cause for concern. Some cells may resemble sebocytes. Aggregates of tumor cells are separated by a fine fibrovascular stroma and tumors are often encapsulated. *Local excision and castration is curative and prevents the development of new perianal gland tumors.*

Perianal gland epitheliomas are tumors of low-grade malignancy comprised of mostly reserve cells. Mitotic activity is increased in comparison to the adenomas but nuclear atypia is not present.

Perianal gland carcinomas account for no more than 5% of all perianal tumors if rigorous diagnostic criteria are used. They are relatively more common in castrated males and in females. They exhibit the usual features of malignancy: variation in nuclear and cytoplasmic mass, poor cytoplasmic differentiation, frequent mitotic figures, and lack of organized lobule formation. Local tissue invasion should be evident. Lymphatic invasion must be diagnosed with caution since compression of reserve cells by lobular expansion may simulate a tumor embolus surrounded by lymphatic endothelium. Direct extension into the pelvic canal or metastasis to regional lymph nodes occurs as a late event in chronically neglected tumors. Castration has no demonstrated effect on tumor behavior.

Tumors arising from apocrine and modified apocrine glands

Tumors of the *apocrine (paratrichial) sweat glands* are the least frequent of the adnexal skin tumors in dogs. They are relatively more common

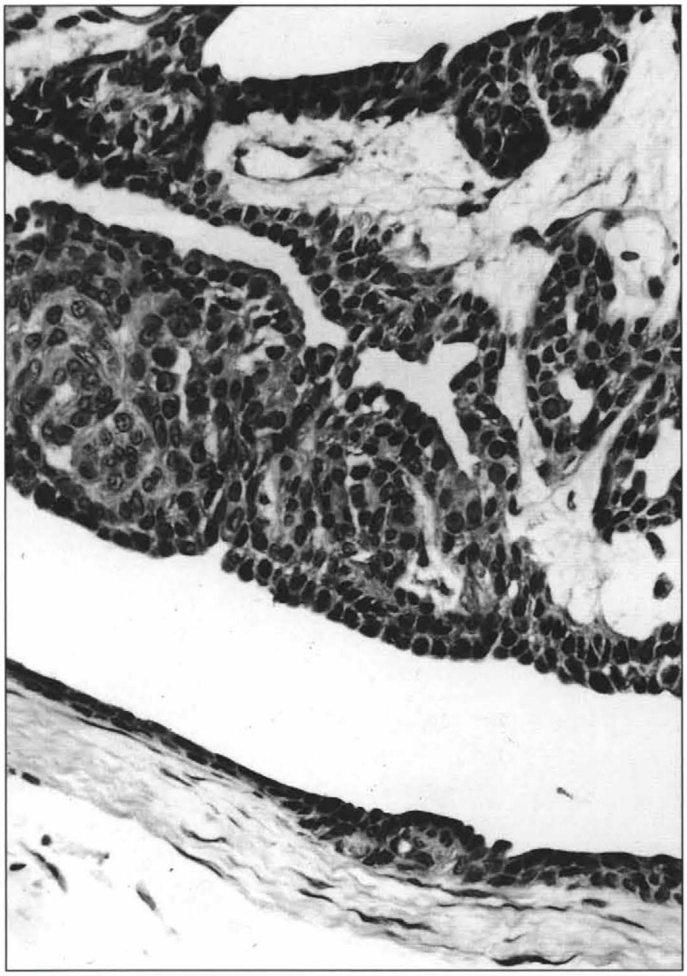

Figure 5.137 Papillary apocrine adenoma.

in cats. There is a single report of a mixed sweat gland tumor in a bull. Tumors of the eccrine sweat glands are rare but histologically distinctive tumors occurring in the footpads.

Apocrine gland adenomas include *cystic and papillary types*, the latter merely a variant of the former. The cystic lesion consists of one or more cavities lined by well-differentiated cuboidal-to-columnar epithelium with eosinophilic cytoplasm and basally located nuclei, often with the apical secretory blebs typical of normal apocrine glands. Many tumors have at least some tubules lined by an orderly bi-layer of cuboidal epithelium, perhaps an effort by the tumor cells to recreate the structure of the duct of the normal gland (Fig. 5.137). Proliferation of epithelium may result in intraluminal papillary growths supported by a delicate fibrous stroma. The proliferation may fill the cyst lumen, or lumens may contain eosinophilic secretions.

Apocrine gland carcinomas include *solid, cystic or tubular types*, the latter clearly predominating. The cystic tumors have intraluminal papillary growths. Apocrine carcinomas are locally aggressive growths, spreading through the dermis, subcutis and muscle from the primary focus. Invasive tumor cells are often accompanied by desmoplasia. Lymphatic invasion and regional lymph node and pulmonary metastasis are common. The histology of carcinomas differs from their benign counterparts primarily in the criteria of loss of polarity and local stromal invasion, as mitotic figures and nuclear and cellular pleomorphism may be variable. The tubular carcinomas have focal cystic or solid areas and are typically very scirrhous. Identification is based upon tubules retaining differentiation to resemble sweat glands, particularly the presence of secretory blebs at the luminal surface. The sweat gland carcinoma is the only primary tubular adenocarcinoma of skin.

Complex and mixed apocrine gland tumors are rare. The proliferation involves both epithelial cells and the periglandular myoepithelial sheath, and may be analogous to the mixed mammary tumor of dogs. Mucinous, chondroid and osseous metaplasia within the tumor stroma is allegedly of myoepithelial origin. The malignant version of this tumor varies from the benign tumor in that the glandular epithelial component demonstrates features of anaplasia and stromal invasion. On rare occasions, both glandular and myoepithelial components demonstrate features of malignancy and the tumor is referred to as an **apocrine gland carcinosarcoma** or **mixed malignant apocrine gland tumor**.

Benign and malignant tumors with differentiation towards apocrine ducts may occur. **Apocrine ductal adenomas** and **ductal carcinomas** are characterized by multilobular and sometimes cystic dermal-to-subcutaneous masses formed by a double layer of basophilic epithelial cells with scant, clear cytoplasm. Cells adjacent to the basement membrane zone may be fusiform. Squamous differentiation may be present. Malignant tumors have nuclear and cellular pleomorphism and stromal invasion. Lymphatic invasion and metastasis are not common.

Ceruminous glands *can give rise to adenomas, complex and mixed adenomas and the malignant versions of these tumors*. Morphologic features are very similar to those described for the apocrine gland counterpart with the additional distinguishing feature of *brown luminal secretions* on H&E-stained sections. In addition, foci of tumor cells may be found within the overlying epithelium and secondary inflammation is more common.

Carcinoma of the apocrine glands of the anal sac is an uncommon but very malignant tumor of *old female dogs*. Males are rarely affected. The tumor histologically varies from solid, rosette, to tubular types. The solid form consists of sheets of relatively monomorphic polygonal cells with scant eosinophilic cytoplasm and round-to-oval hyperchromatic nuclei. In the rosette form, tumor cells with peripheral nuclei are arranged radially, sometimes surrounding small amounts of eosinophilic secretory material. The tubular arrangement has larger cells with abundant eosinophilic cytoplasm and hyperchromatic nuclei. Tubules are filled with eosinophilic secretions. These tumors are invasive, induce a desmoplastic response, and almost invariably spread to regional lymph nodes and then various viscera. Over half have already metastasized prior to diagnosis. Tumor growth is often directed inward through the pelvic canal so that a grossly visible perianal mass is seen in only about 50% of cases. The unusual feature of the tumor is its ability regularly to *induce hypercalcemia in affected dogs* (see Vol. 3, Endocrine glands).

Tumors of **atrichial (eccrine) glands** are rare but do occur as *adenomas or scirrhous tubular carcinomas* within the loose connective tissue of the pad of dogs and cats. Tumor cells have very pale eosinophilic cytoplasm and basally located nuclei. **Eccrine gland carcinomas** are morphologically similar to apocrine gland carcinomas. Differentiation is dependent upon knowing the site of origin.

Melanocytic tumors

Tumors derived from melanocytes or melanoblasts are of *neuroectodermal origin*. They have been reported in most species of domestic animals and many wildlife species, although they are most common in dogs, horses, and some breeds of swine. There are some species differences in melanocytic tumors. In **dogs**, *melanomas in the oral cavity and non-haired skin of the lip are almost invariably malignant.* Those of the nailbeds also are frequently malignant, whereas cutaneous tumors are more commonly benign. In **horses**, melanomas occasionally occur as congenital tumors, however they are most common in *older gray horses with a site predilection for the perineum, genital area, and distal limbs* (Fig. 5.138). The behavior of melanomas in horses is difficult to predict based on histologic features. They can be clinically malignant and aggressive from the outset, or they may demonstrate slow growth for years with a sudden onset of malignant behavior, or growth can be slow for many years without evidence of metastasis. In some breeds of **swine**, such as Sinclair miniature swine and Hormel crosses (MeLiM), melanomas can occur as *congenital tumors*, and these breeds have been extensively used in biomedical research. Melanomas are uncommon in **cats** and are often *amelanotic*. Melanomas in **cattle** may occur as a congenital lesion, or they may occur at any age. Most are benign in cattle, although occasional tumors are malignant. Melanocytic tumors are uncommon in **goats** and **sheep** and are generally pigmented.

The *histologic diagnosis* of melanocytic tumors is complicated by the fact that they can display various degrees of pigmentation, from heavily pigmented to amelanotic. In addition, neoplastic melanocytes can be pleomorphic, and melanocytic tumors can display a variety of cell shapes, including *spindle cell, balloon cell (clear cell), epithelioid cell, and signet-ring cell*, thus making them difficult to distinguish from poorly differentiated sarcomas and carcinomas. *Junctional activity can be helpful in identification* (Fig. 5.139), as the only other tumors to display this activity are epitheliotropic lymphoma, and rarely, cutaneous histiocytomas. The advances in development of immunohistochemical detection of melanocytic markers has aided greatly in diagnosis of these tumors, particularly in the diagnosis of amelanotic melanomas. While antibodies against vimentin, S-100, and neuron-specific enolase are sensitive for tumors of melanocytic origin, they are not specific for these tumors and react with many other tumors. Currently *Melan A is the most specific immunohistochemical marker for melanomas*, albeit not 100% sensitive, and has been shown to be useful in many species, including the dog, cat, and horse.

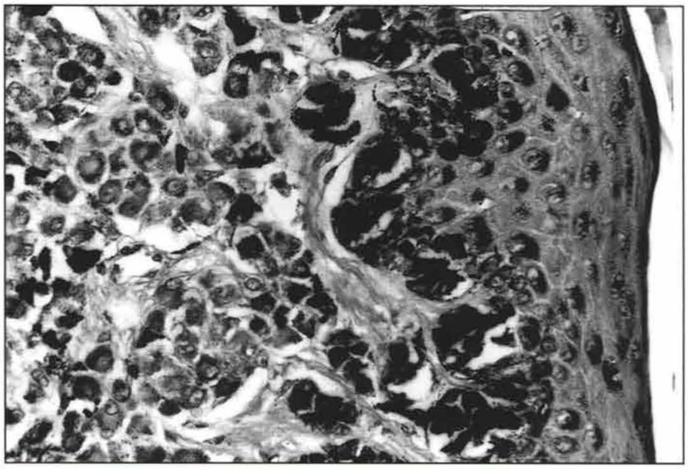

Figure 5.139 Benign melanoma demonstrating junctional activity.

Various studies on canine melanomas have attempted to establish criteria on which to base the prediction of biologic behavior of melanomas. These studies suggest *that the most significant factor predicting the clinical behavior of a melanocytic tumor in the dog is mitotic index* (total number of mitotic figures in ten randomly selected high-power (×40) fields). In one study, a mitotic index of three or greater, notwithstanding the cytologic features, was regarded as indication of malignancy, whereas in another study mitotic activity together with atypical cytologic features was regarded as predictive of clinical behavior. Several proliferation markers have been examined as an aid in predicting survival. It is reported that Ki67, but not PCNA, is a useful prognostic factor in melanomas of dogs and cats, however Ki67 is not useful in predicting clinical behavior in equine melanomas. The degree of pigmentation and cell type are reported not to be associated with prognosis.

Benign melanocytic tumors

Lentigo (lentigo simplex)

A lentigo is a proliferation of melanocytes that is usually confined to the epidermis, resulting clinically in a pigmented circumscribed macule. This lesion is considered to be a hyperplastic melanocytic lesion rather than neoplastic (see Disorders of pigmentation).

Melanocytoma (benign melanoma, melanocytic nevus)

Cutaneous melanocytomas are usually solitary, black, brown, or gray cutaneous nodules. Histologically, melanocytomas can be *junctional* (confined to the epidermis and dermoepidermal junction), *compound* (involving both epidermis and dermis), or *dermal*. Of these, the most common in domestic animals are compound and dermal melanocytomas. They are moderately circumscribed but not encapsulated and may be composed of any melanocytic cell type, i.e., spindle, epithelioid, balloon cell (clear cell), or signet ring. Most commonly they are composed of spindle cells, epithelioid cells, or a mixture of these cell types. The epithelioid cells often occur in nests in the dermis or in the epidermis and along the dermoepidermal junction, or in follicular epithelium. The spindle cell component may form whorls and fingerprint patterns in the dermis. The degree of pigmentation can vary, with the epithelioid cells commonly being darkly pigmented, and the spindle cells lightly pigmented or amelanotic. Mitotic figures are rare, and in the dog a mitotic index of less than three is reported to predict benign behavior.

Balloon-cell melanocytoma is a well-recognized variant in which the circumscribed dermal mass is composed of large epithelioid to polygonal cells with plentiful pale amphophilic to eosinophilic cytoplasm that has a faintly granular appearance. Fine melanin granules can sometimes be detected in low numbers of tumor cells. The nuclei are small, hyperchromatic, and uniform.

Melanocytoma-acanthoma

This tumor is composed of both melanocytic and epithelial cells. It is well described in humans but is rare in domestic animals and has been reported only in dogs. The tumors are seen as solitary pigmented nodules, generally 1 cm or less in diameter. Histologically, the tumor is a *combination of a junctional melanocytoma together with a benign epithelial tumor*. The epithelial population forms a mass in the dermis composed of cords and nests with occasional small cystic structures containing keratin. Melanocytic cells form nests in the epidermis and sometimes in the cords of epithelial cells within the dermal mass; melanocytic spindle cells can form whorls and bundles between the epithelial cords and nests.

Malignant melanoma (melanosarcoma)

Malignant melanomas are generally tumors of older animals, however they have been reported in juvenile animals of many species. Criteria for malignancy and prognosis are described in the introduction to this section; *in the dog, a mitotic index of 3 or greater appears to be the most accurate predictor of a poor prognosis*. In addition, several studies have indicated that *the degree of pigmentation and the histologic pattern are not correlated with prognosis*. Malignant melanomas can be composed of a variety of cell morphologies including spindle cells, epithelioid cells, a mixture of spindle cells and epithelioid cells, signet-ring cells, or balloon cells (clear cells). In addition, the cells can be heavily pigmented or amelanotic and form bundles, sheets, nests, and whorled patterns. Focal areas of chondroid or osseous metaplasia within the tumor may be seen on rare occasion. The most common types of malignant melanoma are composed of epithelioid cells, a mixture of epithelioid and spindle cells, or spindle cells alone, forming an unencapsulated mass in the dermis or subcutis. Various degrees of junctional activity may be present in the epithelioid cell form and in the mixed epithelioid-spindle cell form. The epithelioid cells tend to form clusters and nests, and the spindle cells tend to form sheets, bundles, or whorls. The neoplastic cells have variable nuclear pleomorphism, usually single prominent basophilic nucleoli, three or more mitotic figures per ten high-power (×400) fields, and mitotic atypia (Fig. 5.140A). Cytoplasm is generally moderate to abundant, and the degree of pigmentation is highly variable, from darkly pigmented to amelanotic. An infrequent form of spindle cell melanoma, composed entirely of amelanotic spindle cells, can be impossible to distinguish from fibrosarcoma or neurofibrosarcoma without the aid of immunohistochemistry. While the epithelioid and spindle cell forms of melanoma are usually pigmented to some degree, the uncommon balloon cell form and signet-ring cell form are usually unpigmented or poorly pigmented.

Balloon cell melanosarcomas (Fig. 5.140B) are dermal masses that are sometimes multilobulated, and exhibit no junctional activity. The cells are large, with large vesicular nuclei, prominent nucleoli, a relatively low mitotic index, and plentiful clear cytoplasm without visible melanin. Rare cells may have fine pale cytoplasmic dust-like granules. Occasional multinucleated cells can be present.

Signet-ring melanosarcomas (Fig. 5.140C) are composed of round to polygonal cells, that have eccentric nuclei compressed by abundant faintly eosinophilic or amphophilic cytoplasm that is not visibly pigmented. Occasional cells have fine pale brown granules. Nucleoli are prominent. Occasional multinucleated cells can be present.

Spindle cell tumors

Tumors arising from spindle-shaped cells of the skin are common in dogs and cats, sporadic in horses, and uncommon to rare in other domestic species. *Classification of these tumors may be difficult and the nomenclature is inconsistent and controversial.* The tumors are classified according to the mature tissue they resemble but histologic differences are frequently subtle and morphologic appearance may not be specific enough to reflect histogenesis, particularly for malignant spindle cell tumors. Consequently, *accurate diagnosis by morphologic features alone may not be possible for many tumors.* An immunohistochemical study of canine cutaneous fibrosarcoma, hemangiopericytoma, and schwannoma found poor correlation between morphologic diagnosis and tumor cell differentiation. Although electron microscopy and immunohistochemistry may be helpful in determining the line of differentiation exhibited by tumor cells, some tumors defy identification because of conflicting results owing to loss or alteration in antigens normally present or acquisition of novel antigens. Classification of neoplasms is considered important because of the expectation that it will provide a prediction of the biologic behavior of the tumor. Exact identification of spindle cell sarcomas of the skin may not be essential, however, because *most soft tissue spindle cell tumors exhibit similar behavior and prognosis. They are typically locally invasive, recur frequently after surgical excision, but metastasize infrequently.* The *mitotic index* is more important than the tumor type in predicting the biologic behavior of most soft tissue sarcomas in dogs. Although soft tissue sarcomas may appear well-circumscribed or even encapsulated, *finger-like microextensions of tumor commonly infiltrate into the surrounding tissue to give rise to satellite lesions not visible grossly.* The apparent tumor circumscription commonly results in incomplete excision, leaving microscopic foci of tumor tissue that result in recurrence. Wide surgical excision may be curative, however. Because determination of adequacy of excision is prognostic, *surgical margins should be marked.*

Benign spindle cell tumors

Skin tags (*fibrovascular papilloma, acrochordon, skin polyp*) are benign, fibrovascular lesions of middle-aged and older dogs that may be a *proliferative response to trauma or inflammation rather than actual neoplasms.* They are solitary or multiple soft, polypoid or filiform hairless masses up to 1 cm in diameter and 2–3 cm long that occur most commonly on the *trunk, sternum, and bony prominences* of the limbs. Microscopically, skin tags are composed of mature collagenous tissue that is more highly vascular than normal dermis and covered by an irregularly hyperplastic, hyperkeratotic and hyperpigmented epidermis. Adnexal structures are absent and mononuclear inflammatory cells may be present in low numbers. Ulceration and neutrophilic inflammation are common sequelae to trauma.

Collagen nevi *are focal nodular accumulations of excessive dermal collagen that are relatively common in middle-aged and older dogs.* They are typically solitary, alopecic, firm, dome-shaped nodules up to 1 cm in diameter. Microscopically, they are composed of haphazardly arranged bundles of collagen and low numbers of mature fibroblasts that entrap adnexal structures and result in their distortion or atrophy. Collagen nevi are usually located in the dermis but large masses may extend into the subcutis. The primary differential is fibroma, which tends to be larger and located deeper in the dermis, displaces and compresses adjacent structures, and is more cellular than a collagen nevus. Some veterinary pathologists believe that collagen nevi are actually fibromas of low cellularity. A syndrome called **nodular dermatofibrosis**, characterized by *multiple cutaneous collagenous nodules*, has been reported as *a marker of renal epithelial neoplasia in German Shepherd Dogs.* The condition is thought to be inherited in an autosomal dominant manner. Affected dogs are adults and most have bilateral renal cystadenocarcinomas. Nodules may number in the hundreds and are located anywhere on the body. Individual cases in several other breeds have also been reported. Histologically the lesions are similar to collagen nevi and are differentiated primarily on the basis of the large number of lesions present and the breed affected.

Fibromas *are uncommon benign tumors of fibroblasts and collagen that occur in adult and aged animals of all species.* Fibromas are usually solitary, soft-to-firm, well-circumscribed, round, dome-shaped or pedunculated masses that vary from 1 to 50 cm in diameter. They are usually alopecic and may be hyperpigmented. Large tumors may be ulcerated secondary to trauma. Microscopically, fibromas are well-circumscribed, nonencapsulated dermal or subcutaneous nodules composed of fibroblasts and abundant collagen. The fibroblasts have uniform, oval-to-elongate bland nuclei that may be slightly larger than fibroblasts in the normal dermis and have fine chromatin, inconspicuous nucleoli, and rare mitotic figures. The cytoplasm merges imperceptibly with collagen that is arranged in whorls and interwoven bundles that are thicker and more dense than those in the normal dermis. Adnexal structures are usually displaced and compressed peripherally. Some tumors contain substantial amounts of *mucinous or myxomatous matrix material in addition to the collagen*, in which case the term **fibromyxoma** may be used. In contrast to collagen nevi, fibromas are typically larger, more highly cellular, and displace rather than incorporate adnexal structures.

Myxomas (myxofibromas) are *rare cutaneous neoplasms arising from fibroblasts or multipotential mesenchymal cells and containing abundant glycosaminoglycan stroma.* They usually occur in adult or aged animals as solitary, infiltrative soft masses that are poorly circumscribed and may extend along fascial planes. The tissue is pale and exudes a clear viscous fluid on cut surface. A report of a myxoma developing at the site of a subcutaneously implanted pacemaker in a dog raised the question of whether the implant may have induced the tumor. Microscopically, myxomas are nonencapsulated dermal or subcutaneous masses composed of small stellate to spindle cells randomly distributed within abundant basophilic mucinous stroma with scant, fine collagen fibers. Cellularity is typically low and the cells have small hyperchromatic nuclei and rare mitotic figures. *Recurrence is common because of the infiltrative growth pattern.* Myxomas are difficult to differentiate from myxosarcomas because both are poorly circumscribed, locally infiltrative, and have low mitotic activity. However, nuclear and cellular pleomorphism is more apparent and atypical mitotic figures may be seen in myxosarcomas.

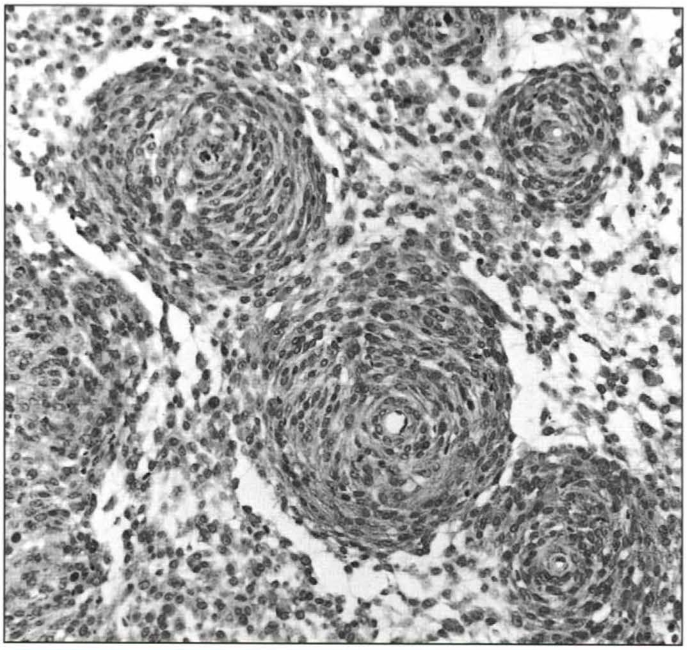

Figure 5.141 Hemangiopericytoma from a dog. Concentric whorls of plump spindle cells around capillary lumina.

Locally infiltrative or malignant spindle cell tumors

Hemangiopericytomas *are relatively common, histologically distinctive, spindle cell tumors of dogs.* Occasional tumors with similar microscopic features are seen in horses and cats. Some ultrastructural and immunohistochemical findings have supported a pericyte origin for this tumor in dogs but *histogenesis is still uncertain.* They usually occur on the *limbs of older dogs* of either sex and any breed but are most common in large breed (>30 kg) dogs. They are usually solitary, slow growing multinodular masses that appear grossly well circumscribed and measure up to 25 cm in diameter. The tissue is usually pale and the consistency varies from soft to very firm. The tumors *frequently recur following excision* owing to the difficulty in identifying tumor margins and inability to perform wide surgical excision because of anatomic constraints. *Metastasis is uncommon*, however.

Hemangiopericytomas are usually located in the dermis and subcutis and are primarily composed of uniform plump spindle cells with oval nuclei, fine chromatin, and small central nucleoli. The characteristic microscopic feature of hemangiopericytoma is *plump spindle cells arranged in concentric layers to form whorls, sometimes with small vessels within the centers* (Fig. 5.141). Sheets and interlacing bundles of similar spindle cells, occasional polygonal cells and multinucleated cells, and variable amounts of collagen also comprise most tumors. Densely cellular areas alternate with loose, myxomatous-appearing areas. Aggregates of lymphocytes may be scattered within some tumors and are usually most prominent along the periphery. At the margins of the tumor, *finger-like microextensions* of tumor cells commonly infiltrate along fascial planes and are the reason many tumors are incompletely excised despite the clinical impression that they are well circumscribed. The mitotic index is usually low but it may not be a reliable prognostic indicator of metastasis. Recurrent tumors may exhibit more prominent pleomorphism and a higher mitotic index. *Tumor cells typically express vimentin intermediate filament and are also frequently positive for actin but are negative for desmin.* A small number of tumors has been positive for S-100 protein, suggesting that some tumors diagnosed as hemangiopericytoma by morphologic features may actually be of neural origin.

Cutaneous tumors of neural origin are uncommon in domestic animals but are likely under-diagnosed because of their histologic similarity to other more common tumors of the skin. They can be composed of one or more elements of a nerve, i.e., axon, Schwann cell, and perineurial fibroblast. Consequently, these tumors are histologically heterogeneous and the histogenesis is frequently uncertain, resulting in varied and confusing classification and terminology in the literature. They have been called neurofibromas/neurofibrosarcomas, neurilemmomas, neurinomas, and schwannomas/malignant schwannomas. The name **peripheral nerve sheath tumor** is a broad term proposed to include all tumors arising from peripheral nerves; however, since most tumors are composed of Schwann cells, the term **schwannoma** is appropriate for the majority of the tumors. Both benign and malignant forms occur; however, tumors that appear histologically benign commonly recur. Schwannomas are common in **cattle** but occur primarily in the heart and rarely involve the skin. A condition termed **neurofibromatosis** has been observed in cattle of all ages and may occur congenitally. It is characterized by multiple neural tumors that usually involve deep nerves and viscera but sometimes also the skin.

Cutaneous peripheral nerve sheath tumors are usually solitary, well-circumscribed, slow growing, soft to firm nodules in middle-aged to aged animals. In cats, the head and distal limbs may be involved most frequently. Schwannomas are usually subcutaneous in dogs; in cats they may be confined to the dermis. Microscopically, *schwannomas are most commonly composed of small spindle cells characterized by oval, spindle-shaped, or wavy nuclei, fine chromatin, small inconspicuous nucleoli, and pale indistinct cytoplasm. The spindle cells form whorls, interlacing fascicles, and palisades reminiscent of nerve* (Fig. 5.142). A delicate collagenous stroma is moderately abundant and a mucinous matrix may be prominent in some tumors. Delicate finger-like projections of tumor cells commonly extend into adjacent tissues and between fascial planes, accounting for frequent recurrences. Cellularity is increased, cellular pleomorphism is more prominent, and there is a decreased tendency to form whorls and palisades in malignant tumors. Mitotic figures are uncommon in benign tumors but may be moderately numerous in malignant peripheral nerve sheath tumors. Histologically and behaviorally, peripheral nerve sheath tumors may be difficult to differentiate from fibromas, well differentiated fibrosarcomas, and hemangiopericytomas. However, *neural tumors express S-100 protein, myelin basic protein, neuron-specific enolase, and glial fibrillary acidic protein, whereas the other more common cutaneous tumors do not.* Immunohistochemical staining of **granular cell tumors** (granular cell myoblastomas) has demonstrated S-100 protein, myelin basic protein, and neuron-specific enolase within tumor cells, suggesting that they also represent a form of peripheral nerve sheath tumor.

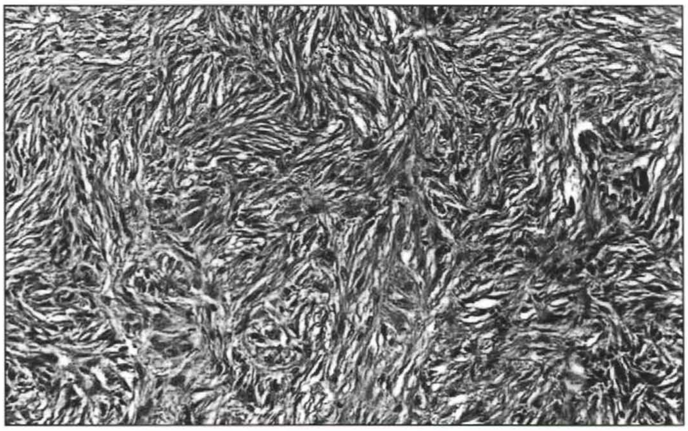

Figure 5.142 Peripheral nerve sheath tumor.

Traumatic neuroma (*tail dock neuroma, amputation neuroma*) is considered an exuberant but non-neoplastic proliferation of the proximal nerve stump occurring in response to injury or surgery. In veterinary medicine, this lesion is rare and occurs most frequently as a result of tail docking in **dogs**. The tumors develop in young dogs, usually within 1 year after caudectomy. They are typically painful, self-traumatized, alopecic, hyperpigmented, lichenified lesions adherent to the underlying deep tissues at the tip of the tail. Microscopically, traumatic neuromas are well-circumscribed nodules composed of *haphazardly arranged myelinated nerve bundles of varying size randomly distributed within a relatively abundant connective tissue stroma.*

Sarcoids *are locally aggressive, non-metastatic fibroblastic skin tumors of horses, mules, and donkeys.* They are the *most common skin tumor of horses*, accounting for up to 30% of tumors, and occur in any breed, sex, or age. However, there appears to be a higher incidence in Quarter Horses, Arabians, and Appaloosas and a lower incidence in Standardbreds. Young adult horses 3–6 yr of age are most commonly affected. A combination of factors appears to be involved in development of the tumors, including *exposure to a viral agent, cutaneous trauma, and a genetic predilection.* Viral etiology has been deduced based on reports of epizootics of cases, transmission studies, detection of virus particles in cultured tumor cells, and demonstration of DNA sequences very similar or identical to that of *Bovine papillomavirus-1* or *-2* genome in tumor cells but not in normal tissues, granulation tissue, or other tumors of horses and donkeys. Sarcoids frequently develop in areas subjected to trauma or at sites of wounds 6 to 8 months after wound healing. A genetically determined predisposition is suggested since an association between susceptibility to sarcoid and certain major histocompatibility complex (MHC) alleles has been found.

Sarcoids develop anywhere but are most common on the *head, legs, and ventral trunk.* They may be single or multiple. The tumors are classified according to their gross appearance as verrucous, fibroblastic, mixed, or occult. The *verrucous type* is a small wart-like growth, usually measuring less than 6 cm in diameter, with a dry, rough surface and variable alopecia. The *fibroblastic type* of sarcoid is more

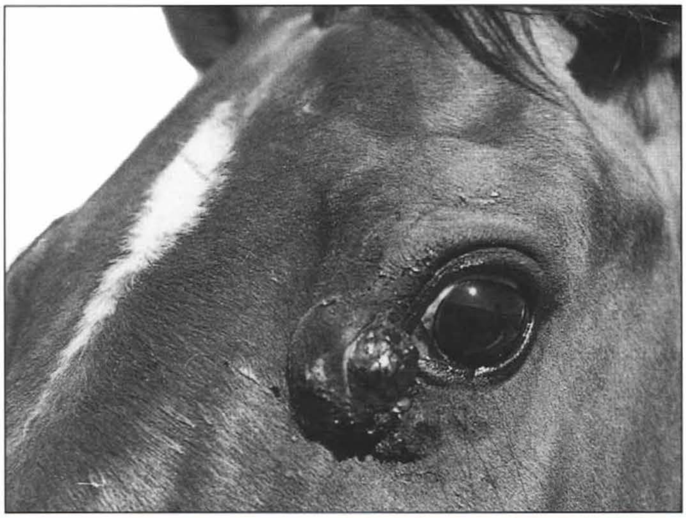

Figure 5.143 Sarcoid from a horse.

variable in appearance and may range from a well-circumscribed firm nodule with intact surface to large masses, greater than 25 cm in diameter, with an ulcerated surface prone to hemorrhage and resembling exuberant granulation tissue. The *mixed type* is a transitional form in which a verrucous sarcoid becomes a fibroblastic type as a result of trauma or biopsy. The *occult form* consists of a slow-growing, slightly thickened area of skin with slight surface roughening and alopecia that remains static for long periods. *Spontaneous remission* may occur after several years in up to 30% of cases. The tumors are characterized by a high rate of recurrence, up to 50%, following surgical excision.

Grossly, sarcoids may resemble many inflammatory and neoplastic diseases including bacterial and fungal granulomas, exuberant granulation tissue, habronemiasis, papilloma, squamous cell carcinoma, fibroma, and other less frequent mesenchymal tumors (Fig. 5.143). Consequently, *histopathology is necessary for definitive diagnosis of a sarcoid.* Wide surgical excision is preferable to a biopsy because the lesions are frequently associated with ulceration, inflammation, and granulation tissue proliferation and the diagnosis may be missed in a small biopsy. Additionally, the trauma associated with obtaining a biopsy of a sarcoid may dramatically stimulate the growth rate and aggressiveness of the tumor. Sarcoids are typically *biphasic tumors composed of both epidermal and dermal components.* The epidermal component may be minimal or absent in some tumors, however. When the epidermis is intact, hyperkeratosis, parakeratosis, and acanthosis with thin rete pegs extending deep into the dermis are common features (Fig. 5.144). The dermal component consists of fibroblasts and collagen in various proportions. The fibroblasts have plump nuclei and nucleoli may be prominent. The mitotic index is usually low. *Fibroblasts at the dermal-epidermal junction are frequently oriented perpendicular to the basement membrane in a "picket fence" pattern, which is a distinctive histologic feature seen in most sarcoids.* The cells are arranged in whorls, interlacing bundles, or haphazard arrays of variable density. Tumor margins are typically indistinct and adequacy of excision is frequently difficult to determine. When the tumor is ulcerated, it may not be possible to differentiate a sarcoid from granulation tissue, fibroma, well-differentiated fibrosarcoma, and peripheral nerve sheath tumor. Immunohistochemical staining for S-100 protein may be useful in confirming a peripheral nerve sheath tumor. Additional biopsies to include intact epidermis may be required to make a diagnosis.

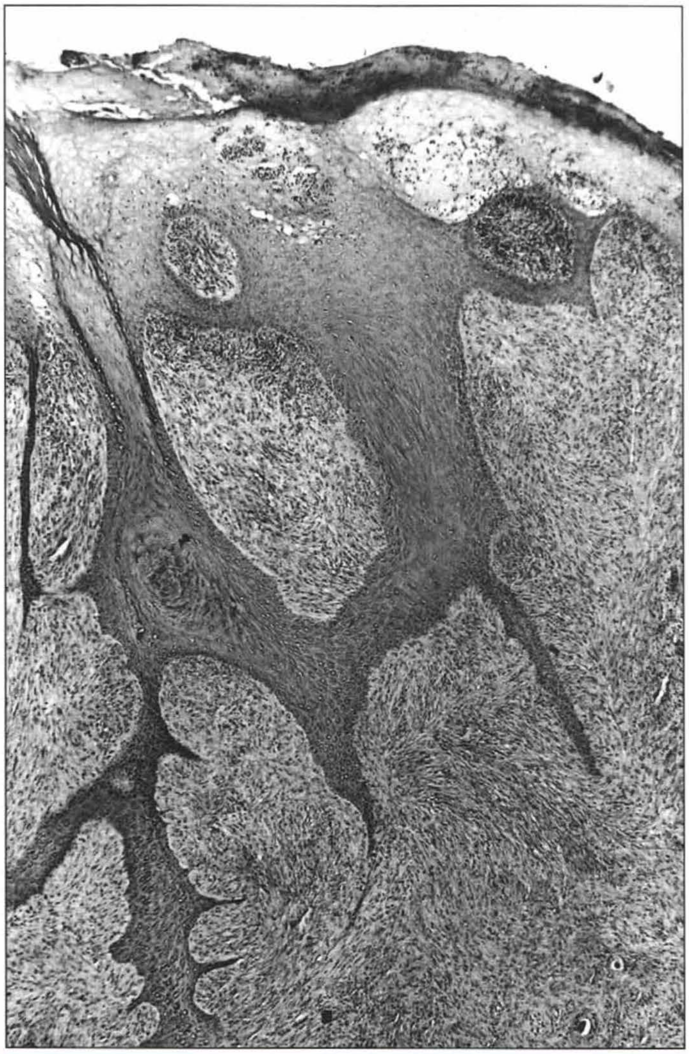

Figure 5.144 Sarcoid from a horse. Note epithelial proliferation and associated dermal fibroblastic proliferation.

A tumor with histologic features similar to equine sarcoid has been described in cats and termed **feline fibropapilloma.** The cats are frequently young, 5 years or less, and have one or several tumors that may be ulcerated. The tumors have been reported in various sites, including the lip, nose, digits, pinna, tail, and gingiva. Recurrence was common but metastasis has not been documented. As in equine sarcoids, papillomavirus DNA has been identified in some of the feline tumors by polymerase chain reaction testing. The nucleotide sequence was similar to a bovine papillomavirus and many of the affected cats had known exposure to cattle.

Fibrosarcomas are malignant tumors of fibroblasts that show no other evidence of cell differentiation. They commonly recur and may metastasize. *Fibrosarcomas are undoubtedly over-diagnosed*, as virtually any anaplastic highly cellular spindle cell sarcoma containing collagen is diagnosed as a fibrosarcoma when more specific histogenesis is not apparent. However, as *immunohistochemistry* has become a routine technique in most diagnostic laboratories, fibrosarcoma can be separated from other spindle cell tumors such as peripheral nerve sheath tumor, leiomyosarcoma, rhabdomyosarcoma, amelanotic malignant melanoma, spindle cell carcinoma, and others.

Fibrosarcomas are common in dogs and cats and uncommon in other domestic species. In **dogs**, they usually occur in older animals and are most common on the trunk and limbs. They usually arise in the subcutis and are poorly circumscribed masses of variable size that may be soft to firm in consistency. Large tumors are often ulcerated and alopecic. Most canine fibrosarcomas are low-grade malignancies that commonly recur locally and metastasize infrequently. Similarities have been noted between canine fibrosarcomas from presumed injection sites and feline post-vaccinal fibrosarcomas, suggesting that post-injection sarcomas may also occur in dogs.

Fibrosarcoma is the most common malignant mesenchymal tumor of **cats**, and three forms of fibrosarcoma have been recognized – virus-induced, solitary in older cats, and post-vaccinal.

Virus-induced fibrosarcoma is rare. *Feline sarcoma virus* (FeSV) is the cause of multicentric fibrosarcoma in cats usually less than 5 years of age. FeSV is a replication-defective retrovirus that requires *Feline leukemia virus* (FeLV) as a helper virus. The genetic recombination of the two viruses produces an acutely transforming virus that induces multiple simultaneous rapidly growing fibrosarcomas after a short incubation period. FeSV-induced fibrosarcomas are typically locally invasive and metastasize to lung and other sites.

Solitary fibrosarcomas in older cats are much more common that virus-induced multicentric tumors. These may arise in the dermis or subcutis. Subcutaneous tumors are usually on the trunk and limbs; dermal tumors primarily involve the digits and pinnae. The clinical appearance and behavior of this type of fibrosarcoma are similar to those in dogs.

Epidemiologic evidence supports a relationship between vaccine administration in cats and the development of *post-vaccinal fibrosarcomas* and, to a lesser extent, other sarcomas in the injection sites. The interval between vaccination and tumor development is 3 months to 3.5 years. The mechanism of tumor development is unknown but persistent injection-site induced inflammation leading to deranged fibrous connective tissue repair response and eventual neoplastic transformation in genetically predisposed cats has been postulated. Alterations in oncogene and growth factor expression may be involved in the pathogenesis. Post-vaccinal fibrosarcomas typically develop in the subcutis of the dorsal cervical and interscapular area, dorsal and lateral thorax, flank, and musculature of the thigh, locations that are all *common vaccination sites*. These tumors arise in cats that are younger (median age, 8 years) than those with fibrosarcomas at nonvaccination sites (median age, 10.5 years) and are larger than nonvaccination site fibrosarcomas. The masses frequently have cystic centers, firm attachments to dorsal spinous processes or other deep structures, and ill-defined margins. *They are biologically aggressive and commonly recur multiple times within a period of weeks to months when removed.* The metastatic rate is not well characterized, but was found to be as high as 24% in one study. The lungs and regional lymph nodes are the most common sites of metastasis. Wide surgical excision prolongs the interval to recurrence but often fails to remove the tumor completely. Radiation therapy and chemotherapy are under evaluation as adjunctive treatment to prevent local recurrence and systemic spread, respectively.

Microscopically, *fibrosarcomas consist of interlacing and intersecting bundles of immature fibroblastic cells.* The tumors show a great deal of variation with respect to cellular pleomorphism and density, mitotic activity, and amount and maturity of collagen. Multinucleated giant cells are seen in many fibrosarcomas but are not numerous. The tumors are dermal, subcutaneous, or both. They are usually nonencapsulated, and local invasion is evident as finger-like projections of tumor cells extending along fascial planes and into surrounding tissues. These microscopic extensions of the tumor account for the difficulty in excising the tumor completely and resultant recurrences. Although collagen is the primary stromal element, mucin may also be produced in small amounts. Immunohistochemical staining is *positive for vimentin* only. *Retrospective studies have found only the mitotic index* (total number of mitotic figures in ten high-power (×400) fields) *to be significant in predicting tumor behavior.* In dogs, a mitotic index less than 9 was associated with greater survival than a mitotic index of 9 or greater. Likewise, cats with solitary fibrosarcomas with a mitotic index of 5 or less had significantly greater survival time than cats with tumors with mitotic index of 6 or greater. Poorly differentiated fibrosarcomas may be difficult to differentiate from a number of other mesenchymal and nonmesenchymal tumors including malignant schwannoma, malignant fibrous histiocytoma, leiomyosarcoma, and spindle cell forms of amelanotic melanoma and squamous cell carcinoma. In such cases, immunohistochemical staining is necessary to exclude other tumors by showing lack of immunoreactivity to antigens typical of other cell types. In small biopsies with a limited amount of tissue to evaluate, it may be difficult to differentiate fibrosarcoma from reactive granulation tissue.

Post-vaccinal fibrosarcomas are typically subcutaneous and have large cavitated centers as a result of extensive necrosis. An inflammatory reaction, consisting of lymphocytes and macrophages that sometimes contain gray-brown or blue globular material typical of a vaccine reaction, is commonly present at the periphery of the tumor. Mitotic activity and cellular pleomorphism tend to be high; however, histologic grade does not appear to be associated with outcome. Tumor cells of vaccination-site fibrosarcomas have been reported to be consistently strongly immunoreactive for platelet-derived growth factor and its receptor, epidermal growth factor and its receptor, and transforming growth factor-β, while nonvaccine-associated fibrosarcomas are negative or only slightly positive.

Malignant fibrous histiocytoma *(giant cell tumor of soft parts, extraskeletal giant cell tumor) is an uncommon tumor of controversial histogenesis.* It was originally believed to be derived from malignant cells of monocyte-macrophage origin capable of acting as "facultative" fibroblasts. Ultrastructural and immunohistochemical findings, however, indicate that malignant fibrous histiocytoma may not be a distinct entity but rather a *collection of anaplastic mesenchymal and nonmesenchymal tumors.* Nevertheless, the diagnosis of malignant fibrous histiocytoma is made for those neoplasms characterized histologically by the *combination of fibroblast-like spindle cells, vacuolated histiocyte-like cells, and variable numbers of pleomorphic multinucleated giant cells along with a collagenous stroma.* The tumor is uncommon to rare in dogs and cats and has been reported in horses and an adult cow. Most cases occur in older animals. They occur on the *legs and shoulders* most commonly. The tumor is usually solitary, firm, and poorly circumscribed and the skin surface may be ulcerated. *The tumors typically have a moderate rate of growth, exhibit locally invasive growth, and recur commonly after surgical excision.* The potential for metastasis is disputed but has been found to be low in most reports. Microscopically, the giant cell type of malignant fibrous histiocytoma is most common and is composed of fibroblastic-like spindle cells arranged in a storiform (or cartwheel) pattern or in interwoven bundles with variable amounts of collagen resembling a fibrosarcoma. Polygonal cells that resemble histiocytes are distributed throughout the tumor or form focal aggregates. Multinucleated giant cells with 30 or more nuclei and abundant eosinophilic cytoplasm usually form aggregates rather than being diffusely distributed throughout the tumor. The giant cells resemble osteoclasts but are not associated with any osteoid production. Mitotic activity is variable but usually moderate to high and atypical mitotic figures are common. There is no immunohistochemical profile unique to malignant fibrous histiocytoma and, in fact, immunohistochemical staining may result in classification of tumors diagnosed as malignant fibrous histiocytoma by light microscopy as various other malignant tumors.

Other mesenchymal tumors

Tumors arising from subcutaneous lipocytes occur in all species. **Lipomas** are most common in dogs and may be multiple. In all species, they usually occur in adult and aged animals and are most commonly located on the trunk and proximal limbs. *Lipomas are masses of well-differentiated lipocytes indistinguishable from normal fat* except for a compressed boundary of delicate stroma that normally serves to delineate the margin between tumor and adjacent normal adipose tissue. Some lipomas contain cartilage, bone, collagen, or blood vessels. In addition, some mesenchymal tumours contain roughly equal proportions of adipose tissue mixed with other mesenchymal components. These form distinctive variants such as *angiolipomas, fibrolipomas* and *leiomyolipomas*. Occasionally hemangiosarcomas and mast cell tumours may be found arising within lipomatous masses, suggesting that lipomas may sometimes provide a local environment suitable for the emergence of these more sinister neoplasms. Necrosis, hemorrhage, fibrosis, and mild macrophage inflammation may occur as a result of trauma to lipomas.

Infiltrative lipomas are uncommon tumors of dogs. *They are usually large, poorly delineated, deep subcutaneous masses composed of well differentiated lipocytes that infiltrate subcutaneous muscle and fascia.* They may cause pain or interfere with limb function and may invade through the body wall.

Liposarcomas are malignant tumors of lipocytes and are uncommon in all species. Liposarcomas in cats have been associated with retrovirus infection and with vaccination sites; a liposarcoma in a dog was associated with a glass foreign body. *Liposarcomas may recur but rarely metastasize. They are usually well-circumscribed, nonencapsulated, highly cellular masses of round to polyhedral cells primarily and fewer stellate, spindle, and multinucleated cells.* Lipocyte origin is recognized by the presence of *cytoplasmic vacuolation* that may be numerous fine vacuoles or a single large clear vacuole that displaces the nucleus peripherally. Mitotic figures are generally infrequent. *Myxoid liposarcomas* have prominent mucinous ground substance. Liposarcomas may be difficult to differentiate from anaplastic sebaceous carcinomas and balloon cell or clear cell melanomas. The tumor cells of liposarcoma are usually arranged in solid sheets of vacuolated cells while in sebaceous carcinoma the cells tend to be subdivided into nests and lobules. The presence of rare cells with cytoplasmic dusting of very fine brown granules can differentiate melanoma from the other two tumors; however, immunohistochemical staining for cytokeratin, vimentin, and a melanocytic marker (such as Melan A) may be needed to differentiate the tumors.

Tumors originating from muscle are rare in the skin of animals. Smooth muscle tumors, **leiomyomas** and **leiomyosarcomas**, can arise from arrector pili muscles (*piloleiomyomas*), cutaneous blood vessels (*angioleiomyomas*), and specialized muscles of genital skin. These tumors are usually solitary, firm, and well-circumscribed in animals. In humans, piloleiomyomas are commonly multiple; and multiple piloleiomyomas have been reported in an old cat. Microscopically, leiomyomas are small, well-circumscribed dermal masses adjacent to and surrounding hair follicles. They are composed of uniform long spindle cells in whorling and interlacing bundles. The cells have bland elongate nuclei with blunt ends ("cigar-shaped") and moderately abundant pale eosinophilic cytoplasm. Mitotic figures are rare. Leiomyosarcomas exhibit nuclear pleomorphism and low to moderate mitotic activity. Angioleiomyomas consist of interlacing bundles of smooth muscle cells between numerous vascular channels. Smooth muscle tumors may be confused with fibromas, fibrosarcomas, or malignant schwannomas. In such cases, *immunohistochemical staining for actin and desmin can confirm muscle origin.*

Cutaneous tumors of skeletal muscle, **rhabdomyomas** and **rhabdomyosarcomas**, are extremely rare. Rhabdomyomas of the ear pinna have been reported in four white-eared cats. The tumors were thinly haired, red-purple, nonulcerated discoid nodules 1–2 cm in diameter on the convex surface of the pinna. Histologically, they were well-circumscribed masses composed of whorls and bundles of long spindle cells with cross-striations evident in a few tumor cells. Mitotic figures were rare. Surgical excision was curative.

Vascular tumors

Cutaneous vasoformative tumors are common in dogs, occasional in cats and horses, and uncommon in other species. The majority are benign in dogs and horses whereas malignant tumors are more common in cats. Vascular tumors may be associated with thrombocytopenia, disseminated intravascular coagulation, and other hemostatic abnormalities.

Hemangioma *is a benign neoplasm of blood vessel endothelium that can originate in the dermis or subcutis.* The tumor is usually a solitary, well-circumscribed, fluctuant to firm, blue to red-black, slow-growing mass. Cutaneous hemangioma in **dogs** usually occurs in older animals (mean, 9–10 years) without apparent sex predilection. The tumor can occur anywhere but lightly pigmented, sparsely haired ventral abdominal and inguinal skin may be predisposed. Chronic solar damage has been suggested as a cause of dermal hemangiomas in this location and they may be multiple. Surgical excision is curative.

Benign cutaneous vascular lesions in **horses** frequently occur in animals less than 1 year of age and some are congenital, raising the question of whether the lesions are true neoplasms or vascular malformations (hamartoma or nevus). The confusion in categorizing these vascular lesions in young horses has resulted in *inconsistent nomenclature* and they have been referred to as **lobular capillary hemangioma** and **vascular nevus** in the literature. The lesions are most commonly located on the limbs and present as a cauliflower or nodular mass or diffuse skin thickening which may become alopecic and ulcerated. The lesions may recur following excision. In some instances they are too extensive to be excised, necessitating euthanasia of the affected animal. Cutaneous hemangiomas usually occur in adult and aged **cattle**; congenital hemangiomas have been reported also and these are frequently multiple.

Microscopically, hemangiomas consist of nonencapsulated dermal or subcutaneous masses composed of blood-filled channels lined by a single layer of flattened, mature endothelium (Fig. 5.145). Mitotic figures are rare. Subcutaneous tumors are usually well-circumscribed, while those in the dermis may not be as well defined and may incorporate adnexal structures within the mass. The tumors are classified as *capillary* or *cavernous* depending on the size of the vascular spaces. The cavernous type is more common in dogs. The vascular channels are usually separated by collagenous septa that contain variable numbers of mast cells, lymphoid cells, and hemosiderin-laden macrophages. Occasional vascular channels contain fibrin thrombi. *Solar-induced dermal hemangiomas* of glabrous skin are located in the superficial dermis and may be associated with solar elastosis. A variant of hemangioma, called **angiokeratoma**, is a raised superficial dermal hemangioma with prominent, irregular hyperplasia of the epidermis which extends down to separate and partially surround the vascular channels. The *lobular capillary hemangioma/vascular nevus of young horses* consists of multiple discrete dermal lobules of closely packed, haphazardly arranged vascular structures of small caliber. The vessels are lined by endothelial cells with plump oval nuclei and low mitotic activity. **Cutaneous angiomatosis** is a multinodular hemangioma with intervening inflamed connective tissue stroma that extends above the skin surface and bleeds spontaneously. It occurs in cattle and horses most commonly and also in cats and goats. This lesion has been compared to the human "pyogenic granuloma."

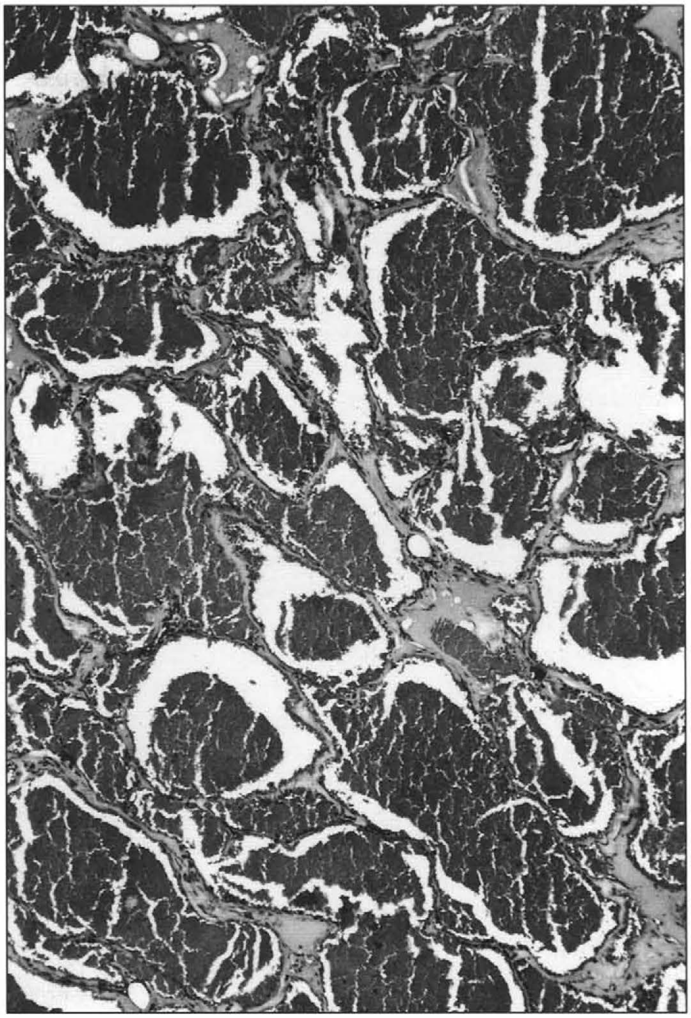

Figure 5.145 Cutaneous hemangioma from a dog.

Hemangiosarcoma, the malignant form of a tumor of blood vessel endothelium, can occur in the skin as a primary site or as a result of metastatic disease from a primary visceral tumor. These tumors usually occur in adult and aged animals. In one study of cutaneous vascular tumors of cats, hemangiosarcomas occurred most frequently in white-haired sites and most commonly involved the pinnae and head. Cutaneous hemangiosarcoma commonly recurs following excision and has the potential for widespread local invasion and metastasis; but in general it appears to be less aggressive, has a longer clinical course, and prolonged survival when compared to visceral hemangiosarcomas. In contrast to the subcutaneous form, dermal hemangiosarcoma may be cured by wide surgical excision alone.

The degree of differentiation is extremely variable, ranging from well-differentiated tumors with well-defined vascular channels to poorly differentiated tumors with minimal lumen formation. *Usually hemangiosarcomas consist of plump pleomorphic endothelial cells arranged in single or multiple layers along trabeculae of collagen or preexisting dermal collagen fibers to form a poorly circumscribed meshwork of blood-filled spaces.* Collagenous trabeculae lined by endothelial cells commonly protrude blindly into the vascular spaces. Mitotic activity may be high. Frequently, portions or entire tumors are composed entirely of sheets or intersecting and anastomosing bundles of pleomorphic spindle cells and they may be indistinguishable from fibrosarcoma or other poorly differentiated spindle cell sarcomas. The presence of slit-like spaces containing erythrocytes between tumor cells may be the only clue to the diagnosis. Immunohistochemical staining may be required to identify the cells in anaplastic tumors. Endothelial cells express vimentin, factor VIII-related antigen (von Willebrand factor), and CD31 (platelet-endothelial cell adhesion molecule/PECAM). However, *immunostaining must be interpreted with knowledge of limitations of the procedure*; in poorly differentiated tumors, very anaplastic cells may not express typical antigens and immature reactive stromal endothelial cells may be mistaken for tumor cells.

Tumors arising from endothelium of lymphatic vessels are rare in domestic animals. Both the benign, **lymphangioma**, and malignant, **lymphangiosarcoma**, forms occur in young animals and it has been suggested that they represent lymphatic malformations resulting from a failure of connection between lymph vessels and the venous system rather than being true neoplasms. *The skin and subcutis appear to be the most common site of tumors of lymphatic endothelium and the caudal ventral abdomen and inguinal areas appear to be predisposed.* They typically present as poorly defined fluctuant or edematous masses that are present for many months and drain clear serous to milky fluid. Rarely they occur as multiple clear turgid vesicles or bullae. It may be difficult to distinguish between lymphangioma and lymphangiosarcoma histologically as the histologic appearance may not correlate well with the biologic behavior of the tumor. Tumors that appear histologically benign commonly recur and may be locally invasive. Lymphangiosarcomas commonly invade local tissues extensively and metastasize to distant sites. They are poorly defined and difficult to remove completely, resulting in poor wound healing and recurrence. In contrast to tumors of vascular endothelium, *lymphangiomas/lymphangiosarcomas are composed of spaces largely devoid of material.* They may contain only small amounts of proteinaceous fluid and low numbers of erythrocytes and/or lymphoid cells. The connective tissue stroma separating the vascular spaces is loose or edematous and may contain aggregates of lymphoid cells. These tumors have been reported to be immunoreactive for factor VIII-related antigen (von Willebrand factor); CD31 reactivity is variable. Ulceration, hemorrhage, granulation tissue proliferation, and inflammation are frequently present because of the chronic clinical course and may result in misdiagnosis when a small biopsy is taken. It may not be possible to differentiate a poorly differentiated lymphangiosarcoma from hemangiosarcoma. Further complicating diagnosis is a condition called **lymphangiomatosis**, which is considered a developmental disorder composed of bland dilated lymph channels involving skin, soft tissue, bone, and parenchymal organs.

Histiocytic proliferative disorders

Proliferations of histiocytic cells in the dog comprise a complex and incompletely understood category of disease. Fortunately, advancement in the characterization of the canine histiocytic proliferative disorders in terms of morphologic characteristics, clinical behavior, and phenotype has led to enhanced diagnostic and prognostic capabilities. The cause and pathogenesis of these conditions remain largely undetermined. Currently, histiocytic proliferative disorders in the dog comprise the entities of **cutaneous histiocytoma, cutaneous histiocytosis, localized histiocytic sarcoma**, and **disseminated histiocytic sarcoma** (formerly known as malignant histiocytosis). These conditions have only been well characterized in the dog.

Histiocytes arise from a CD34+ precursor cell found in the bone marrow and differentiate into cells of the mononuclear-phagocyte system or the dendritic cell system. Dendritic cells and macrophages have overlapping functions in that both can function as antigen-presenting cells and can act as effector cells. *Macrophages* are primarily effector cells and act as elements of the innate immune system, whereas *dendritic cells* function primarily in antigen presentation and hence provide a strong influence on the adaptive immune system. The morphological features of neoplastic or abnormally reactive histiocytes are similar and can mimic tumor cells of different histogenic origin or be confused with granulomatous inflammation. Differentiation often requires immunophenotyping and sometimes ultrastructural characterization.

Canine cutaneous histiocytoma

Canine cutaneous histiocytomas (CCH) (Langerhans cell histiocytosis) are tumors arising from proliferations of the intra-epidermal dendritic cell, the Langerhans cell. Langerhans cells acquire and process foreign cutaneous antigens, migrate to regional lymph nodes and present the antigen to T cells. Immunophenotypic markers of Langerhans cells and therefore cells comprising CCH include MHC I and II, CD1a, CD1c, CD11a, CD11b, CD11c, CD18, CD44, CD45, CD45R, CD49d, ICAM-1, and E-cadherin. Expression of the above markers may vary with the state of activation of the tumor cells and clinical stage of the tumor. CCH should also express vimentin. Lysozyme is a useful but not a reliable marker for these tumors. Histiocytoma cells are negative for Thy-1 and CD4. Unfortunately, at the time of writing, the majority of the above markers are not commercially available and/or require the use of cryopreserved tissues. Establishing the diagnosis may rely on attempting to rule out other round cell neoplasms for which commercially available antibodies for formalin-fixed specimens are available.

Canine cutaneous histiocytomas are most often solitary, benign tumors but can be multiple and on very rare occasion have been noted to lead to regional and distant metastasis. Greater than 70% of CCH occur in *dogs <4 years of age* and are most often found on the *head (pinna), or limbs* but can occur anywhere on the body. There is no sex predilection. Grossly, the tumors are raised, red, frequently ulcerated, 0.5–4 cm nodules that grow rapidly. The tumors are well demarcated but unencapsulated and located primarily in the dermis with the base of the tumor smaller in configuration than the more superficial aspect ("top heavy"). Microscopically, *tumor cells form diffuse sheets that displace adnexal structures and dermal collagen, and extend from the dermoepidermal junction into the subcutis.* Epidermotropism may be evident in some CCH. A clear zone usually surrounds intra-epidermal tumor cells. Care must be taken to differentiate the lesion from an epidermotropic lymphoma. The epidermis is often attenuated or ulcerated and associated edema may lead to *vertical rowing of tumor cells* near the surface. Ulceration is associated with infiltrates of neutrophils. The intact epidermis may be hyperplastic. Individual tumor cells are round to oval with moderate to abundant eosinophilic, slightly foamy cytoplasm. Cell borders are fairly distinct in areas of low density but obscure when cells are arranged in diffuse sheets. Nuclei are centrally located, oval, to indented and vesicular with most often a single nucleolus that may be inconspicuous. *Mitotic figures are variable but most often numerous* with up to 10–15/hpf. The base of the tumor may have infiltrates of CD8+ cytotoxic T lymphocytes, a sign of *host-mediated spontaneous tumor regression.* Infiltrates of lymphocytes may also be found in perivascular or periadnexal regions. In older lesions, the lymphocytic infiltrates may be more extensive than the remaining tumor cell infiltrates, leading to a misinterpretation of primary inflammatory process. *Tumor cell apoptosis and zones of necrosis are common findings,* particularly in regressing lesions but are not present in all CCH. As the function of Langerhans cells is to capture antigen and migrate to regional lymph nodes, regional lymph nodes may be enlarged but are not painful and should regress to normal size after tumor removal. Histologic changes in regional lymph nodes have not been well documented but in rare cases have been shown to be due to infiltrates of Langerhans cells.

The histologic appearance of tumors in dogs with *multiple cutaneous histiocytomas* is the same as described above, however spontaneous regression may be delayed and secondary bacterial infection may be a complication. Shar-Peis, Shar-Pei crosses and the English Cocker Spaniel are reported to have a higher incidence of multiple cutaneous histiocytomas. At least one author has proposed the term; "*progressive Langerhans cell histiocytosis*" for cases characterized by multiple, treatment-refractory canine cutaneous histiocytomas shown to be of Langerhans cell origin.

The overwhelming majority of CCH are benign and cured by surgical excision or by the spontaneous regression that usually occurs within a few weeks. Immunosuppressive drugs are contraindicated as this may delay natural regression of the lesions. Morphological features that suggest possible malignant behavior of a CCH include aggregates of tumor cells that are primarily in the deep dermis and subcutis, lack of lymphocytic infiltration, presence of plasma cells, and plugging of lymphatic vessels by tumor cells. The histologic differential diagnosis includes inflammatory lesions and other round cell neoplasms such as lymphomas, plasma cell tumors, and mast cell tumors. The deep dermal lymphocytic infiltrates, presence of typical histiocytes in the superficial regions, high mitotic index, infrequent presence of eosinophils, signalment and anatomical location are useful features in confirming the diagnosis of a histiocytoma. Immunophenotyping may be needed in some cases to distinguish CCH from other round cell tumors such as cutaneous lymphoma, particularly if epidermotropism is present.

Cutaneous reactive histiocytosis and systemic reactive histiocytosis

Cutaneous reactive histiocytosis (CRH) is *a reactive disorder targeting the skin that is characterized by single to multiple, non-painful plaques or nodules comprised of proliferations of histiocytes accompanied by lymphocytes and neutrophils.* **Systemic reactive histiocytosis** (SRH) is *the term used to designate a similar condition that affects not only the skin, but also lymph nodes and other body organs.* Cutaneous reactive histiocytosis does not necessarily lead to systemic reactive histiocytosis and not all cases of systemic histiocytosis have cutaneous lesions. The histiocytic cells in CRH and SRH are immunophenotypically CD1+, CD11b+, CD11c+, MHCII+, CD4+, and CD90+ (Thy-1+), ICAM-1+ activated dendritic cells. The lymphocytes are CD3+, CD8+, TCRαβ+ T lymphocytes, and the neutrophils label for CD11b+. Cultures and special stains fail to reveal causative agents and the condition responds favorably, at least for a time, with immunomodulatory therapy, hence it is thought to be the result of immune dysregulation.

Gross lesions of CRH are restricted to the skin and subcutis, may be alopecic or haired, and are most often on the *head, neck, perineum, scrotum, and extremities* (Fig. 5.146). The condition occurs in dogs 2–11 years of age with no sex or breed predilection. Systemic histiocytosis can have similar cutaneous lesions in addition to infiltrates of other tissues and organs such as the nasal cavity, sclera, retrobulbar tissues, lung, spleen, liver, lymph nodes, and bone marrow. Systemic reactive histiocytosis can occur in any breed, but Bernese Mountain Dogs, Rottweilers, Golden and Labrador Retrievers are predisposed. The age range for SRH is 1–9 years.

Histologically, cutaneous lesions are *"bottom heavy" multinodular infiltrates of large round-to-oval, rather bland histiocytes* mixed with

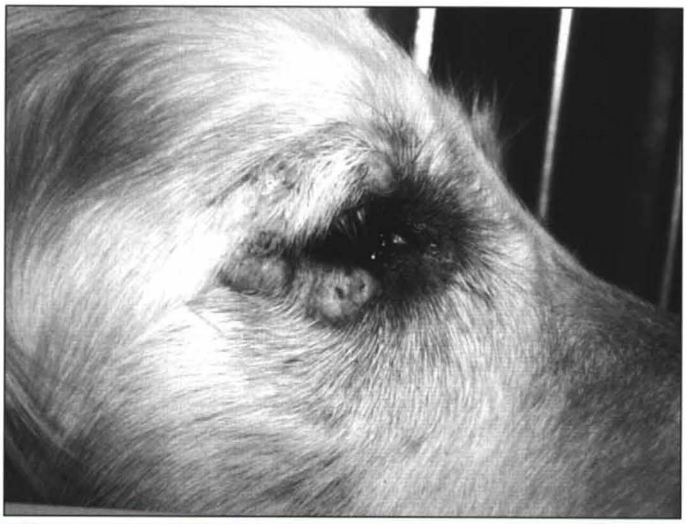

Figure 5.146 Cutaneous histiocytosis from a dog.

lymphocytes and neutrophils in the deep dermis and subcutis. In some cases, the histiocytes may be vacuolated, giving the infiltrate a lipomatous appearance. Lymphocytes may comprise 50% of the infiltrate. Eosinophils and rare plasma cells may occasionally be present. Vessels are often surrounded and invaded by the infiltrate leading to thrombosis and tissue necrosis. Older lesions extend into the more superficial dermis and may have a periadnexal distribution. Epitheliotropism is not a feature. Infiltrates of other tissues and organs in SRH are morphologically similar to the cutaneous infiltrates.

The *histologic differential diagnoses* include a response to infectious agents, other causes of periadnexal granulomas such as idiopathic sterile pyogranulomas, drug reactions, cutaneous histiocytoma, and lymphomatoid granulomatosis.

The prognosis for CRH and SRH is guarded. Lesions may wax and wane and the minority of cases of CRH may spontaneously regress. Many times, the lesions are slowly progressive and require long term management with immunosuppressive therapy and often lead to death, particularly if there is systemic involvement.

Localized histiocytic sarcoma

Localized histiocytic sarcomas are rapidly growing malignant neoplasms occurring most often in the skin, subcutis, and associated soft tissues of the extremities. The tumors are often found in periarticular regions and invade the joint capsule, tendons and muscles of the region. Other reported sites for LHS include the spleen, brain, liver, gastric wall, and tongue. LHS are most often reported in Bernese Mountain Dogs, Golden, Labrador, and Flat-coated Retrievers, and Rottweilers, but can occur in any breed. There is no sex predilection and reported age range is 2–11 years.

Immunophenotypically, the histiocytic cells comprising these lesions are variable but most consistent with a *dendritic cell origin or occasionally a macrophage origin (hemophagocytic histiocytic splenic sarcoma).* Splenic histiocytic sarcomas are comprised of cells phenotypically characteristic of interdigitating dendritic cells of the white pulp (CD1+, CD11c+, MHCII+) while histiocytic sarcomas arising in periarticular regions have phenotypic evidence of interstitial dendritic cell origin.

Grossly, the tumors are comprised of white, multinodular tissue that invades and destroys surrounding tissues. Metastasis to regional lymph nodes has been reported. Splenic histiocytic sarcomas metastasize to the liver. Histologically, histiocytic sarcomas consist of a mixture of pleomorphic, anaplastic, plump, round histiocytic cells and pleomorphic spindle-shaped cells. Tumor cells have abundant eosinophilic cytoplasm and large oval-to-indented or twisted vesicular nuclei. Multinucleated giant cells are common. Neutrophils and CD8+ lymphocytes may be present as well. Mitotic activity is high and phagocytosis may be evident. Immunophenotyping reveals positive labeling for CD1, CD11c, MHCII, ICAM-1, variable reactivity to CD90 (Thy-1) and negative reactivity for CD4. Histologic differential diagnoses include a wide variety of other sarcomas. Definitive diagnosis often requires immunohistochemistry. The prognosis is guarded but best when early, wide resection is performed (amputation) and the regional lymph nodes are determined to be uninvolved.

Disseminated histiocytic sarcoma

Disseminated histiocytic sarcoma is the term now used to refer to the previously described condition of malignant histiocytosis. Disseminated histiocytic sarcoma is a term used to reflect the multicentric form of histiocytic sarcoma described above. Histologically and immunophenotypically, the lesions are identical. It is unclear whether the disseminated histiocytic sarcoma represents metastasis of a primary lesion or multicentric malignant transformation of histiocytes. The condition was originally described in Bernese Mountain Dogs but has since been documented in Golden and Labrador Retrievers and Rottweilers. It is likely that cases in other breeds will be reported as well. The condition has been reported in the spleen, lung, liver, lymph nodes, bone marrow, central nervous system, kidneys, skeletal muscle, stomach, vertebral bodies, and adrenal glands. Cutaneous involvement is rare. The age at presentation ranges from 3–11 years and there is no sex predilection. The prognosis is extremely poor and the condition is rapidly progressive and there no known successful therapy.

Histiocytic diseases in cats

Histiocytic diseases in cats are inadequately characterized at this time to provide details regarding morphologic features, immunophenotyping, and clinical behavior. To date, a small number of cases of epitheliotropic cutaneous histiocytic proliferative conditions identified as Langerhans cell histiocytosis, histiocytic sarcomas, and an angiocentric pleocellular dendritic antigen presenting cell proliferative disorder have been documented. Further studies are needed before conclusions regarding histiocytic proliferative disorders in cats can be drawn.

Mast cell tumors

Single or multiple nodular dermal proliferations of mast cells occur in all domestic species but are *most common in dogs* (Fig. 5.147A). When the mast cells are present in large numbers and as an essentially pure population, a diagnosis of mast cell tumor (*mastocytoma*) is usually made. Some, more cautiously, consider such growths as *cutaneous mastocytosis* until invasive growth or morphologic evidence of anaplasia confirms their neoplastic nature. As heavy accumulations of mast cells may occur in a variety of parasitic, mycotic, allergic and idiopathic inflammatory syndromes, such caution is warranted; however, sheets of mast cells are not present in these other conditions. Multiple spontaneously regressing mast cell tumors have been reported in young dogs, cats, pigs, calves, foals, and humans suggesting the underlying process may have been mast cell hyperplasia rather than a true neoplasm. Diffuse dermal and subcutaneous infiltrates of well-differentiated mast cells occurring over large areas of the body have been reported in cats, dogs and a foal. The condition has been compared to *urticaria pigmentosa* described in humans.

The histologic lesion is seldom a diagnostic challenge except in the very poorly differentiated tumors. *The mast cells form diffuse loose sheets or densely packed cords of round cells with a central round nucleus, abundant granular basophilic cytoplasm, and distinct cell membrane* (Fig. 5.147B). Scattered diffusely among the tumor cells are mature eosinophils. Even solid tumors tend to have some areas composed of cords of tumor cells alternating with collagen bundles, particularly at the infiltrative border of the tumor. They are never encapsulated or even well demarcated except at their superficial edge. A Grenz zone typically separates them from an intact epidermis. Ulceration in large or traumatized tumors may bring the skin surface in contact with the tumor. Eosinophils are few to numerous. Edema may be very severe, giving the tumor an appearance that macroscopically and microscopically resembles acute inflammation. Foci of tumor necrosis, eosinophilic or mononuclear leukocytic vasculitis, vascular necrosis, mineralization, mucinous extracellular matrix, collagen degeneration or tumor cells with giant or multiple nuclei are all occasionally encountered. Degenerating collagen may incite granulomatous inflammation.

In **dogs**, *mast cell tumors account for 15–20% of skin tumors and are the most frequent malignant or potentially malignant tumor of the skin.* The mean age of affected dogs is ~9 years with a range of 3 weeks

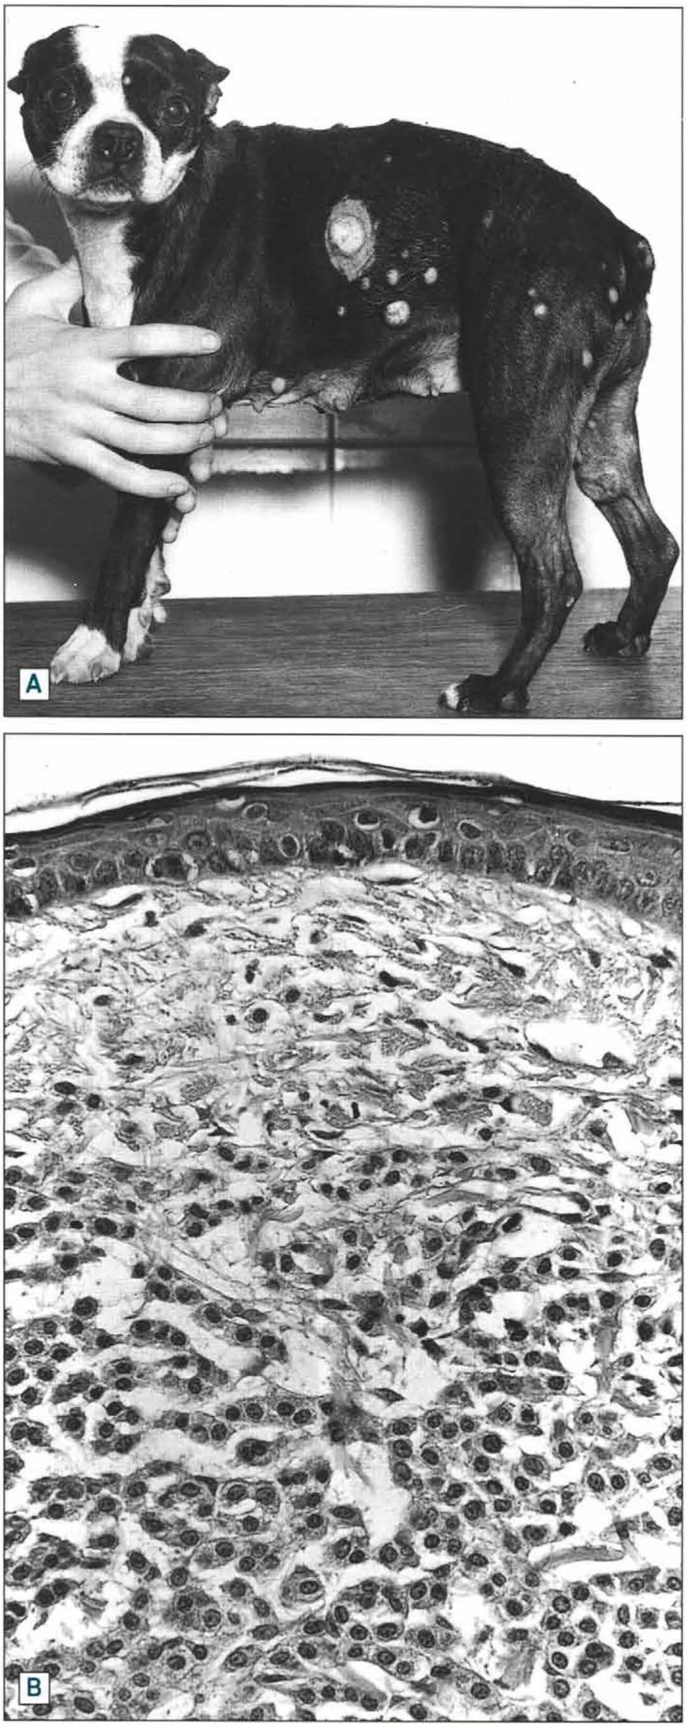

Figure 5.147 Cutaneous mast cell tumors. A. Multiple tumors in a Boston Terrier. **B.** Well-differentiated cutaneous mast cell tumor from a dog. Short cords of uniform round cells with sparing of the superficial dermis.

to 19 years. Boxers, Terriers, Boston Terriers, Labrador Retrievers, Beagles, and Schnauzers are reportedly predisposed. Shar-Peis are also predisposed and in this breed, mast cell tumors often occur at an earlier age than in other breeds. Site predilections vary with the breed. Studies investigating mast cell tumors in the dog have attempted to correlate clinical outcome with histologic grade, breed, tumor location, growth rate, clinical stage, argyrophilic nucleolar organizer region (AgNOR) counts, DNA ploidy, *p53* tumor suppressor gene product alterations, and proliferating cell nuclear antigen reactivity. Analysis of matrix metalloproteinases and expression of stem cell factor receptor and their correlation with histologic grade has also been investigated. Alterations in stem cell factor receptor expression are postulated to contribute to the proliferation of mast cells. To date, the most reliable criterion upon which to base a prognosis remains the histologic grade, however, establishing the histologic grade is subjective and less useful in tumors determined to be of intermediate differentiation. All mast cell tumors in the dog maintain a degree of unpredictability and should be regarded as potentially malignant.

There are currently two accepted grading systems for canine mast cell tumors, *the Patnaik system* (most commonly used) and *the Bostock system*. Well-differentiated tumors are considered Patnaik grade 1, while well-differentiated tumors in the Bostock system are considered grade 3. To avoid confusion, it is best to designate mast cell tumors as *well-differentiated, intermediate, or poorly differentiated*. Well-differentiated tumors carry an approximate metastatic potential of 10% while poorly differentiated mast cell tumors have a 55–96% rate of possible metastasis. Mast cell tumors metastasize first to regional lymph nodes and then most often to the liver and spleen. Mast cells may be detected in the peripheral blood and bone marrow in cases of widespread dissemination. Some mast cells may be present in the blood, bone marrow, and peripheral lymph nodes in the absence of disseminated disease, in normal animals and in animals with other diseases and these findings must be interpreted with caution.

- The **well-differentiated mast cell tumor** consists of round cells with a central small nucleus with a single inconspicuous nucleolus, and abundant, well-granulated cytoplasm. Cytoplasmic borders are distinct. There is very little cellular variation and mitotic figures are almost never seen. Tumor cells are arranged in rows or nests separated by collagen bundles. The tumor is confined to the dermis. Tumors of this type account for ~50% of the mast cell tumors of dogs and their behavior is usually benign. Excision is usually curative, with over 90% of affected dogs surviving >4 years.
- **Mast cell tumors of intermediate grade** are comprised of closely packed cells with distinct cytoplasmic boundaries, an increased nuclear-to-cytoplasmic ratio and fewer granules than a well-differentiated tumor. Giant, binucleate or occasional spindle-shaped cells may be present. Mitotic figures may be present in small numbers. The tumor cells are arranged in rows or nests separated by a collagenous stroma that may be thick or hyalinized with areas of edema and necrosis. The tumor may infiltrate the lower dermis and subcutis. The 3.5 year survival rate is ~55%.
- The cells of **undifferentiated (anaplastic) mast cell tumors** exhibit poor cytoplasmic granulation, large nucleus in relationship to cytoplasmic volume, irregular nuclear shape, moderate variation in nuclear size, several nucleoli and occasional binucleate, multinucleated or giant cell. Mitotic figures may be numerous. The cytoplasmic granulation may be inapparent or visible only as fine cytoplasmic dusting, and may require staining with Giemsa or toluidine blue to demonstrate the metachromatic granules. Tumor cells infiltrate the subcutis and deeper tissues. About 20% of the canine tumors fall into this prognostic category. Dogs with poorly differentiated tumors have a 3.5 year survival rate of approximately 15%.

The *macroscopic appearance* of canine mast cell tumors varies widely with their stage of progression and degree of histologic differentiation. Well-differentiated tumors most often appear as a rubbery, nodular nonencapsulated variably alopecic dermal mass 1–4 cm in diameter that clinically resembles a lipoma. Poorly differentiated tumors tend to achieve a large size more quickly, are less circumscribed and often associated with inflammation and edema of the surrounding dermis and possible satellite lesions. Tumors of intermediate grade have a gross appearance that varies between those described above.

Other clinical signs may occasionally result from the release of histamine or other vasoactive products from the mast cells. *Gastroduodenal ulceration* is relatively frequent in dogs with disseminated disease, occurring in 35–83% of cases. Histamine release stimulates the specific H2 gastric parietal cell receptors, resulting in increased acid secretion and perhaps local mucosal ischemia. Ulceration follows and may lead to fatal exsanguination. *Hypotensive shock* from massive synchronous degranulation, as may occur with cryosurgery, is a rarely reported complication.

Mast cell tumors in **cats** exist as *primary cutaneous mast cell tumors* and as *visceral mastocytosis*. They are separate diseases. Mast cell tumors are the second most common cutaneous neoplasm in the cat and account for 20% of skin tumors of cats in the USA. The metastatic potential of feline cutaneous mast cell tumors is very low (~5%) and those destined for behavioral malignancy are easily detected by anisocytosis, hyperchromasia and mitotic activity. Apparent recurrence at the surgical site or elsewhere in the skin is seen in 25–50% of the cases, but most of these probably represent multicentric origin. Cats with multiple mast cells tumors are often FIV positive. There is *no widely accepted grading system* for feline mast cell tumors.

Mast cell tumors in cats appear as one or several firm, raised pink, alopecic papules varying in size from millimeters to several centimeters. Less commonly, the tumor appears as a poorly defined area of swelling due to an infiltrative rather than nodular lesion. The head and neck are preferred sites. Histologically the cells are usually extraordinarily uniform, polygonal to round, and grow in a diffuse sheet interrupted only by small clusters of lymphocytes and rare eosinophils. The cytoplasm is clear, eosinophilic or only faintly basophilic. Obvious granularity is infrequent. The nucleus is round, central and relatively hyperchromatic in comparison to that of canine mast cells. Even with metachromatic stains such as Giemsa or toluidine blue, cytoplasmic granules may stain poorly, yet ultrastructurally they are abundant. Occasionally, binucleate, multinucleated or cells with giant nuclei measuring up to 25 μm may be seen. Eosinophils are seen in only a small number of feline mast cell tumors. The tumor is not encapsulated and is most often confined to the dermis. Collagen degeneration and stromal proliferation are rare. Much less frequent is a *second histologic type* seen most often in young cats as multiple, simultaneous or sequential, tumors located at the junction of the dermis and subcutis. Siamese cats are predisposed. The tumor mast cells resemble histiocytes and the lesion may be mistaken for granulomatous inflammation. Toluidine blue or Giemsa staining may be equivocal. The cells are confirmed as mast cells on electron microscopic examination. Eosinophils, lymphoid aggregates, well-circumscribed growth habit and benign behavior are similar to the more usual mast cell tumor of cats described above.

Mast cell tumors in **horses** have been cautiously termed *cutaneous mastocytosis*, but the growths are comparable to the cutaneous tumors of other species. They most commonly present as solitary nodules on the head, trunk, neck, and limbs. The tumors may be hyperpigmented, alopecic or ulcerated. Collagen degeneration, large aggregates of eosinophils, necrosis, and focal mineralization are more prominent. While in some respects resembling such lesions as cutaneous onchocerciasis, habronemiasis or collagenolytic granulomas, none of these three is characterized by sheets of mast cells. Multiple congenital mast cell tumors that spontaneously regress have been reported. There are no reports of metastasis of mast cell tumors in the horse.

Mast cell tumors in **ferrets** resemble the well-differentiated feline mast cell tumor grossly, histologically and in terms of biological behavior.

In **pigs**, mast cell nodules have been described as tumors and as multifocal inflammatory aggregates, perhaps in response to *Eperythrozoon*. Their morphology resembles that of well-differentiated feline tumors. In the pigs with multiple skin lesions, visceral aggregates were also found.

In **cattle**, scant data suggest the cutaneous tumors are usually multiple and are associated with visceral mast cell aggregates, although purely cutaneous tumors have been reported. Congenital cutaneous mast cell tumors consisting of well-circumscribed 1–7 cm nodules randomly distributed all over the body have also been reported. Histologically, the tumors had features of well-differentiated mast cell tumors. There are more reports of cutaneous metastases of multicentric visceral tumors than there are of primary skin disease. Cattle of any age, including calves, may be affected.

Cutaneous lymphoma

Lymphomas in the skin can be a primary cutaneous neoplasm or can be part of a multicentric lymphocytic neoplasm. Cutaneous lymphomas have been reported in most domestic animals and in many wildlife species, however the tumor has been most closely studied in the dog, cat, horse, and in cattle. The body of information about cutaneous lymphomas in veterinary dermatopathology has expanded rapidly in recent years, and is still a subject under close study. The development of *monoclonal antibodies directed against lymphocyte antigens* has greatly enhanced immunophenotypic analysis of tissue sections and needle aspirate preparations of these tumors. There are currently several antibodies that are routinely used in formalin-fixed tissue to characterize cutaneous lymphomas. As in humans, *T lymphocytes* in many domestic species consistently express the cell surface antigen CD3, and *B lymphocytes* can be identified in fixed tissues in many species by expression of CD79a. Many other monoclonal antibodies have been developed to identify lymphocyte subsets and others to identify lymphocyte antigens in fresh-frozen tissue. A description of these is beyond the scope of this chapter and the reader is referred to more detailed information on this topic in the bibliography. Classification schemes to predict behaviour of cutaneous lymphomas have been controversial. Several classification schemes devised for human lymphomas have been used, however they were based on lymphomas in lymph nodes. These schemes have included Rappaport, Lukes-Collins, Kiel, National Cancer Institute working formulation, and more recently, the Revised European-American Classification of Lymphoid Neoplasms (REAL). Since primary cutaneous lymphomas differ histologically and immunophenotypically from primary nodal lymphomas and often carry a better prognosis, *classification of primary cutaneous lymphomas using lymph node schemes has been difficult and unsatisfactory.* A new classification scheme devised for primary cutaneous human lymphomas has been

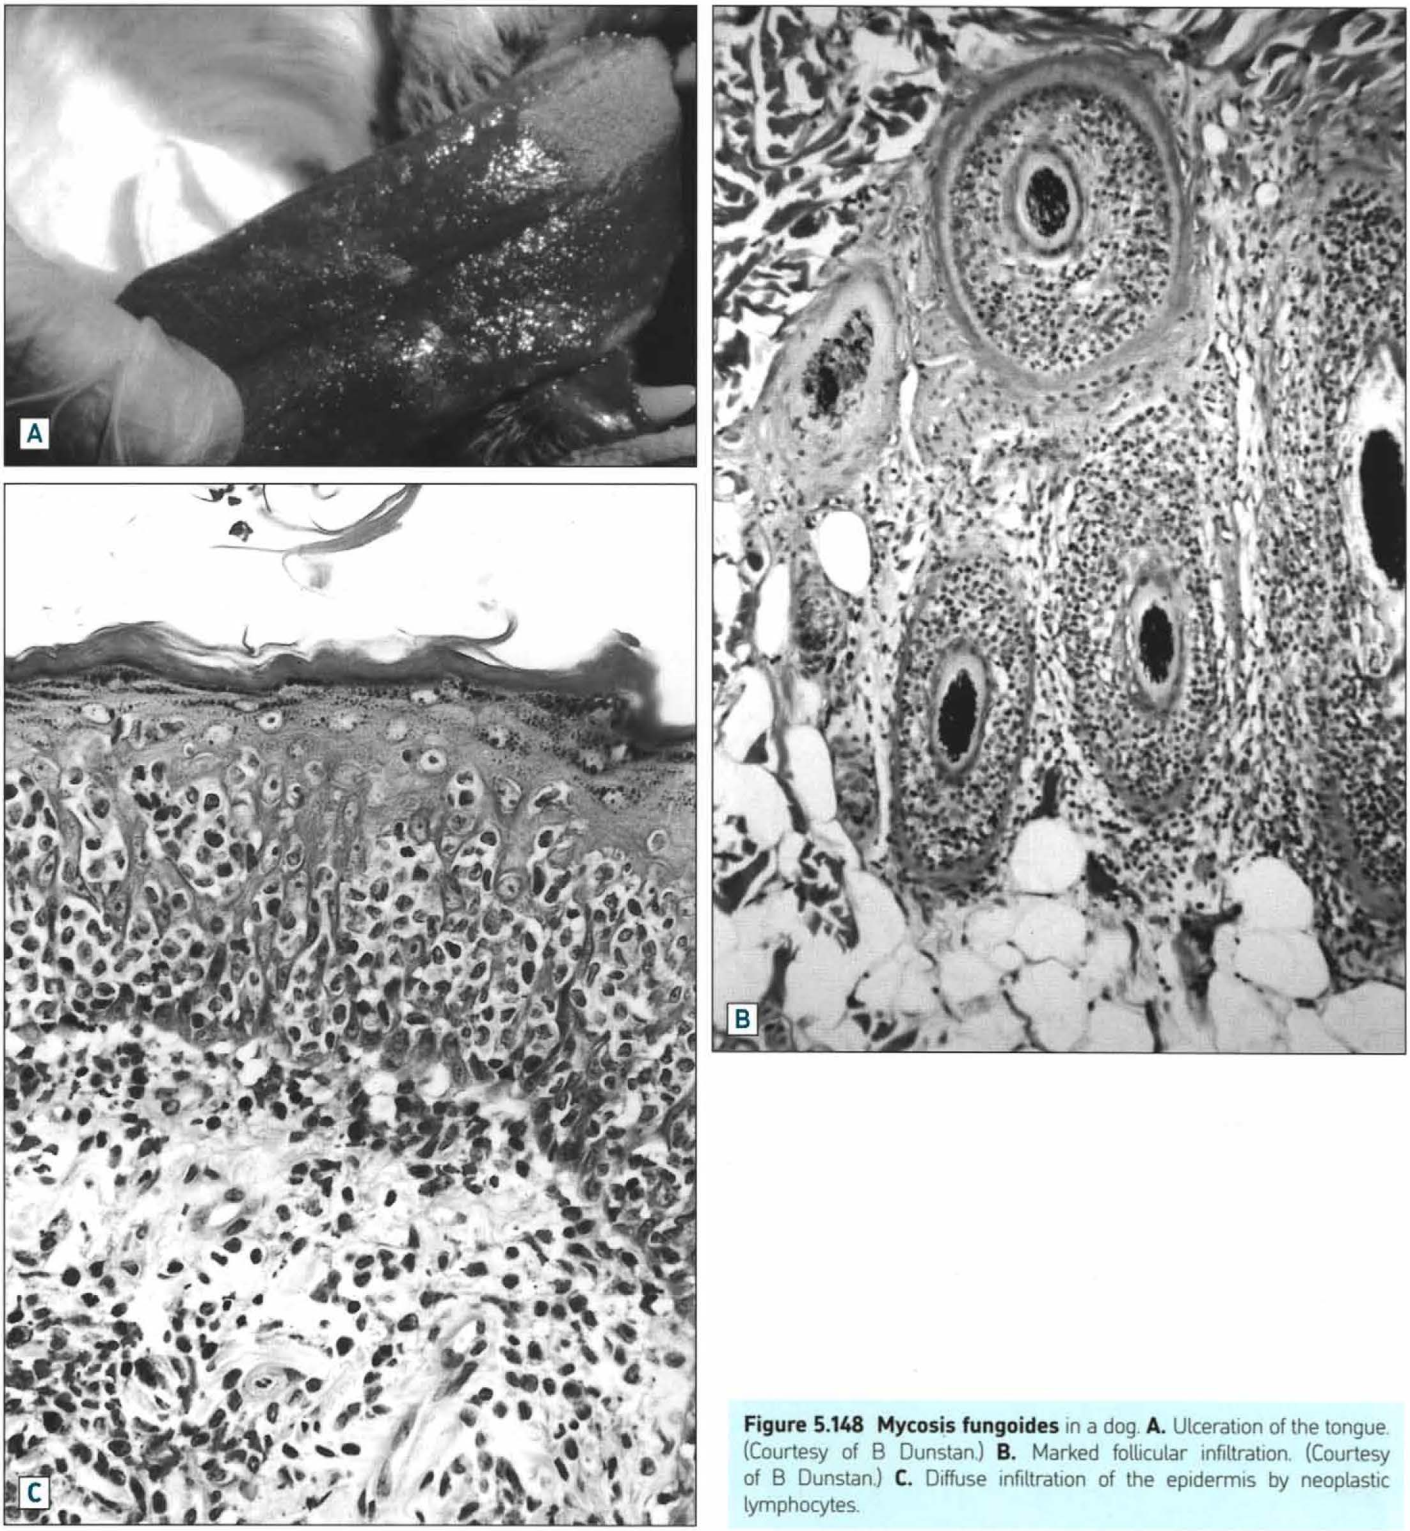

Figure 5.148 Mycosis fungoides in a dog. **A.** Ulceration of the tongue. (Courtesy of B Dunstan.) **B.** Marked follicular infiltration. (Courtesy of B Dunstan.) **C.** Diffuse infiltration of the epidermis by neoplastic lymphocytes.

proposed by the European Organization for Research and Treatment of Cancer (EORTC). It is based on a combination of clinical, histologic, immunophenotypic, and genetic criteria. The EORTC and REAL schemes use similar terminology, and these two systems may allow for recognition and comparison of similar tumors in cutaneous and non-cutaneous sites. Currently there have been no studies using the EORTC system on primary cutaneous lymphomas in domestic animals.

Cutaneous lymphomas in domestic animals are usually divided into two groups; *epitheliotropic cutaneous lymphomas*, in which the neoplastic lymphocytes invade the epidermis and/or adnexal epithelium, and *nonepitheliotropic lymphomas* that involve the dermis and subcutis. With the increasing use of immunohistochemical characterization of cutaneous lymphomas in domestic animals, division into *T-cell cutaneous lymphomas* (which would include mycosis fungoides, Pagetoid reticulosis, and angiocentric lymphomas/lymphomatoid granulomatosis), and *B-cell lymphomas*, will become more useful.

Epitheliotropic cutaneous lymphoma in domestic animals is represented primarily by **mycosis fungoides**. Mycosis fungoides has been reported in the *dog, cat, horse, rabbit, and cattle*. Mycosis fungoides is a disease of *older animals* and frequently there is a history of chronic erythematous, exfoliative dermatitis or multiple plaques and nodules. Lesions can be anywhere, however mucocutaneous junctions of the mouth, nose, eyes, anus, vulva, or the gingiva and palate are often involved (Fig. 5.148A). Histologically the neoplastic lymphoid infiltrate involves epidermis but can also involve the epithelium of adnexal structures (Fig. 5.148B). The lymphoid infiltrate in the epithelium can be diffuse (Fig. 5.148C), scattered, or form aggregates ("*Pautrier's microabscesses*") (see Fig. 5.10). Dermal involvement varies from a mixed perivascular cellular component that contains low numbers of neoplastic lymphocytes to a more fulminating diffuse monomorphic neoplastic infiltrate. Epidermotropic cutaneous lymphomas frequently ulcerate and verification of the epitheliotropic nature of the neoplasm can be difficult, however, a neoplastic lymphocytic component that abuts the ulcerated epidermis suggests epidermotropism. The neoplastic lymphocytes can vary from a small cell type, with a low mitotic index, hyperchromatic nucleus and scant cytoplasm, to a large cell type with moderate mitotic index together with moderate amounts of pale basophilic to clear cytoplasm. Although less well characterized than the human form of mycosis fungoides, epitheliotropic lymphomas in domestic animals also express T-cell surface antigens such as CD3. However, in contrast to human epitheliotropic lymphomas, which are reported to express CD4 in approximately 90% of cases, 80% of epitheliotropic lymphomas in domestic animals express CD8. Mycosis fungoides with a leukemic blood component (**Sezary syndrome**) has been reported in the dog, cat, horse, and cow. **Pagetoid reticulosis (Woringer–Kolopp disease)** is a localized solitary plaque form of epidermotropic lymphoma that is well recognized in humans and has been reported rarely in the dog. In this form, the neoplastic lymphocytes are confined primarily to the epidermis and the dermal component is a mixture of mature lymphocytes and macrophages.

Angiocentric lymphoma (lymphomatoid granulomatosis) in the skin is usually a cutaneous manifestation of pulmonary lymphoma, however, it is thought to occur rarely as a primary cutaneous disease. Although well described in humans, this form of lymphoma has been reported infrequently in domestic animals. It is characterized by *angiocentric, angioinvasive, and angiodestructive neoplastic lymphocytes in the dermis and subcutis, resulting in intramural and extravascular neoplastic infiltrates*, in contrast to the luminal accumulations of lymphocytes in malignant angioendotheliomatosis. The neoplastic cells are medium- to large-sized lymphoid cells that can have a histiocytic appearance, with a cleaved or reniform nucleus. Inflammatory cells such as eosinophils, plasma cells, and small lymphocytes may accompany the neoplastic cells. In the small number of cases reported, the neoplastic lymphocytes have been identified as T lymphocytes by immunophenotyping. Clinically the presentation is one of multiple alopecic and frequently ulcerated dermal or subcutaneous nodules. The angiodestructive nature of the neoplasm can result in multifocal necrotic or infarctive lesions.

Nonepitheliotropic cutaneous lymphomas appear to be less common than epitheliotropic lymphomas in most domestic animal species. Clinically the animals have multiple dermal and subcutaneous nodules that infrequently ulcerate. Histologically the neoplastic cells form *"bottom-heavy" nodules in the dermis and subcutis*, often with a Grenz zone. The neoplastic cells may be large cells with a histiocytic appearance, and immunophenotyping is often necessary to distinguish them from the histiocytic proliferative diseases. The neoplastic cells can efface adnexal structures, but invasion into the epidermis or adnexal epithelium is very unusual.

Nonepitheliotropic lymphomas that have been studied are usually of B-lymphocyte origin, with the exception of the angiocentric lymphomas discussed previously. An interesting form of nonepitheliotropic lymphoma is the **T-cell-rich B-cell lymphoma,** which is well recognized in humans and has now been reported in the *cat, pig, dog, and horse*. In the horse, it appears to be the most common form of cutaneous lymphoma. In this form, the nodular masses are composed of neoplastic large B lymphocytes accompanied by a background population of smaller reactive T lymphocytes that usually comprise the majority of the cell population. The large neoplastic B cells exhibit cellular atypia, with large vesicular nuclei and numerous mitotic figures that are often atypical. Since the neoplastic population is often the minority population, mitotic index should be evaluated carefully taking into account the fact that the majority population is non neoplastic small T lymphocytes with normal morphology and low mitotic index. These tumors also usually contain variable numbers of macrophages, epithelioid macrophages, and occasionally multinucleated giant cells. The mixed nature of the population can lead to this tumor being mistaken for inflammation, or a neoplasm of T lymphocytes. T-cell-rich B-cell lymphomas in the horse appear to be histologically the same as the neoplasm referred to in the older literature as *equine cutaneous histiolymphocytic lymphosarcoma*.

Intravascular lymphoma (malignant angioendotheliomatosis, intravascular lymphomatosis, angiotropic large-cell lymphoma) is *characterized by intravascular neoplastic lymphocytes in the vessels of the skin and other organs in the absence of a primary mass or circulating neoplastic cells*. This condition is rare in humans and was originally thought to be a proliferation of endothelial cells, which lead to the original name of malignant angioendotheliomatosis. At present it has been reported rarely in the dog and cat. Clinically the skin lesions appear as plaques and nodules, and histologically vessels in the dermis and subcutis are partially or completely filled with *large atypical lymphoid cells*. In humans, the intravascular neoplastic cells are of B-lymphocyte origin, however in dogs the majority of cases so far have been of T-lymphocyte origin.

Cutaneous pseudolymphomas *are benign reactive proliferations of lymphocytes that mimic cutaneous lymphomas histologically and sometimes clinically*. These proliferations are poorly characterized in the veterinary literature, but are well recognized in humans as forming both a band-like infiltrate in the superficial dermis (*T-cell pattern*) and nodular to diffuse infiltrates in the dermis and subcutis (*B-cell pattern*). Pseudolymphomas in humans can be due to many antigenic stimuli, such as drug eruptions, arthropod or tick-bite reactions, and contact dermatitis. *Differentiation between benign inflammatory lesions and early cutaneous lymphoma can be extremely difficult*. Although immunophenotyping can distinguish between T-cell and B-cell lymphomas, methods to distinguish between inflammatory and malignant lymphocyte proliferations are unreliable at present.

Cutaneous plasmacytoma

Cutaneous plasmacytomas are common in dogs and rare in cats. Most cases are benign however malignant cutaneous plasmacytomas demonstrating local invasion and tissue destruction do occur. It has not been described in other species. It occurs most often in *middle-aged or old dogs* with a marked predilection for *feet, ear canal, and mouth.* The typical tumor is a small spherical mass grossly similar to benign cutaneous histiocytoma, but its histology is distinctive. *Sheets of pleomorphic round cells are divided into solid lobules by a fine fibrous stroma.* The cells often have marked variation in nuclear size and degree of basophilia, with binucleation or multinucleation and numerous mitotic figures. *At least some of the cells retain a perinuclear halo (suggesting a Golgi zone), "clockface" nucleus, and basophilic cytoplasm considered typical of plasma cells.* Russell bodies are sometimes seen even in very atypical cells, and the cytoplasm of most cells is pyroninophilic. Cells recognizable as plasma cells are most easily found near the periphery (Fig. 5.149). A Grenz zone is usually present and there is no epithelial invasion. Electron microscopy or immunohistochemistry for canine immunoglobulin confirms the diagnosis but seldom are these tests necessary. Occasionally a particularly anaplastic example must be distinguished from amelanotic epithelioid melanoma or lymphoma. The distinction is critical, since even bizarre plasmacytomas are cured by excision. Extracellular amyloid (AL) is found in a small percentage (perhaps up to 10% of plasmacytomas). They bear no apparent relationship to multiple myeloma. Multiple tumors, rarely > 2–3, have been reported, as has a very low prevalence (~5%) of local recurrence.

Merkel cell tumor

Merkel cell tumors have rarely been reported in the **dog**. Clinically, the tumors appear as nodular lesions that may resemble a histiocytoma. Too few cases have been reported to establish age, site or sex predilections. Microscopically, the tumors are comprised of *dermal infiltrates of round cells arranged as solid nests or clusters separated by collagenous stroma.* Individual tumor cells are reported to have indistinct margins and moderate amounts of pale cytoplasm. The nuclei are oval or spherical with dispersed chromatin. The nucleolus is not conspicuous. A small number of mitotic figures may be present. *Differential diagnoses* include cutaneous plasmacytoma and basal cell epithelioma. Definitive diagnosis requires ultrastructural examination or immunohistochemistry. Merkel cell tumors label for cytokeratin and chromogranin A and do not label for immunoglobulins.

Electron microscopic evaluation demonstrates *electron dense-core granules typical of neuroendocrine cells.* Merkel cell tumors in the dog are most often benign with only one report documenting metastasis. A malignant neuroendocrine carcinoma of the skin (Merkel cell tumor) has been reported in a Maine coon **cat**.

Tumors of the mammary gland

Mammary masses are *very common in dogs and to a lesser extent cats,* but are rare in other domestic species. In the dog, mammary tumors vary greatly in their morphologic appearance and biological behaviour. The high prevalence of canine mammary tumors, the need to identify dogs that would benefit from aggressive therapy, and the potential usefulness as an animal model has led to many investigations into the factors governing mammary tumor development and behavior in the dog. These studies have attempted to correlate histologic features and clinical outcome with characteristics such as hormone receptor expression, oncogene and tumor suppressor gene alterations, intratumoral vessel density, argyrophilic nucleolar organizer counts, tumor cell kinetics and intermediate filament expression. Results of these studies have added to the current state of knowledge regarding mammary gland tumors in the dog but have not completely defined parameters upon which to base a prognosis. **Invasion** *by the tumor into surrounding tissue is considered one of the most important predictors of behavioral malignancy.* In dogs, 80% of animals with invasive tumors will have a survival time of <2 years. Metastases to lung and lymph nodes are frequently found at necropsy. Conversely, 80% of dogs with non-invasive tumors – regardless of any other histologic features – will be alive at 2 years post-diagnosis. *The presence of tumor emboli in lymphatics or veins is absolute evidence for local invasion and metastatic potential.* In its absence, care must be taken to ensure that the invasion is really into surrounding normal tissue and not just into the abundant stroma accompanying the tumor itself.

Classification schemes for mammary tumors may be based on histogenesis of the neoplastic cells, morphologic appearance, or prognostic factors. *No scheme is completely satisfactory, and correlation of histopathological diagnosis and clinical outcome vary.* The scheme utilized in this text follows that outlined by the current World Health Organization International Histological Classification of Tumors of Domestic Animals, and considers both morphologic features and known indicators of prognosis for the dog. One exception to the WHO classification scheme that is included here is the findings of a recent study documenting the morphologic features and biological behavior of all mammary neoplasms occurring during the lifespans of 1343 Beagles. This study found a specific tumor type, the **ductular carcinoma** (arising from interlobular or intralobular ductules) had a higher fatality rate than other types of adenocarcinomas arising in the mammary gland. The ductular carcinoma is not a specific morphological subtype currently recognized by the WHO classification scheme but it will be included in this discussion as *it carries a poorer prognosis that other types of mammary gland adenocarcinomas.* The Beagle study also found that there was no difference in the frequency of metastasis between simple and complex carcinomas or between these tumors and adenocarcinomas in mixed tumors. They also reported that carcinosarcomas metastasized more frequently than adenocarcinomas in mixed tumors.

In **cats**, *mammary tumors are 85–90% behaviorally malignant* and are classified as subtypes of carcinomas based on morphologic features alone. Hyperplastic and dysplastic lesions of the mammary gland will also be considered here.

Mammary hyperplasia and dysplasia

Mammary ductal hyperplasia occurs frequently in bitches and occasionally in queens. Single or multiple extralobular ducts are distended with proteinaceous fluid and some cellular debris. Their leakage may induce sterile granulomatous inflammation rich in ceroid-laden macrophages. Histologically, the lesion consists of *patchy intraductal hyperplasia of epithelial cells.* Papillary proliferations of epithelium may fill the duct lumens. Proliferative cells are small, uniform and associated with an orderly myoepithelial layer. They may spontaneously regress, and ovariectomy reliably causes their regression, whereas progestogen administration induces their development. It is not known whether they predispose to, or even progress to neoplasia although neoplastic transformation would seem likely.

Mammary lobular hyperplasia *consists of patchy hyperplasia of secretory acini indistinguishable from the normal lactating gland.* Proliferation involves intralobular ductular epithelium, myoepithelium, and fibrous tissue in varying proportions. The lobular architecture of the gland is maintained. It occurs in intact, nonpregnant and non-lactating bitches, and occasionally in queens. Serial sectioning of the mammary glands reveals numerous small (1–4 mm diameter) hyperplastic foci in 50% of clinically normal bitches even at 3 years of age. They are most numerous in the caudal two glands, paralleling the greater prevalence of neoplasia in these glands. Circumstantial evidence supports the view that such lesions should be considered *preneoplastic changes.* Indeed, many hyperplastic lobules contain dysplastic foci with some degree of epithelial disorganization and hyperchromasia, blurring the distinction between hyperplasia, dysplasia and in situ neoplasia.

Mammary fibroepithelial hyperplasia *(fibroadenomatous change) occurs in young cycling, or pregnant cats.* It also can be induced in old unspayed females and males by treatment with *megestrol acetate.* Progesterone receptors are present in high concentrations. The condition appears most often 1–2 weeks post-estrus, usually affects one or more glands, and may regress spontaneously or require ovariectomy. Grossly, the mammary tissue is markedly swollen and erythematous. Necrosis and ulceration may be present. Edema may involve the rear limbs. Histologically there is *branching and proliferation of mammary ducts lined by simple columnar epithelium, surrounded by massive and concentric proliferation of edematous stroma compatible with myoepithelium* (Fig. 5.150). The prominence of the stroma is in sharp contrast to mammary neoplasia in cats, which almost always is solid or alveolar carcinoma with little stroma.

Mammary neoplasia in dogs and cats

Mammary tumors have been reported to comprise 50% of all neoplasms in the **bitch**. They occur most often in bitches 10–11 years old and are

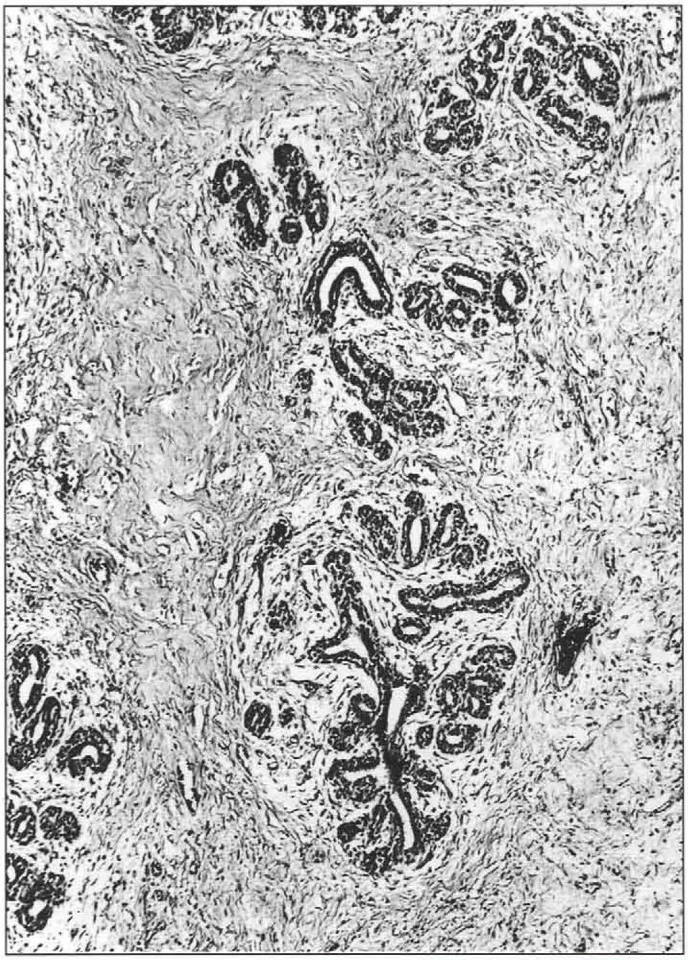

Figure 5.150 Fibroepithelial hyperplasia in the mammary gland of a cat.

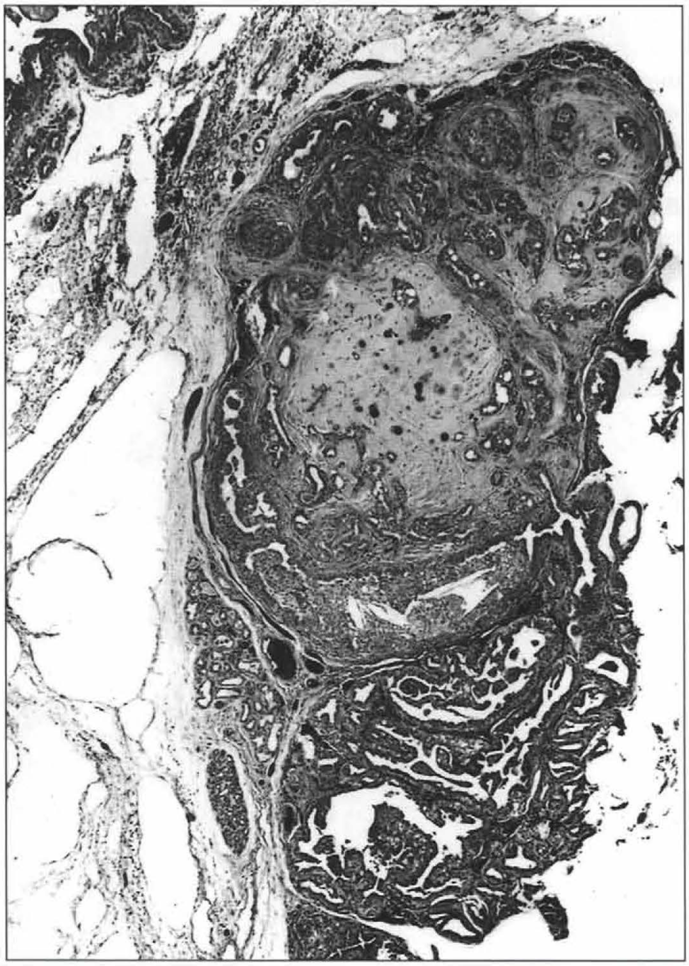

Figure 5.151 Benign mixed mammary tumor with typical mixture of tubular, papillary, and cartilaginous elements.

very rare in dogs less than 5 years of age. Dogs have five pairs of glands and 70% of all tumors develop in glands 4 and 5. Tumors can involve the lobular tissue or the nipple. Mammary tumors in the dog are hormonally dependent. Ovariohysterectomy at or prior to first estrus dramatically decreases the risk of development of mammary tumors. Between 41–53% of mammary tumors in the dog are considered malignant. *Metastasis occurs via hematogenous or lymphatic routes to seed the lung and regional nodes, respectively*. Carcinomas that metastasize to the inguinal lymph nodes may spread to the internal iliac nodes and lead to colonic compression. Many tumors with histologic criteria of malignancy such as cellular atypia or invasion, do not exhibit malignant biological behavior. In addition, the morphologic appearance of the tumor can vary significantly within the section and the lack of consensus regarding criteria for the diagnosis of malignancy leads to a variation in interpretation of lesions.

Benign tumors of the canine mammary gland include simple adenomas, complex adenomas, basaloid adenomas, fibroadenomas, and benign mixed tumors. The *malignant tumors* include ductular carcinoma, carcinoma in situ, complex carcinoma, simple carcinoma, spindle cell carcinoma, squamous cell carcinoma, mucinous carcinoma, lipid-rich carcinoma, and a variety of sarcomas.

- **Simple adenomas** are comprised of either well-differentiated luminal epithelium arranged as simple acini with or without secretions, or as solid nodules of spindle cells (**myoepithelioma**).
- Tumor comprised of both myoepithelium and secretory epithelium that are encapsulated and demonstrate no cellular atypia are classified as **complex adenomas**.
- **Basaloid adenomas** are comprised of solid lobules of monomorphic basaloid epithelium that palisade against a basement membrane. Central cells may show squamous or secretory epithelial differentiation.
- **Fibroadenomas** are tumors comprised of luminal epithelium and possible myoepithelium mixed with stromal elements. The stroma may be sparsely cellular or highly cellular.
- **Benign mixed tumors** are comprised of well-differentiated luminal and/or myoepithelial cells accompanied by a mesenchymal population that has produced cartilage, bone, or fat in combination with a fibrous component (Fig. 5.151).

Carcinomas occurring in the mammary glands of dogs will be discussed in order of increasing malignancy.

- **Carcinomas in situ** (noninfiltrating carcinoma) consist of cerebriform or solid clusters of neoplastic epithelium confined by the basement membrane of a duct, lobule, or cyst. The tumor may be necrotic in the center. These lesions are often multicentric.
- **Complex carcinomas** are comprised of both luminal epithelium and myoepithelium. Complex carcinomas demonstrate

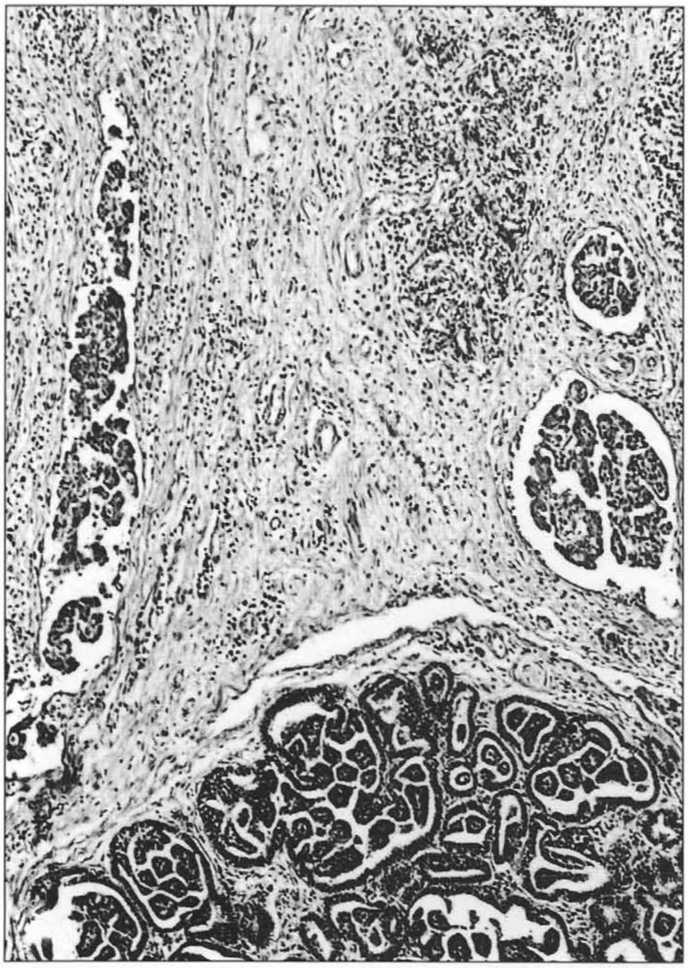

Figure 5.152 Mammary gland papillary adenocarcinoma with lymphatic invasion from a bitch.

infiltrative growth, lack of encapsulation, high cellularity, necrosis and numerous mitotic figures. Squamous metaplasia is frequently present. Lymphatic invasion is present in about 10% of the tumors.

- **Simple carcinomas** are comprised of luminal epithelium **or** myoepithelium. They may have a tubulopapillary or solid arrangement (Fig. 5.152). If the tumor cells are highly pleomorphic and defy histologic recognition as luminal or myoepithelium, the tumors are classified as **anaplastic carcinomas.** Anaplastic carcinomas may be positive for vimentin and cytokeratin with immunohistochemistry. Simple carcinomas are highly invasive and frequently metastasize.
- **Spindle cell carcinomas** are rare malignant tumors comprised of spindle cells arranged as solid or tubular patterns, and are thought to arise from myoepithelium as the cells label for vimentin and cytokeratin.
- **Ductular carcinomas** are comprised of branching duct-like structures filled with solid sheets, papillary projections or cystic aggregates of neoplastic epithelium. They may be simple or complex.
- **Squamous cell carcinomas** arising in the mammary gland are usually highly invasive and frequently invade lymphatics. The periphery of the tumor has predominantly basal cells with cellular atypia. Care must be taken to distinguish these tumors from cutaneous squamous cell carcinomas as the former are more aggressive.
- **Mucinous carcinomas** are of the simple or complex type and produce large amounts of mucin.
- **Lipid-rich carcinomas** are comprised of highly vacuolated epithelial cells that are positive for neutral lipids.

Primary mammary sarcomas *are infrequent in dogs and very rare in cats.* They presumably arise from the fibrous stroma of the gland or of the adjacent subcutaneous tissue. Histologic changes that suggest malignancy are occasionally seen in the myoepithelial stroma, or in the metaplastic bone or cartilage of mixed mammary tumors (so-called malignant mixed tumors). If such tumors metastasize, it is usually the epithelial component that spreads. **Osteosarcomas, chondrosarcomas, liposarcomas, fibrosarcomas,** and **carcinosarcomas** (malignant luminal or myoepithelial cells admixed with malignant stromal cells) have all been reported to arise in the mammary gland.

Mammary tumors in the **cat** represent the third most commonly reported tumor in the cat. Tumors develop most often in intact female cats with a mean age of 10–12 years. Tumors occasionally develop in spayed females or male cats. Spaying decreases the incidence of tumors but does not have the dramatic protective effect as seen in dogs. *At least 85–90% of the tumors are malignant* (Fig. 5.153A, B) *and metastasis to regional lymph nodes, lungs, pleura, liver, adrenal glands, and kidneys is common.* Tumors are firm, nodular and may be ulcerated. Any gland may be affected and tumors are usually multiple. Differences in biological behavior based on histologic subtype of mammary gland carcinomas in the cat have not been shown. **Carcinoma in situ, tubulopapillary carcinoma, solid carcinoma, squamous cell carcinoma, mucinous carcinoma,** and **carcinosarcomas** have all been reported in the cat. These tumors are morphologically similar to the same tumor described in the dog. In addition, a subtype referred to as a **cribriform carcinoma** comprised of malignant epithelial cells arranged in a solid pattern with many small apertures is common in the cat.

Mammary tumors in other species

In **mares**, the few reported tumors have been *scirrhous solid carcinomas* that have been extremely invasive locally, and all have had widespread metastasis.

In **cows**, the literature is old and of variable quality in that many diagnoses had no histologic confirmation. Most descriptions are of fibropapilloma-like growths in the teat canal or large ducts, but everything from fibroma, squamous cell carcinoma, osteoma to fibrosarcoma has been diagnosed. Many of the polypoid teat or cisternal growths were probably hyperplastic inflammatory polyps. **Goats** and water buffalo are cited in review articles as having a very low prevalence of mammary neoplasia.

Tumors metastatic to the skin

A variety of tumors can metastasize to the skin, but *the process is uncommon*. The usual routes of lymphatic, hematogenous, or implantation from a surgical procedure apply. A thorough search for a primary tumor, knowledge of prior history of a tumor, and an awareness of a few unique tumor patterns of metastasis are necessary to help establish the condition as a metastatic process.

Pulmonary carcinomas in the **cat** have a propensity to metastasize to the digits, often prior to onset of clinical signs referable to the primary tumor. Clinically, the lesions are suggestive of paronychia. Histologically, nests, solid sheets and glandular structures formed by malignant epithelial cells are found in the dermis and subcutis. Bony lysis of the third phalanx may be evident radiographically and histologically. Tumor cells have abundant eosinophilic cytoplasm, basally oriented nuclei and, frequently, apical cilia. Squamous differentiation is also common. Desmoplasia is usually present.

Visceral **hemangiosarcomas** may metastasize to the subcutis in the dog. Subcutaneous hemangiosarcomas, particularly if multiple, should prompt the clinician to search for a primary visceral tumor. Metastatic tumors may be fairly well-differentiated or anaplastic.

Mammary gland carcinomas in the dog may metastasize to the dermis of the inner thigh. Spread of tumor cells occurs via direct invasion of dermal lymphatics or from retrograde metastasis of tumor cells from the external inguinal lymph node. Mammary gland carcinomas in the cat may also metastasize to the ventral abdominal tissues using similar pathways. Primary apocrine gland carcinoma of the skin may be difficult to distinguish.

Abdominal surgeries to remove **transitional cell, colonic** or **prostatic carcinomas** have the potential for implantation of tumor cells in the skin at the surgical site. Tumor cells may also reach the skin via retrograde lymphatic metastasis.

ACKNOWLEDGMENT

We appreciate the contributions of Dr. Brian P. Wilcock to this chapter.

ORAL CAVITY

Examination of the oral cavity should be standard procedure during any postmortem examination. To obtain a clear view of the mucous membranes of the buccal and oral cavities, teeth, tongue, gums, and tonsils, it is essential to split the mandibular symphysis and separate the mandibles as far as possible. A thorough examination of all structures will reveal not only local lesions, but often those that may be due to systemic disease. Lesions may be associated with congenital anomalies; trauma (physical and chemical); bacterial, mycotic, viral, and parasitic infections; metabolic and toxic diseases; and immune-mediated, dysplastic, or neoplastic disease. The poor physical condition of an animal may be directly related to oral lesions that result in difficulties of prehension, mastication, or swallowing of food.

Congenital anomalies

The development of normal facies and the oral cavity requires the integration of many embryonic processes. The complexity and duration of this development may lead to a great variety of aberrations. These are usually expressed in the newborn in the form of *clefts resulting from failures of integrated growth and fusion.* A common failure of fusion is that of the maxillary processes to the frontonasal process. This may leave facial fissures, cleft lip (harelip, cheiloschisis) and uni- or bilateral primary cleft palate involving the area rostral to the incisive papilla.

Facial clefts may involve the skin only, or the deeper tissues as well. They are variously located, and not all are obviously related to normal lines of fusion. All are rare. The least uncommon is a complete cleft from one angle of the mouth to the ear of that side. This results from failure of fusion of the lateral portions of the maxillary and mandibular processes. A defect extending from a cleft lip to the eye results from failure of fusion of the maxillary and frontonasal processes; its least expression is superficial and a failure of closure of the nasolacrimal duct.

Primary cleft palate (harelip, cheiloschisis) includes developmental anomalies of the lips rostral to the nasal septum, columella, and premaxilla. They may be uni- or bilateral and superficial or extend into the nostril. The defect arises from incomplete fusion of the frontonasal process with the maxillary processes.

Secondary cleft palate (cleft palate, palatoschisis) (Fig. 1.1) is often associated with primary cleft palate. The normal hard palate is formed, except for a small rostral contribution from the frontonasal process, by the bilateral ingrowth of the lateral palatine shelves from the maxillary processes. At the midline, they fuse with each other and with the nasal septum, and undergo intramembranous ossification, except in their caudal part, which becomes the soft palate. Inadequate growth of the palatine shelves leaves a central defect, in either or both of the hard and soft palates, which communicates between the oral and nasal cavities. Other manifestations of disordered palatogenesis include unilateral defects in the soft palate; bilateral hypoplasia of the soft palate; or dorsal displacement of the soft palate, with excess soft tissue on the caudal portion. Affected animals have difficulty sucking, may have nasal regurgitation, and usually die within the first few days of life from aspiration pneumonia.

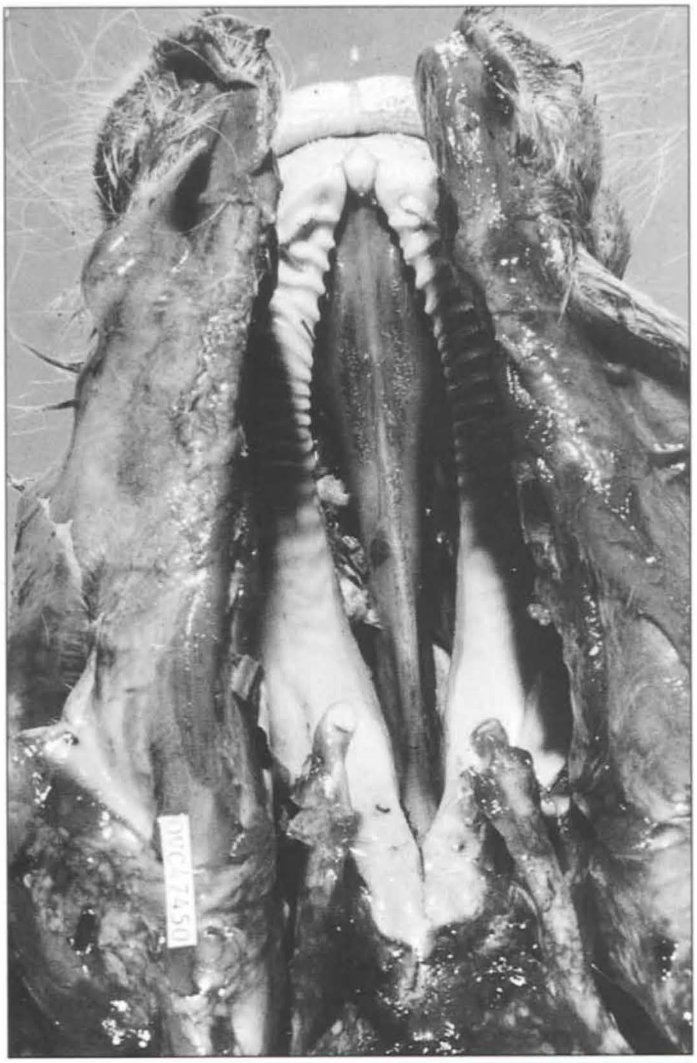

Figure 1.1 Secondary cleft palate exposing the nasal cavity in a calf.

Cleft palates have been reported in most species of domestic animals. In one extensive survey of Thoroughbred foals, 4% of congenital defects were secondary cleft palates. Most of these foals had a complete cleft of the hard palate; a few had clefts or hypoplasia of the soft palate only. In calves, cleft palate is one of the most common anomalies, but is very uncommon in sheep. Primary cleft palate is less common than secondary cleft palate in swine, although the two anomalies often occur together.

The etiology of cleft palate is usually unknown, but examples of *hereditary causes*, maternal ingestion of certain *drugs*, or maternal consumption of *teratogenic plants* during pregnancy have been demonstrated. Secondary cleft palate and arthrogryposis frequently occur together in Charolais calves, and appear to be hereditary (probably simple autosomal recessive), as in Hereford cattle. These two anomalies have also been associated with the ingestion of certain lupines by cows during gestational days 40–70. Cleft palate in lambs may be genetic in origin, but also is associated with the ingestion of *Veratrum californicum*. Secondary cleft palates have been induced experimentally in newborn pigs by feeding gilts seeds or plants of poison hemlock (*Conium maculatum*) during gestational days 30–45. Both tree tobacco (*Nicotiana glauca*) in western USA and tobacco stalks (*N. tabacum*) when fed to gilts early in pregnancy can induce a high incidence of cleft palate and arthrogryposis in newborn pigs. Piperidine alkaloids (coniine, coniceine, and anabasine) in hemlock and tobacco plants are responsible for the teratogenic effects of these plants. Lupines (*Lupinus formosus, L. arbustus*) produce piperidine alkaloids, including the teratogen ammodendrine, which can cause cleft palate and arthrogryposis (crooked calf disease) in calves born of dams fed the lupine at days 40–50 of gestation. Palatoschisis in piglets has also been associated with consumption of feed contaminated with *Crotalaria retusa* seed by sows during gestation. Primary and secondary cleft palate of German Boxer dogs appear to be hereditary, probably due to a single autosomal recessive gene. Secondary cleft palate occurs in Siamese and Abyssinian cats and is thought to be hereditary, although the mode of inheritance has not been determined. Griseofulvin treatment of the pregnant queen and mare will result in palatoschisis in the offspring. The defect has also been reported in both parts of the doubled face in diprosopus cats.

Anomalies in the growth of jaws are quite common. **Brachygnathia superior**, *shortness of the maxillae*, is an inherited breed characteristic among dogs and swine. It has been reported in the Large White or Yorkshire breed. The condition is progressive with age, resulting in malapposition of the incisor and cheek teeth, which interferes with prehension and mastication. In swine, brachygnathia superior may be confused with atrophic rhinitis. In Angus and Jersey cattle, brachygnathia superior occurs as a hereditary trait. It may, in any species, be associated with chondrodysplasia and is also present with other facial defects.

Brachygnathia inferior or micrognathia, *shortness of the mandibles*, may be a mild to lethal defect in cattle and sheep and is a breed characteristic of long-nosed dogs. Micrognathia is a common defect in calves. It is inherited, probably as a simple autosomal recessive trait. There is a higher incidence in males. In Aberdeen Angus cattle, the defect may occur concurrently with cerebellar hypoplasia, and with osteopetrosis in this and other breeds (see Vol. 1, Bones and joints). Mild brachygnathia inferior, termed *parrot mouth*, is a common conformational defect in horses.

Prognathism refers to *abnormal prolongation of the mandibles*. It is rather common, especially in sheep. It may develop with recovery from calcium deficiency in this species (see Vol. 1, Bones and joints). The malformation is relative, and it is not always easy to determine whether the jaw is absolutely long or merely apparently so, relative to a mild brachygnathia superior.

Agnathia is a mandibulofacial malformation characterized by *absence of the lower jaw*, due to failure of development of the first branchial arch and associated structures. The defect is one of the most common anomalies in lambs but is rare in cattle. Associated malformations in lambs may include ateloprosopia (incomplete development of the face), microglossia or aglossia, and atresia of the oropharynx. Concurrent anomalies affecting other body systems may also be evident.

A lethal glossopharyngeal hereditary defect, termed **bird tongue** and caused by a simple autosomal recessive gene, has been reported in dogs. Affected pups have a narrow tongue, especially the rostral half, where the margins are folded medially on to the dorsal surface. The pups are unable to swallow. The muscle fibers of the affected tongues are normal histologically. **Hypertrophy of the tongue** occurs as a congenital anomaly in pigs.

Persistent oropharyngeal membrane in a Hereford calf resulted in separation of the oral cavity from the pharynx, and inability to swallow milk. The cause was unknown, and the lesion is very rare.

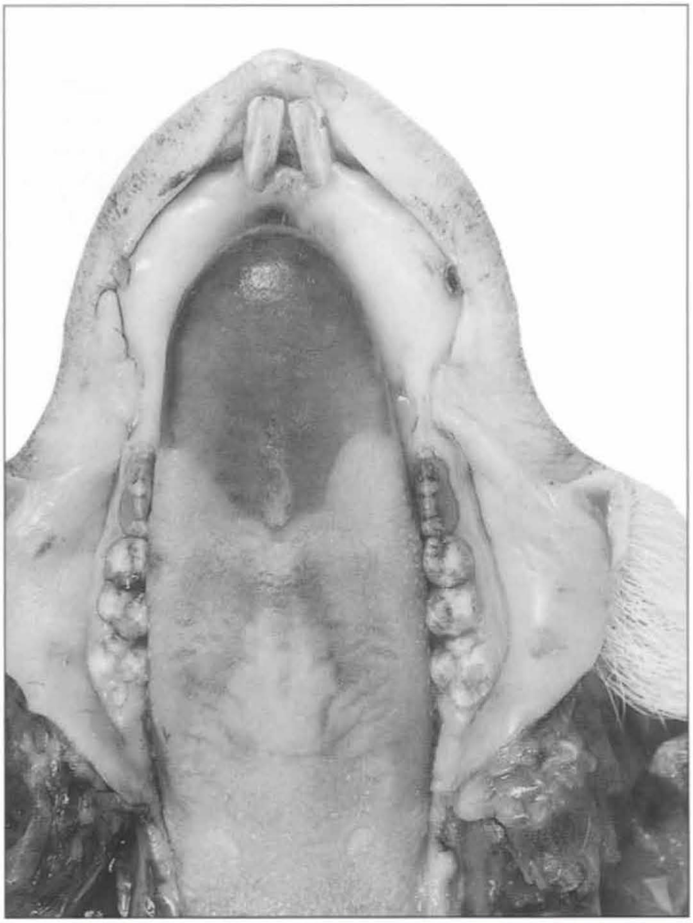

Figure 1.2 Epitheliogenesis imperfecta of the tongue of a pig.

Epitheliogenesis imperfecta is an anomaly causing *widespread defects in cutaneous epithelium, and also affects the epithelial lining of the oral cavity, especially the tongue* (Fig. 1.2) (see Vol. 1, Skin and appendages). The condition is characterized by irregular, well-demarcated, red areas from which the epithelium of the oral mucosa is absent. Histologically, these consist of abruptly defective areas in the squamous mucosa with inflammation of the submucosal connective tissues. The anomaly occurs in most species and is inherited as a simple autosomal recessive character in cattle, horses, and pigs; the mode of inheritance is unknown in the other species. There are several hereditary skin conditions in animals, such as epidermolysis bullosa simplex in collie dogs, ovine epidermolysis bullosa in Suffolk and South Dorset Down sheep, and familial acantholysis of Aberdeen Angus calves, which have minor involvement of the lips and oral mucosa (see Vol. 1, Skin and appendages).

Diseases of teeth and dental tissues

Dental examinations in animals are usually cursory, except to assess age, but dental disease is common and often is the factor that limits useful lifespan, especially of sheep. The comments on dental development and anatomy are intended to assist the understanding of dental disease.

Teeth develop from horseshoe-shaped thickenings in the oral ectoderm called *dental laminae*. Neural crest cells beneath the laminae induce formation of *tooth buds*, which generate the *enamel organs*. These epithelial structures grow into the underlying ectomesenchyme and organize it to form *dental papillae*, which they enclose like a cap. Surrounding both is another mesenchymal condensation, the *dental sac*, which has a collagenous inner layer, the dental follicle, and an outer fibrovascular layer. Developing teeth erupt through a combination of root elongation, alveolar bone remodeling, and periodontal ligament formation. *Periodontal ligament formation* may be more important for species in which the teeth continuously erupt during life. Tooth eruption is induced by the enamel organ that secretes mediators transforming growth factor-α and interleukin-1β to recruit monocytes in the dental follicle for osteoclast resorption and formation of an eruption pathway.

The *inner enamel epithelium* of the enamel organ induces differentiation of odontoblasts from the mesenchyme of the papilla. Odontoblasts produce *dentin*, which in turn induces enamel formation by the inner enamel epithelium. Formation of dentin is essential for the formation of enamel. These inductive interactions of epithelium and mesenchyme are considered important in the histodifferentiation of some tumors of dental tissues.

The free edge of the enamel organ extends beyond the enamel–dentin junction, and this extension is called *Hertwig's epithelial root sheath*. It molds the dental papilla to form the root or apex of the tooth. Subsequently it fragments, allowing mesenchymal cells from the dental sac to contact the root dentin, differentiate into cementoblasts, and deposit cementum on the dentin. Remnants of the root sheath are called *epithelial rests of Malassez*. They persist in the periodontal ligament, and may give rise to tumors or cysts. They may be important in the induction or repair of cementum, and in periodontal reattachment following injury. In pigs and sheep, the rests may be incorporated into the junctional epithelium as it migrates apically in chronic periodontal disease. Cells of the root sheath that adhere to the dentin can produce *enamel pearls*.

Once the dental lamina has produced the buds of the permanent teeth, it degenerates. Epithelial remnants persist as *epithelial pearls or islands* in the gingiva and jaws. These remnants also may give rise to tumors and cysts.

There are important differences between the **brachydont teeth** of humans, carnivores, and swine, in which the enamel is restricted to the tooth crown, and the **hypsodont teeth** of herbivores. In hypsodont teeth, enamel extends far down on the roots, and is invaginated into the dentin to form *infundibula*. Also, the hypsodont teeth of herbivores, except the mandibular premolars of ruminants, are covered by cementum, which more or less fills the infundibula. Exceptions to these rules are provided by the tusks of boars, which are hypsodont, but not covered by cementum, and by ruminant incisors, which are brachydont but do have enamel covering part of the root dentin and cementum covering the root enamel.

The three hard tissues of teeth are dentin, enamel, and cementum. **Dentin** is light yellow and constitutes most of the tooth. It consists of ~35% organic matter and ~65% mineral. Thus its composition is similar to that of bone, and like bone, it contains type I collagen. Dentin is produced by columnar cells with basal nuclei called *odontoblasts*, which differentiate from mesenchyme of the dental papilla. It is formed as unmineralized predentin. The odontoblasts move away from the dentin–enamel junction, gradually encroaching on the pulp cavity as they produce dentin. Each odontoblast has a process extending into the dentin, encased in a dentinal tubule, which arborizes at the dentin–enamel junction. The process also anastomoses with the processes of other odontoblasts. Dentinal tubules are visible in histologic sections, but the anastomoses are not. Except for the processes, and nerve endings in the dentinal tubules near the pulp, dentin is acellular.

Normal dentin contains incremental or *imbrication lines of von Ebner*, which are fine basophilic lines running at right angles to the dentinal tubules. They represent normal variations in the structure and mineralization of dentin. Sublethal injury caused by certain infections, metabolic stresses, or toxic states may injure the odontoblasts, which then produce accentuated incremental lines known as the *contour lines of Owen*. Sometimes irregular zones of unmineralized or poorly mineralized dentin form between foci of normal mineralization. These are zones of *interglobular dentin*, which may be caused by hypophosphatemia.

Odontoblasts normally are active throughout life, producing layers of secondary dentin, which often contain fewer dentinal tubules than primary dentin. *Reparative dentin* is produced locally in response to injury to dentinal tubules, and contains a limited number of twisted tubules and sometimes a few odontoblasts, which soon die. Reparative dentin may resemble bone and is sometimes called *osteodentin*. *Sclerotic* (*transparent*) *dentin* is formed when dentinal tubules are occluded by calcium salts. The junctions between primary, secondary, and reparative dentin are usually demarcated by basophilic lines.

Enamel has ~5% organic matter and ~95% mineral. It is produced by the tall columnar *ameloblasts* of the inner enamel epithelium. Enamel is produced in the form of prisms or rods, cemented together by a matrix. Mineralization begins as soon as it is formed and is a two-stage process, somewhat similar to that in bone, but much more rapid. The cells of the inner enamel epithelium also move away from the dentin–enamel junction as the tooth is formed, but, unlike odontoblasts, they do not have processes. Enamel is hard, dense, brittle, and permeable, and is translucent and white. Mature enamel is not present in demineralized sections, but some of the matrix of immature enamel may be visible near ameloblasts of developing teeth.

Ameloblasts are very sensitive to environmental changes. Normal enamel contains *incremental lines of Retzius*, which are analogous to the incremental lines of von Ebner in dentin, and also reflect variations in structure and mineralization. The incremental lines are accentuated during periods of metabolic stress. More severe injury, as in fluorosis, or infections by some viruses can produce focal **hypoplasia or aplasia of enamel**.

Formation of enamel ends before tooth eruption. The inner enamel epithelium then merges with the cells of the underlying stratum intermedium and the outer enamel epithelium to form the *reduced enamel epithelium*. It protects the enamel of the formed tooth prior to eruption. Degeneration of this protective layer permits connective tissue to contact the enamel, and there may be resorption of enamel or deposition of a layer of cementum on it. This normally occurs during odontogenesis in horses.

Cementum is an avascular, bonelike substance, produced by *cementoblasts*; it contains ~55% organic and ~45% inorganic matter. In general, the dentin of brachydont teeth is covered by cementum wherever it is not covered by enamel. When dentin formation has begun in the root, degeneration of Hertwig's epithelial root sheath begins and permits mesenchymal cells from the dental sac to contact dentin. They differentiate into cementoblasts, which produce *cementoid*, and later mineralize it. Some layers of cementum do not contain cells (acellular cementum), but in other layers, *cementocytes* are enclosed in lacunae. Sharpey's fibers from alveolar bone are embedded in the cementum. Cementum is more resistant to resorption than is bone, and unlike bone, normally is not resorbed and replaced as it ages; instead a new layer of cementum is deposited on top of the old layer. In some pathologic conditions cementum is resorbed; subsequently, cellular or acellular cementum is deposited, and more or less repairs the defect.

Hypercementosis is abnormal thickening of cementum and may involve part or all of one or many teeth. When extra cementum improves the functional properties of teeth, it is called *cementum hypertrophy*; if not, it is called *cementum hyperplasia*. Extensive hyperplasia is often associated with chronic inflammation of the dental root.

The **periodontal ligament** is very cellular, well-vascularized connective tissue that develops from the dental sac. The **periodontium** comprises the periodontal ligament, gingival lamina propria, cementum, and alveolar bone. The ligament supports the tooth and adjusts to its movement during growth. It is well supplied with nerves and lymphatics, which drain into alveolar bone. The periodontal ligament is also a source of the cells that remodel alveolar bone and, in disease, cementum.

Epithelial rests of Malassez are present in the periodontal ligament and are particularly numerous in the incisor region of sheep. In all species, they may proliferate and become cystic when there is inflammation of the periodontium. The periodontium is also a site of origin of tumors. The periodontal ligament is normally visible in radiographs as a radiolucent line between tooth and alveolar bone. In prolonged hyperparathyroidism, alveolar bone is resorbed, and the ligament is no longer outlined radiographically, a change referred to as *loss of the lamina dura*.

Developmental anomalies of teeth

Anodontia, *absence of teeth*, is inherited in calves, probably as a sex-linked recessive trait in males, and is associated with skin defects. **Oligodontia**, *fewer teeth than normal*, occurs sporadically in horses, cats, and dogs, and also as an inherited trait in dogs. In brachycephalic breeds, the cheek teeth are deficient; in toy breeds, the incisors are deficient. *Pseudo-oligodontia* and *pseudoanodontia* result from failed eruption. These defects may be associated with bone-modeling defects in gray lethal mice with osteopetrosis. Delayed eruption of permanent teeth occurs in Lhasa Apso and Shih Tzu dogs. **Polyodontia**, *excessive teeth*, occurs in brachycephalic dogs; the incisors are involved, and the defect is probably related to breeding for broad muzzles. A high incidence of canine polyodontia, involving particularly an extra maxillary premolar, is reported from the Netherlands. Polyodontia also occurs in horses and cats, involving either incisors or cheek teeth. **Pseudopolyodontia** *is retention of deciduous teeth after eruption of the permanent dentition*. It occurs in horses, cats, and dogs, especially in the miniature breeds.

Heterotopic polyodontia *is an extra tooth, or teeth, outside the dental arcades*. The best-known example is the *ear tooth of horses*, which develops in a branchiogenic cyst. The cysts originate from failure of closure of the first branchial cleft, or from the inclusion of cellular rests in this area. They are lined by a stratified mucous or cutaneous-type epithelium, and may contain one or more teeth, either loosely attached in the cyst wall or deeply embedded in the petrous temporal bone. The tooth is derived from misplaced tooth germ of the first branchial arch, which is displaced toward the ear with the first branchial cleft. The cysts form in the parotid region and may fistulate to the exterior. They are occasionally bilateral.

Rarely the tooth may form a pedunculated mass enclosed by skin, and attached by a pedicle to the skin of the head. Heterotopic polyodontia also occurs in cattle, dogs, pigs, and sheep.

Developmentally **misshapen teeth** are classified as **geminous** (dichotomous) when there is a single root and partially or completely separate crowns; **fused**, when the dentin of two teeth is confluent; and **concrescent** when the dentin is separate but the roots are joined by cementum. Gemination represents the embryologic partial division of a tooth primordium. It occurs in dogs, usually involving the incisors, and the affected tooth usually has a groove dividing the crowns, whose pulp chambers can be seen radiographically to merge in a common root. Misshapen teeth and missing teeth have also been reported in dogs as an X-linked recessive trait of ectodermal dysplasia. Fusion and concrescence represent the joining of two adjacent tooth primordia, one of which may be supernumerary. *Malformation and malpositioning of teeth* accompany abnormalities of the jaw bones. Aberdeen Angus and Hereford calves with congenital osteopetrosis have brachygnathia inferior, malformed mandibles, and impacted cheek teeth. Impacted molars occur as an inherited lethal in Shorthorns; an association with osteopetrosis apparently has not been investigated in this breed.

Odontogenic cysts are epithelium-lined cysts derived from cell rests of Malassez, cell rests of dental laminae, reduced enamel epithelium, or malformed enamel organs. **Dentigerous cysts** are, by definition, *cysts that contain part or all of a tooth*, which is often malformed. Of the odontogenic cysts listed, all except those derived from cell rests of Malassez are potentially dentigerous. (The rests of Malassez are the probable source of periodontal cysts.) Dentigerous cysts originating in malformed enamel organs should include malformed teeth, since development of enamel is incomplete until the organ degenerates. Those teeth in cysts of reduced enamel epithelium or rests of dental laminae are not necessarily abnormal. The affected teeth probably erupt into the preformed cysts. Dentigerous cysts enclose at least the crown of the tooth, but may include it all. The most common forms of odontogenic dentigerous cysts in animals are those involving the *vestigial wolf teeth* of horses and the *vestigial canines*, especially of mares. The smaller cysts appear as tumors of the gums, whereas some of the larger ones may cause swelling of the jaw or adjacent maxillary sinus. Dentigerous cysts of animals are not as destructive as those in humans, in which species they are regarded as the most common benign destructive lesion of the skeleton.

The ear tooth of horses is probably the most common non-odontogenic dentigerous cyst. Occasionally true dentigerous cysts form when a tumor prevents normal eruption or when there is maleruption due to odontodystrophy.

Cystic dental inclusions about vestigial supernumerary teeth also occur in juxtamolar positions in cattle, but are insignificant. These too may be dentigerous, or they may be primordial cysts developed before the stage of enamel formation, and hence contain no mineralized tooth structures. Either type of cyst may give rise to ameloblastomas.

A high incidence of dentigerous cysts involving incisors occurs in some sheep flocks in Scotland, Australia, and New Zealand. A congenital disease involving the jaws and teeth of calves in Germany (*odontodysplasia cystica congenita*) is characterized by massive fibro-osseous enlargement of the maxillae and horizontal rami of the mandibles. Some teeth are malformed, misshapen, or absent. Cystic spaces in the jaws are lined by fibrous tissue or epithelium, the latter probably derived from enamel organs. The dental changes are thought to be secondary to those in bone. Most affected calves are aborted or stillborn, and many have ascites and hydrocephalus. The disease may be caused by environmental influences.

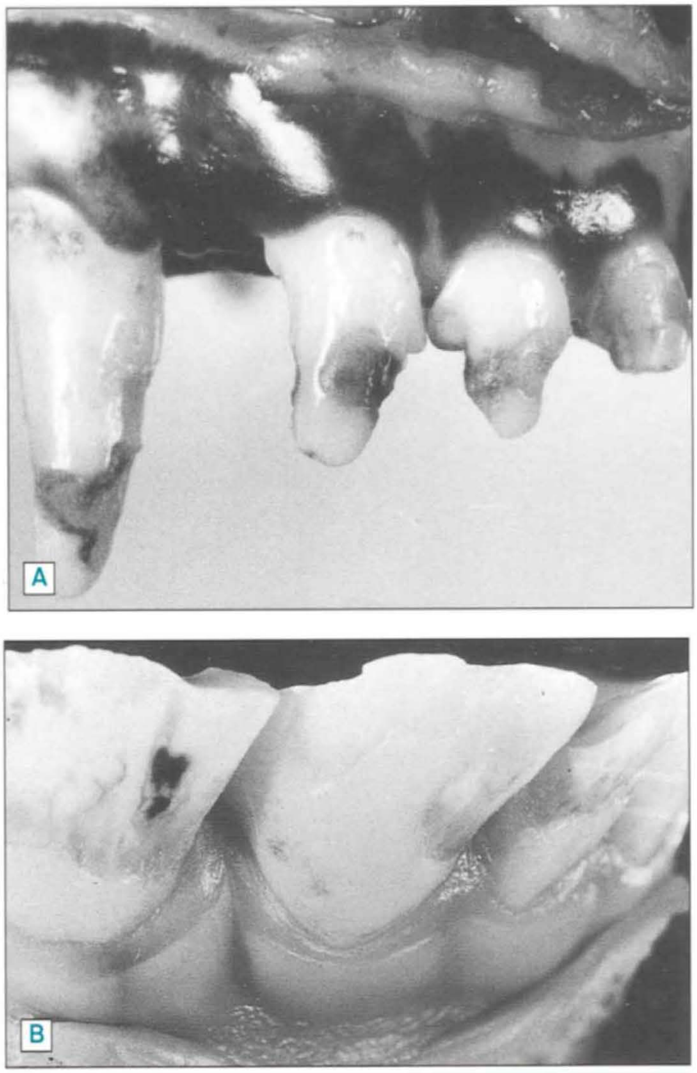

Figure 1.3 Enamel hypoplasia. A. A sequel to *Canine distemper virus* infection in a dog. **B.** Subsequent to intrauterine infection by *Bovine viral diarrhea virus* in a calf. (Courtesy of RB Miller.)

The permanent teeth are unique in that they continue to develop for a long time after birth. Thus, inflammatory and metabolic disease of postnatal life, for instance *Canine distemper virus* infection (Fig. 1.3A), can produce hypoplasia of dentin and enamel. Hypoplasia of the enamel of deciduous teeth occurs in some calves with intrauterine *Bovine viral diarrhea virus* infection (Fig. 1.3B). It has also been described in calves and pigs following irradiation of the dam during gestation. Dysplastic proliferation of dentin and enamel involving mandibular premolars and molars has been seen in young uremic dogs. Extreme fragility of deciduous teeth is a feature of bovine osteogenesis imperfecta (see Vol. 1, Bones and joints). Dental dysplasia, characterized by normal dentin, absence of enamel matrix, and excess irregular cementum, is described in a foal with epitheliogenesis imperfecta involving the oral mucosa.

Degenerative conditions of teeth and dental tissue

Pigmentation of the teeth

Normal enamel is white and shiny, but normal cementum is off-white to light yellow, and normal dentin is slightly darker yellow. Depending on the tooth, or the part of the tooth being examined, the normal color may be any one of these. Normal enamel is never discolored. Hypoplastic enamel of chronic fluorosis is discolored yellow through brown to almost black. Discoloration of brachydont teeth results from pigmentation of dentin, which is then visible through the semitransparent enamel, or pigmentation of the cementum of the root. Dentin may be colored red-brown by pulpal hemorrhages or inflammation, gray-green in putrid pulpitis, and yellow in icterus. Congenital erythropoietic porphyria of calves, cats, and swine discolors the dentin red in young animals (pink tooth) and darker brown in adults, although in swine, the discoloration may disappear with aging. Transient porphyria with pink discoloration of teeth is reported in a dog.

Yellow to brown discoloration of teeth, and bright yellow fluorescence in ultraviolet light, due to deposition of *tetracycline* antibiotics in mineralizing dentin, enamel, and probably cementum, occurs in all species. Treatment of the pregnant dam may cause staining of deciduous teeth in the offspring. Tetracyclines are toxic to ameloblasts in late differentiation and early secretory stages and, at high dose rates, may produce enamel hypoplasia. Black discoloration of ruminant cheek teeth is extremely common, and is caused by impregnation of mineral salts with chlorophyll and porphyrin pigments from herbage.

Dental attrition

Dental attrition is loss of tooth structure caused by mastication. The mature conformation of teeth is largely the outcome of opposed growth and wear, and the degree of wear depends on the type of tooth, the species of animal, and the material chewed. Wear is most evident in herbivores, and irregularities of wear are perhaps the most common dental abnormalities. In general, with normal occlusion and use, the extra-alveolar portion of the tooth does not shorten. Its length is maintained initially by growth, the period of growth depending on the species, then by hypertrophy of the root cementum and/or dentin and by proliferation of alveolar bone, which serves to push the tooth out. Finally, senile atrophy of the alveolar processes and gingival recession may maintain or increase the length of the clinical crown. Cementum hypertrophy and alveolar atrophy may also result in loss of teeth in senility, or, if combined with subnormal wear, produce teeth that in old age are excessively long. Normal wear of the complicated cheek teeth of horses and cattle causes smoothing of the occlusal surfaces. As soon as wear of enamel exposes the dentin, which, being softer, wears more rapidly, secondary or irregular dentin is deposited to protect the pulp. In time, this may fill the pulp cavity and cause death of the tooth. Abnormalities of wear are most common in herbivores (Fig. 1.4). Excessive wear of the deciduous and permanent central incisors occurs in certain sheep flocks in New Zealand. The wear is intermittent and may be severe enough to expose the pulp cavity. The cause is unknown but may be related to delayed eruption of adjacent teeth, leading to increased use of the affected pairs.

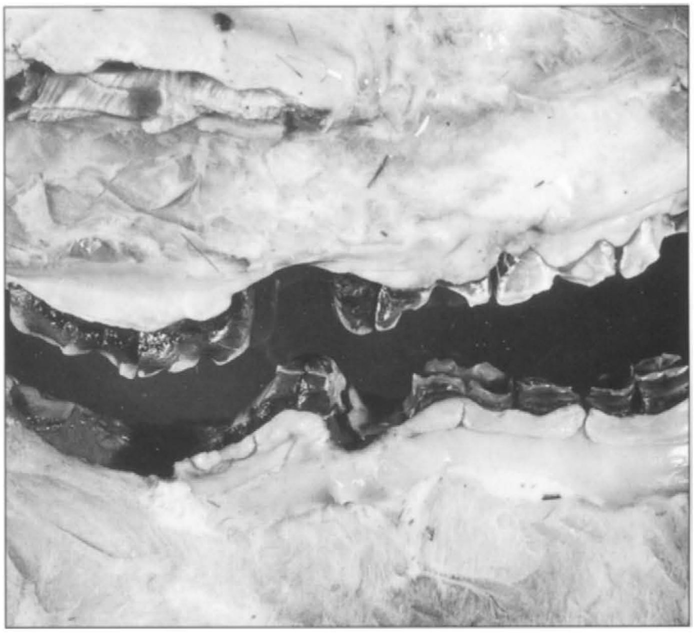

Figure 1.4 Irregular wear of the teeth of a horse.

Subnormal wear, due to loss of the opposing tooth, occurs in oligodontia, abnormal spacing of adjacent teeth, and acquired loss of teeth; it results in *abnormal lengthening*. Such elongated teeth may grow against the opposing gum or, if deviated, into an adjacent soft structure such as cheek or lip. These teeth usually wear in abnormal places because complete loss of antagonism is unusual, since the upper and lower arcades do not coincide exactly, and the coincidence is further reduced by the displacement of chewing. Incomplete longitudinal coincidence of the molar arcades allows irregular wear and hook formation on the first and last cheek teeth.

Abnormal wear due to abnormal chewing is caused by voluntary (as in painful conditions) or mechanical impairment of jaw movement. Lateral movements of the jaws without the normal rotary grinding movements allow the ridges of the teeth of herbivores to become accentuated. Steep angulation of the occlusal surfaces results from inadequate lateral movement of the jaws, and sharp edges form on the buccal aspect of the maxillary teeth and the lingual aspect of the mandibular teeth. This may be unilateral when the animal chews with only one side of its mouth, the other side then being affected. The teeth wear progressively sharper, and pass each other like shear blades; hence the term **shear mouth.** Subnormal resistance to wear on the part of the molar teeth is common, and results in **wave mouth** ("weave mouth") or **step mouth**, in which successive teeth in an arcade wear at different rates. The wave or step form of the antagonistic arcade is reversed, so that the teeth of the two arcades interdigitate. This pattern of attrition is caused by variation in the hardness of opposing teeth, and is usually caused by intermittent odontodystrophy. Opposing teeth of the upper and lower jaws do not develop at the same time; thus, discontinuous nutritional deficiencies often result in unequal wear. Certain vices, such as crib biting, also produce abnormal wear. In severely worn ruminant incisors, a central black core may be visible, which is secondary dentin deposited in the pulp cavity. It is not carious, but stains darker than the surrounding primary dentin.

Odontodystrophies

Odontodystrophies are diseases of teeth caused by nutritional, metabolic, and toxic insults. They are manifest by changes in the hard tissues of the teeth and their supporting structures. Lesions of enamel and dentin are emphasized here. The most prominent effects of odontodystrophies appear in enamel, and lesions of enamel are most significant because they are irreparable.

Formation of enamel occurs in a set pattern. It begins at the occlusal surface and progresses toward the root. Mineral maturation occurs in the same sequence, but for each level, it begins at the dentin–enamel junction and moves toward the ameloblast. Deleterious influences have their most severe effects on those ameloblasts that are forming and mineralizing enamel. Depending on the severity on the insult, ameloblasts may produce no enamel, a little enamel, or poorly mineralized enamel. Removal of the insult permits those ameloblasts that were not yet active to begin making normal enamel. Thus, enamel defects vary in severity from isolated opaque spots or pits on the surface to deep and irregular horizontal indentations. These defects are most clearly seen on the incisor teeth and canine teeth and are usually bilaterally symmetrical. Similar lesions are also produced by infectious agents that injure ameloblasts, such as *Canine distemper virus* and *Bovine viral diarrhea virus* (Fig. 1.3).

Odontoblasts are susceptible to many of the same influences as ameloblasts, but they can be replenished from the undifferentiated cells of the dental pulp. Thus, lesions in actively forming dentin may be repaired, whereas those in enamel are permanent.

Because of their close anatomical association with the jaws, teeth are very susceptible to disruption in the harmony of growth. This harmonious arrangement is often upset in the odontodystrophies and osteodystrophies, and leads to malocclusion and anomalous development of teeth.

Several nutritional and toxic conditions produce odontodystrophy. **Fluorine poisoning** is exemplary (see Vol. 1, Bones and joints). In **vitamin A deficiency**, ameloblasts do not differentiate normally, and their organizing ability is disturbed. As a result, odontoblastic differentiation is abnormal. Several lesions develop, including enamel hypoplasia and hypomineralization, cellular, vascularized dentin (osteodentin), and retarded or obviated eruption.

Calcium deficiency retards eruption, and causes enamel hypoplasia and mild dentin hypoplasia. Teeth formed during the period of deficiency are very susceptible to wear. In sheep, recovery from prolonged calcium deficiency results in malocclusion due to inferior prognathia. This reflects inadequate maxillary but normal mandibular repair during the recovery phase.

Phosphorus deficiency, combined with vitamin D deficiency, depresses dentin formation slightly, but has virtually no effect on enamel, at least not in sheep. Hypophosphatemia is associated with formation of interglobular dentin in humans. Malocclusion and abnormalities of bite in rachitic sheep are secondary to mandibular deformity.

Severe, experimental **malnutrition** also produces malocclusion. Recovery from malnutrition does not correct the lesion, and in addition, is associated with misshapen, malformed teeth, oligodontia, and polyodontia.

The major **effects of odontodystrophies** in herbivores are *malocclusion*, and/or accelerated *attrition*. Sometimes a high incidence of these abnormalities is attributable to one of the causes previously discussed, but often they are idiopathic. Most of the lesions described in experimental odontodystrophies also occur in natural diseases.

A syndrome of dental abnormalities of sheep in the North Island of New Zealand is characterized by excessive wear of deciduous teeth, maleruption and excessive wear of permanent teeth, periodontal disease involving permanent teeth, and development of dentigerous cysts involving permanent incisors. Mandibular osteopathy is also present. Animals older than 5 years are culled for dental problems. The odontodystrophy (and osteodystrophy) is possibly caused by deficiencies of calcium and copper, and perhaps other nutrients, such as protein, and energy. This syndrome exemplifies the naturally occurring odontodystrophies, in that it probably has a complex pathogenesis, and is associated with an osteodystrophy. The latter association is to be expected, since *bones and teeth are usually susceptible to the same insults.*

While dental lesions are not described, tooth loss due to periosteal dysplasia and osteopenia occurs in Salers cattle afflicted with hereditary hemochromatosis.

Infectious and inflammatory diseases of teeth and periodontium

The role of viruses in enamel hypoplasia is mentioned above. Bacterial plaque, along with other tooth-accumulated materials, is discussed here.

Bacterial diseases involving tooth surfaces are caused by the development of supragingival and subgingival **plaque**. *Supragingival plaque* is located on the exposed crown of the tooth and causes dental caries. *Subgingival plaque* is found in the crevicular groove and causes periodontal disease. Tooth enamel is covered by a translucent pellicle, the *acquired enamel pellicle*, which is formed by selective adsorption of complex salivary proteins, and that is essential to the development of supragingival plaque. This is a dense, nonmineralized, bacterial mass, firmly adherent to tooth surfaces, which resists removal by salivary flow and prevents the buffering capacity of saliva from influencing plaque metabolites. Formation of this plaque involves adhesion of bacteria to the pellicle, and adhesion of bacteria to each other, producing a *biofilm*. Only organisms with the ability to adhere to the pellicle can initiate the formation of supragingival plaque; those that cannot are removed by oral secretions and mechanical action. Pathologic reduction of salivary flow increases the prevalence of caries in some species.

The bacteria in supragingival plaque are members of the indigenous oral flora and are usually gram-positive aerobes. Most are streptococci and *Actinomyces* spp., which form an organized array on the tooth surface. Some plaque-forming bacteria synthesize extracellular polymers, which constitute the matrix of the plaque and permit adhesion between organisms of the same species. Some utilize polymers derived from host secretions to adhere to the pellicle, whereas others attach to bacteria of a different species that are already fixed to the tooth. Plaque increases in mass with time, and its composition becomes more complex as anaerobic gram-negative bacteria join the streptococci and actinomycetes that initiated plaque formation.

Supragingival plaque is metabolically active. It utilizes dietary carbohydrates to produce the adhesive polymers and the acids needed to demineralize enamel, and as energy sources for maintenance and for production of various enzymes and stimuli for inflammation. Extensive deposits of supragingival plaque are virtually invisible unless treated with a disclosing solution.

Subgingival plaque is less organized than supragingival plaque, and many of the organisms involved are gram-negative anaerobes that are asaccharolytic, weakly adherent, and motile. They derive their nutrients from the crevicular fluid. The flora of subgingival plaque is less well characterized than that of supragingival plaque. Culture results vary with sample collection technique, site of collection, and selectivity of media, and appear to under-represent the flora detected by molecular means in humans. At least *Porphyromonas* spp. (formerly *Bacteroides*) and spirochetes are likely periodontal pathogens in animals.

Dental calculus (*tartar*) *is mineralized plaque.* It is formed by the deposition of mineral, mainly from saliva, in dead bacteria. In horses and dogs, calculus is predominantly calcium carbonate. Calculus is often found in old dogs and cats, occasionally in horses and sheep, and rarely in other species. The distribution is often uneven, but it is *usually most abundant next to the orifices of salivary ducts.* Calculus on horses' teeth is chalky and easily removed. In dogs, it is hard, firmly attached, and often discolored. Red-brown to black calculus with a metallic sheen develops in pastured sheep and goats. It usually involves all the incisors, principally on the neck of the buccal surface. Minor amounts are common along the gum–tooth junction of the molar teeth, but occasionally larger (up to 2 cm) hard, black, rounded concretions may protrude from between opposed surfaces of the premolars. A high prevalence of calculus in sheep on the Scottish island of North Ronaldsay was related to their predominantly seaweed diet. Calculus was most severe around the cranial cheek teeth, increased in severity with age, was associated with periodontal disease, and contained large amounts of calcium, magnesium, and phosphorus.

Materia alba, which adheres to teeth, is a mixture of salivary proteins, desquamated epithelial cells, disintegrating leukocytes, and bacteria. The bacteria are not organized, and materia alba is easily removed. It is distinct from dental plaque, and from food debris, which also accumulates between uncleaned teeth.

Dental caries

Dental caries is a disease of the hard tissues of teeth, characterized by *demineralization of the inorganic part and enzymatic degradation of the organic matrix.* **Erosions** of teeth are characterized by removal of hard tissues layer by layer. These definitions permit the inclusion of equine infundibular necrosis as a form of caries (see following sections). Caries is common in horses and sheep but rare in dogs. Cats are commonly subject to caries-like odontoclastic resorptive lesions of uncertain etiopathogenesis.

There are two types of caries:

1. **Pit or fissure caries** develops in irregularities or indentations, which trap food and bacteria, usually on the occlusal surface of the tooth. Plaque is not essential for initiation of this form of caries, of which *equine infundibular necrosis* is an example.
2. **Smooth-surface caries** usually occurs on proximal (adjacent) surfaces of teeth, typically just below contact points, or around the neck, and requires dental plaque for its initiation.

The organic acids, principally lactic, which initiate demineralization, are produced by bacterial fermentation of dietary carbohydrates. In smooth-surface caries, plaque produces the acid and maintains a low pH on the surface of the tooth. Progression of lesions depends on various factors such as salivary pH, hardness and resistance to demineralization of enamel, and frequency of access to carbohydrate. Demineralization of enamel often occurs in the subsurface enamel but progresses to caries only with prolonged exposure to acid. Infrequent exposure allows remineralization of enamel between meals. The enzymes that lyse the organic matrix are probably produced by plaque, but may be derived from leukocytes, for which plaque is chemotactic. Carious enamel loses its sheen and becomes dull, white, and pocked. When dentin is exposed, it becomes brown or black. Dentin is softer and more readily demineralized than enamel, and a pinpoint lesion in enamel may lead to a large defect when the carious process reaches the dentin. Nerve endings have not been identified at the enamel–dentin junction, and the pain of caries is thought to be caused by chemical or pressure changes in the dentinal tubules. Spread of infection along the tubules to the pulp cavity may result in formation of secondary or reparative dentin, pulpitis, or periapical inflammation and tooth loss.

In **horses, infundibular necrosis** develops most often on the occlusal surface of the maxillary first molar. The enamel invaginations (infundibula) in the cheek teeth of horses are normally filled with cementum before the teeth erupt. Filling proceeds from the occlusal surface toward the apex, but often is not completed before eruption. At this time the blood supply is cut off, and ischemic necrosis of any residual cementogenic tissue in the infundibula occurs. The deficiency of cementum is called *hypoplasia.* Rostral infundibula are affected more frequently than are caudal, and the first molar more often than other teeth (Fig. 1.5A).

Teeth with incompletely filled infundibula may accumulate food material and bacteria (Fig. 1.5B), and, in some animals, the cavitated area expands to involve all the cementum and the adjacent enamel and dentin. Decay of the mineralized tissues sometimes progresses to coalescence of the cement lakes, fracture of the tooth, root abscess, and empyema of the paranasal sinuses. The incidence of infundibular necrosis increases with age, and 80–100% of horses older than 12 years may have the lesion. Most are without signs, and in most, the lesion does not progress. Inflammation of the dental pulp, in horses and in other species, may result from direct expansion of caries from penetration of bacteria and bacterial degradation products along the dentinal tubules. Production of reparative dentin in the pulp cavity is expected.

In **sheep**, the proximal surfaces of mandibular teeth are usually affected by caries, which is commonly accompanied by periodontitis. Erosions of the neck region of the deciduous teeth occurred in sheep in New Zealand. The lesions were mainly located apical to the enamel–dentin junction on the labial or lingual surface. They did not seem to be related to the usual causes of localized tooth destruction.

Cattle develop loss of dentin just below the crown of incisor teeth at increasing frequency with age. This usually follows recession of the gingiva, and is not considered to be a form of caries, but proteolytic digestion of dentin by chyme in an alkaline pH.

In **dogs**, caries most commonly involves the fourth premolar and the first and second molars. Although relatively uncommon, when caries occurs, defects are often multiple and advanced, leading to therapeutic extraction.

Cats, whose teeth do not have centers where food can collect, very commonly develop multiple caries-like **odontoclastic resorptive lesions**, initially involving the subgingival neck or upper root,

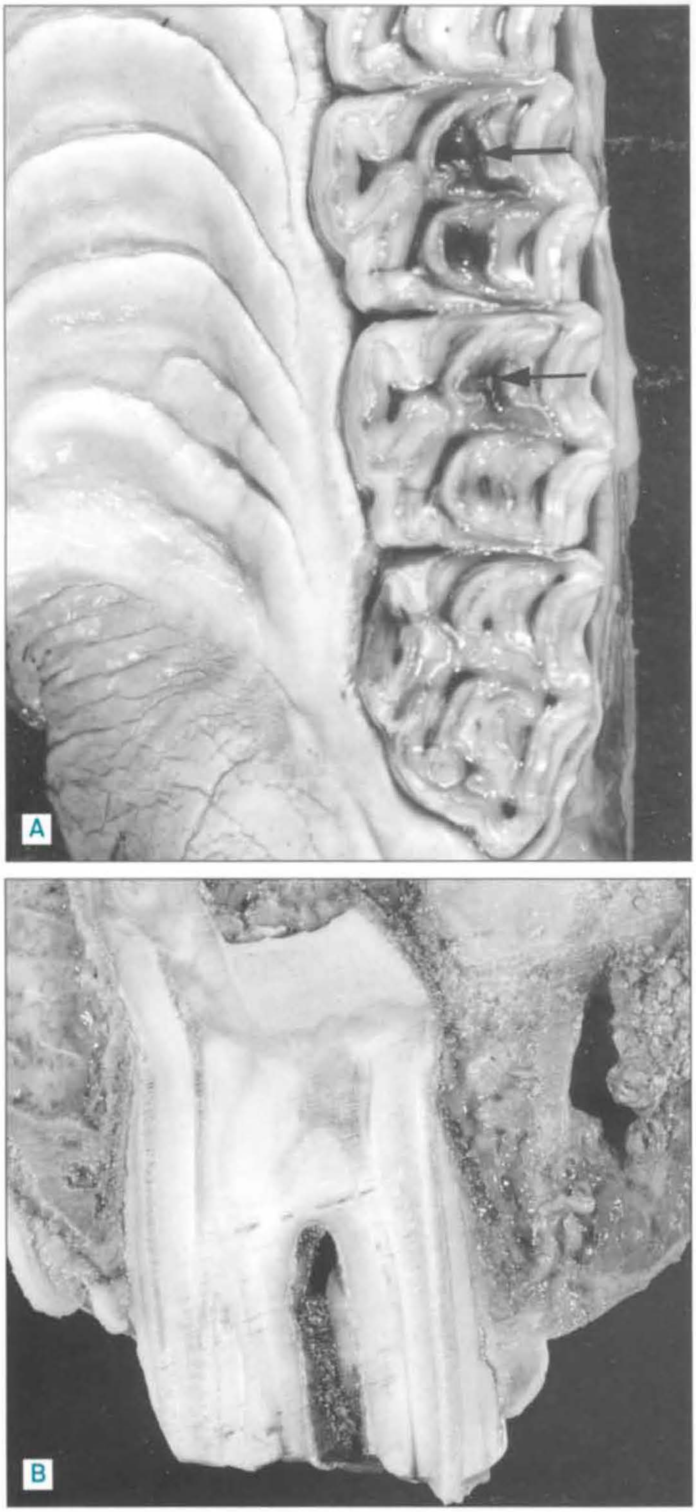

Figure 1.5 A. Infundibular necrosis of first and second maxillary molars (arrows) in a horse. Necrosis is confined to cement lakes. **B.** Section through **(A)** showing black discoloration of infundibulum.

most often of cheek teeth, and increasing in prevalence with age. A reddened swollen area of gingiva or granulation tissue often lies over the lesion, which may be on the labial or buccal aspect, and frequently is painful to touch. The resorptive lesions begin as shallow defects in the cementum, lined by odontoclasts, facing a somewhat disorganized periodontal ligament. They progress into the underlying dentin, and, with time, into the root canal. Either or both coronal and apical extension of lesions may occur. Extension of the process coronally more superficially undermines the enamel, which is resorbed or breaks off, causing destruction or loss of the crown. Extension of the dentinal lesion apically leads to resorption of the root. Remnants of the root may persist, often overgrown by gingiva, following loss of the crown. Conversely, destruction primarily of the root may result in obliteration of the periodontal ligament, resorption of adjacent alveolar bone, but with odontoalveolar ankylosis by reparative hard tissues, retaining the crown in the dental arcade. In addition to the odontoclasts that line the resorbing cementum or dentinal surfaces of the lesion, more advanced defects contain a mixed leukocyte population, macrophages, and disordered granulation tissue. Repair is often superimposed, with cementoblastic or osteoblastic cells producing new mineralized tissue of varied osteoid, bone, cementum, or osteodentin morphology. Pulpitis may occur in the affected root canal, and reparative dentin may be deposited there. The prevalence of such lesions has increased markedly in the past 40 years, suggesting an association with changes in form of diet, but the lesion is idiopathic, with no clear relationship to periodontitis, mechanical trauma, viral infections, nutritional or metabolic disturbances. However, it is suggested that lack of masticatory stimulation may lead to loss of the functional integrity of the periodontal ligament, triggering the lesion.

Pulpitis

The dental pulp is derived from the dental papilla. It is surrounded by odontoblasts and dentin, except at the apical foramen, through which vessels and nerves pass. Pulp is a loose syncytium of stellate fibroblasts, and contains histiocytes and undifferentiated mesenchymal cells. The latter are odontoblastic precursors.

The apical foramen is narrow, and this predisposes to vascular occlusion, ischemic necrosis of the pulp, and death of the tooth. Production of abundant secondary dentin and reparative dentin can cause occlusion, but the usual cause is inflammation. Normally, pulp is the only vascular tissue of the tooth, and, along with the periodontium, the only site of conventional inflammation. *Pulpitis is always related to infection*, the effector bacteria or their products entering through the surface of fractured teeth, carious perforations (especially in teeth with enamel defects), perforations resulting from abnormal wear or trimming, from periodontitis, and possibly hematogenously. In herbivores, in which the pulp is divided by enamel foldings, inflammation is usually limited to one division, and is usually purulent. Very mild pulpitis may heal, but usually it terminates in tooth necrosis, periapical abscessation, perhaps with fistula formation, osteomyelitis, or gangrene as inflammation of the pulp extends to the periodontium and the jaws.

Periapical abscess and osteomyelitis of the jaws are complications of pulpitis that may follow clipping the tusks ("needle teeth") of piglets. Trimming of the incisor teeth of sheep to avoid the effects of broken mouth often exposes the pulp cavity, but the pulpitis that ensues is rarely chronic. The exposed pulp canal is healed in 30–50 days by deposition of reparative dentin and secondary dentin. Similar healing presumably occurs in most piglets. *Maxillary (malar) abscess of dogs* involves the periapical tissues usually of the carnassial tooth, and may cause a discharging sinus beneath the eye. The pathogenesis of the abscess is obscure, but it may be a sequel to crown fractures or to pressure necrosis of periapical tissues. Some chronic inflammations of the pulp are confined to the periodontium and become slowly expansive spherical granulomas about the root apex (*root granulomas*). Occasionally these granulomas are enclosed by an epithelial cyst (*periodontal cyst*) derived from cell rests of Malassez. The epithelium contains plasma cells, and the combination may have a protective role in periapical sepsis.

Periodontal disease

Periodontal disease is the *most common dental disease of dogs and sheep*, and an important problem in other ruminants, horses, and cats. Although there are minor differences among species, in general, periodontal disease *begins as gingivitis associated with subgingival plaque*, and may progress through gingival recession and loss of alveolar bone to chronic periodontitis and exfoliation of teeth.

The gingival sulcus, or crevice, is an invagination formed by the gingiva as it joins with the tooth surface at the time of eruption. Clinically normal animals have a few lymphocytes, plasma cells, and macrophages under the crevicular epithelium of the gingiva, which forms the outer wall of the crevice, and under the junctional epithelium, which is apposed to the enamel of the tooth.

Clinical **gingivitis** is usually initiated by accumulation of plaque in the crevice, but may be associated with impaction of feed, especially seeds, between teeth. Gingivitis is initially characterized by increased numbers of leukocytes and fluid in the gingival crevice, and then by acute exudative inflammation and accumulation of neutrophils, plasma cells, lymphocytes and macrophages in the marginal gingiva. If the disease progresses, marked loss of gingival collagen occurs in a few days, probably related to the activity of prostaglandins and matrix metalloproteinases generated in inflamed tissue, or possibly enzymes from plaque bacteria, such as *Porphyromonas gingivalis*, which also produce enzymes (gingipains) thought to damage junctional epithelium. *Porphyromonas* spp. are implicated as obligate pathogens for canine gingivitis, and as probable participants in feline gingivitis/periodontitis. Grossly the gingiva is red and swollen, due to the hyperemia and edema of inflammation. Acute gingivitis may become quiescent, with lymphocyte aggregations beneath the junctional epithelium. Halitosis is associated with gingivitis in small animals.

Continuation and exacerbations of the inflammation cause apical recession of the tooth–gingiva junction, and resorption of alveolar bone (Fig. 1.6). Alterations in the periodontal flora may be responsible for these exacerbations. A major part of chronic periodontal disease is *resorption of alveolar bone*, which modifies the attachment site of the periodontal ligament. If concomitant bone loss precedes gingival recession, the sulcus is deepened to form a periodontal pocket, which is lined by transformed junctional "pocket" epithelium, and becomes the site of chronic active inflammation. When gingival recession precedes loss of alveolar bone and gingival collagen, pockets do not form, but tooth roots are exposed. In either case, destruction of the periodontium and periodontal ligament, and resorption of alveolar bone, cementum, and root dentin, *lead to exfoliation of teeth*.

Gingivitis is common in **dogs**. Usually it is proliferative, the gingiva being replaced by collagen-poor, highly vascular granulation tissue, which appears as a red, rolled edge next to the tooth. In dogs, gingival pocket formation is quite unpredictable and may be present on one root of a tooth and absent on the other. Bone loss in dogs is often more severe at the bifurcation of two-rooted teeth than in interproximal areas. Resorption of bone is associated with osteitis as the inflammation extends from the periodontium into alveolar bone. In dogs, the premolars and, to a lesser extent, the first molars and central incisors are most severely affected, whereas the second molars and mandibular canines are quite resistant.

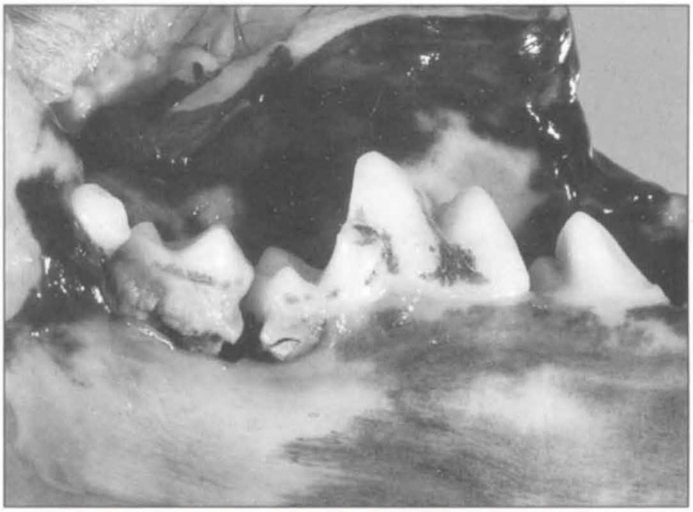

Figure 1.6 Marked gingival recession with exposure of roots of the molar teeth in advanced **periodontal disease** in a dog.

Gingivitis is among the most common veterinary problems in **cats**. In general, it resembles that in dogs.

In **sheep**, periodontal disease may involve all teeth, but the effects are most severe on the incisors, and periodontal disease is a major cause of premature exfoliation. Sheep develop acute gingivitis during tooth eruption, in association with accumulation of subgingival plaque around the tooth. In some sheep, chronic gingivitis involving the lingual aspect of the incisors ensues, and on farms with a high incidence of broken mouth (lengthening of the incisor crown, forward protrusion, and loosening of the teeth), this progresses to chronic active periodontal disease.

Cara inchada (swollen face) is an epidemic periodontitis of **cattle**, formerly common in the west-central part of Brazil. Animals of 2–14 months were mostly affected, and herd prevalences of more than 50% were recorded. When progressive, cara inchada causes loss of teeth, leading to malnutrition. It is associated with dental eruption, and ingestion of forage thought to contain low levels of antibiotics derived from soil actinomycetes that permit colonization of the periodontal space by a variety of gram-negative bacteria, including *Prevotella (Bacteroides) melaninogenica*.

Severe periodontitis and tooth loss are an important part of the syndrome associated with *bovine leukocyte adhesion deficiency*.

The sequelae of suppurative periodontitis are many, being mainly variations on a theme of *osteomyelitis*. The osteomyelitis of actinomycosis is discussed in Vol. 1, Bones and joints. If the mandible is involved, the fistula usually develops on the ventral margin. If the maxillary molars are involved, fistulation may occur into the maxillary sinus. If the premolars are involved, fistulation may develop into the nasal cavity or externally. In dogs, involvement of the canine teeth may produce internal or external fistulae, and involvement of the maxillary carnassials usually produces a fistula beneath the eye, and orbital inflammation. Fistulation may be prevented for some time, or permanently, by ossifying periostitis over the involved bone. Fistulae in the upper jaw tend to be persistent. In the lower jaw, they may heal, usually with extensive deposition of new bone. Occasionally, especially in horses, chronic mild periodontitis may be confined by the periodontium, which is, however, expanded by granulation tissue to form a root granuloma. Under the same circumstances there may be hyperplastic exostosis of the cementum.

Diseases of the buccal cavity and mucosa

Pigmentation

Melanotic pigmentation is normal and common in most breeds of animals and increases with age. It may be irregular, or the mucosa may be entirely pigmented. Diffuse yellow discoloration may be seen in icterus.

Circulatory disturbances

Examination of the mucous membranes is an essential detail in any clinical or necropsy examination. Pallor may indicate anemia. In cyanosis, the mucosa is dark red-blue. The mucosa are muddy in methemoglobinemia. Acute congestion and cyanosis, associated with ulceration, are common in dogs and sometimes in cats in chronic uremia.

Hemorrhages are indicative of septicemia, and larger ones may accompany local inflammation, trauma, and the hemorrhagic diatheses. Petechiae on the ventral surface of the tongue and frenulum in horses are consistent with equine infectious anemia, or other thrombocytopenic or purpuric conditions. The active hyperemia that gives the diffuse pink coloration to the mucosa in diffuse stomatitis disappears immediately at death, so that at autopsy the inflamed mucosa is disappointingly blanched.

Foreign bodies in the oral cavity

The presence of feed in the mouth of a cadaver is abnormal, except in ruminants, which may eructate and have feed in the caudal pharynx at the time of death. In most cases it is attributable to disease, which results in paralysis of deglutition or semiconsciousness. It is common in horses with encephalitis, leukoencephalomalacia, and hepatic encephalopathy. The food in such cases is usually poorly masticated and readily differentiated from that refluxed postmortem. Bones or other large foreign bodies lodged in the pharynx of cattle suggest pica of phosphorus deficiency. They may cause asphyxiation or pressure necrosis in the wall of the pharynx. Large portions of root crops may also lodge in the pharynx. Dogs often have bones and sticks that tend to be wedged across the palate behind the carnassial teeth.

In dogs, **foreign-body stomatitis** occurs, caused by plant fibers, burrs, or quills (Fig. 1.7). In mild cases, gingivitis surrounds the incisors and canine teeth. Small papules or vesicles and shallow ulcers may be evident on the tongue. Plant fibers may protrude from the lesions. Chronic cases are characterized by *exuberant granulomas* associated with lingual ulceration and gingival hyperplasia with plant fibers deeply embedded in these lesions. Long-haired dogs are especially prone to develop this type of lesion when they attempt to remove plant material that is trapped in their hair coat. The granulomas must be differentiated from neoplasms.

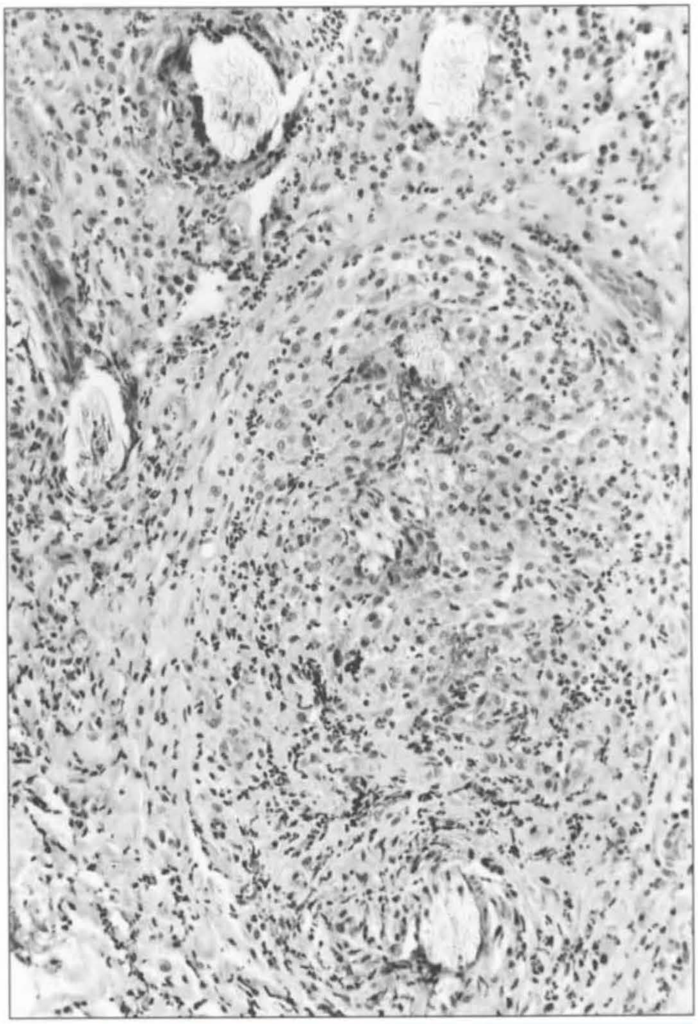

Figure 1.7 Granulomatous reaction to plant material in the tongue of a dog: **foreign-body glossitis** or "burr tongue."

Sharp foreign bodies which cause laceration of the mucosa predispose to necrotic and deep stomatitis. Grass seeds and awns frequently impact between the retracted gingival margin and teeth in periodontitis of ruminants and exacerbate the local initial lesion, perhaps predisposing to the development of osteomyelitis. Horses fed dry triticale hay may develop severe oral ulceration, with masses of awns embedded in the ulcers. The ulcers vary in size from 1 mm to 5 cm in diameter and are mainly located at the junction of the labial and gingival mucosa adjacent to the upper corner incisors, the lingual frenulum, the sublingual folds, the base of the dorsum of the tongue, and the soft palate. Similar lesions in horses have been associated with contamination of hay by foxtail.

Swine have a diverticulum of the pharynx in the caudal wall immediately above the esophagus, and barley awns and other rough plant fibers occasionally lodge here and penetrate the pharynx. This occurs mainly in young pigs, and death follows pharyngeal cellulitis. Similar problems occur in sheep following improper use of drenching guns, and in cattle injured by balling guns.

Inflammation of the oral cavity

Inflammatory processes of the oral cavity may be diffuse (*stomatitis*) or localized predominantly in certain regions to produce, if (1) the pharynx is involved, *pharyngitis*; (2) the tongue, *glossitis*; (3) the gums, *gingivitis*; (4) the tonsils, *tonsillitis* (Fig. 1.8); and (5) the soft palate, *angina*. Lesions limited to the mucosa of the oral cavity are termed *superficial stomatitides*. Processes seated in connective tissues of the mouth, the *deep stomatitides*, are usually sequelae to transient superficial lesions.

Superficial stomatitis

Inflammatory changes may be associated with ingestion of irritating chemicals such as caustic or toxic compounds. An example is paraquat, a herbicide, which may cause severe erosive stomatitis in dogs. Dogs and cats that chew on the plant *Dieffenbachia* may develop oral erosions and ulcers. Electrical burns are occasionally seen in puppies or kittens that chew through electrical wires. It is often not possible to differentiate the cause of diffuse stomatitis, but an attempt to do so is important because it may indicate a systemic disease state. Viral diseases causing stomatitis will be considered in detail in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Inflammatory disease, localized to the buccal cavity, and not part of systemic viral disease, is also common and important. It is generally due to the indigenous bacterial flora. The oral microbiota

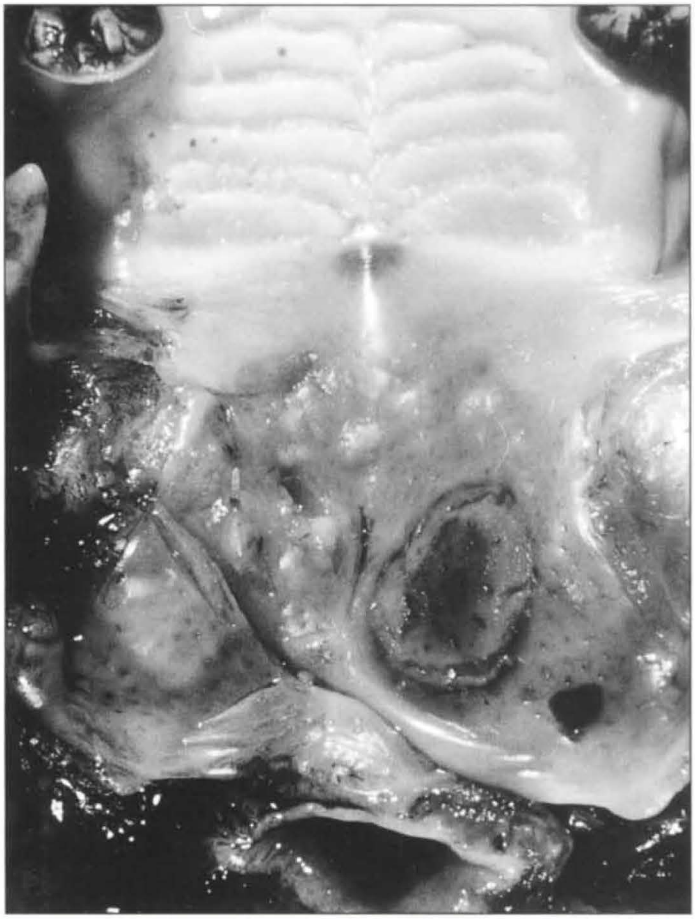

Figure 1.8 Necrotic palatine **tonsillitis** in a pig.

ordinarily contains many microbial species, mainly anaerobes such as *Actinomyces, Fusobacterium*, and spirochetes, which exist in balance with each other and in harmony with the host. Disruption of this microfloral balance may lead to stomatitis. The oral mucosa is quite resistant to microbial invasion for several reasons. These include the squamous mucosal lining; antibacterial constituents of saliva such as lysozyme; immunoglobulins, especially immunoglobulin A (IgA), in oral secretions; and the presence of a rich submucosal vascular network and inflammatory cells. Factors altering the balance of indigenous organisms are not well delineated. Systemic illness, stress, and nutritional and hormonal imbalances may alter the microbial population by altering the amount, composition, and pH of saliva. The integrity of the oral epithelium depends on a high rate of epithelial regeneration to balance loss due to a high rate of abrasion and desquamation. Rapid epithelial replication promotes quick healing of superficial lesions.

The lamina propria of the oral epithelium is well vascularized, but generally dense and relatively inelastic. For this reason, there is little distension of lymphatics and tissue spaces with fluid exudate, and therefore, swelling due to edema is not a significant part of stomatitis involving hard palate and gums, with the exception of the gingival margins.

Catarrhal stomatitis

Catarrhal stomatitis is superficial inflammation of the oral mucosa, which usually involves the caudal fauces and may be associated with mild gingivitis. It is a common nonspecific lesion, which often develops in the course of debilitating diseases. The mucosae are hyperemic, and the loose texture of the submucosa in the fauces permits development of edema. The swelling is aggravated by edema and hyperplasia of the abundant lymphoid tissues of the soft palate, tonsil, and pharyngeal mucosa. The epithelium accumulates, producing a dull gray mucosal surface. Palatine glands produce excessive mucus. Catarrhal stomatitis resolves with the return of normal oral function.

Thrush, or **oral candidiasis**, occurs most commonly in foals, pigs, and dogs. It involves the proliferation of yeasts and hyphae in the parakeratotic superficial layers of the oral epithelium. It appears grossly as patchy pale-gray pseudomembranous material on the oral mucosa and back of the tongue, and probably reflects alterations in epithelial turnover and oral flora (see section on Infectious and parasitic diseases of the alimentary tract, later in this chapter). Mold products of *Stachybotrys alternans* cause catarrhal and necrotizing stomatitis, as well as colitis, if feed is contaminated. Gingivitis and ulceration of the oral mucosa may rarely be associated with infection due to *Nocardia* spp. in dogs.

Vesicular stomatitides

Stomatitis characterized by the formation of *vesicles* occurs in most species of domestic animals. The vesicles develop as accumulations of serous fluid within the epithelium or between the epithelium and the lamina propria. These may coalesce to form *bullae*, and the elevated epithelium is easily rubbed off during chewing to leave raw eroded patches with bits of epithelium adherent. *The transition from vesicle to erosion occurs rapidly*, so that, in individual animals, vesicles may not be seen. This is especially so in dogs and cats because the oral mucosa is very thin. Because the basal epithelium or basement membrane remains intact, regeneration and healing are complete in a few days unless the local lesions are complicated by bacterial or mycotic infections. However, foci of previous erosion may be identifiable for some months by their slight depression and lack of pigmentation.

Traditionally, vesicular stomatitides in animals were associated with *viral infections*, and these are still important causes. Vesicular stomatitis and foot-and-mouth disease are associated initially with vesicle formation; however, rinderpest, bovine viral diarrhea and malignant catarrhal fever produce sharply demarcated erosive/ulcerative lesions without initial vesicle formation. *Oral erosions and ulcers in horses, ruminants, and swine should be regarded as indicating one of the vesicular diseases to which the species is susceptible, until proven otherwise* (see section on Infectious and parasitic diseases of the alimentary tract, later in this chapter). Sunburn, photoirritation associated with grazing on celery and related crops, and lesions associated with parvovirus infection in swine may cause lesions of the snout resembling vesicular diseases. Animals exposed to irritant chemicals in feed or bedding may develop vesicles and erosions of the face and oral cavity, for example, toxicity in horses and dogs associated with irritant quassinoids found in wood shavings derived from Simaroubaceae species.

Bullous immune skin diseases are recognized with increased frequency, especially in dogs, and some of these have severe oral lesions, which will be described here (see also Vol. 1, Skin and appendages).

Pemphigus vulgaris is a severe, acute or chronic, vesiculobullous autoimmune disease mediated by autoantibodies to the desmosome protein desmoglein 3. It is characterized by acantholysis of the epidermis, which results in formation of flaccid bullae and erosions involving mainly mucocutaneous junctions, oral mucosa and, to a lesser extent, skin. Clinically affected dogs and cats have erosions/ulcerations of the oral mucosa and may drool. The oral lesions are generally more prominent than, and precede, the skin lesions. They are most obvious on the dorsal surface of the tongue, which is bright red, with a few scattered pink raised areas representing islands of normal mucosa. The lesions vary greatly in severity and distribution, although the hard palate is often severely ulcerated. Bullae are rarely seen in the oral cavity, because they ulcerate rapidly.

Microscopically, the earliest lesion consists of *suprabasilar acantholysis*, which is followed by the formation of clefts. These lead to ulceration of the mucosa. The basal cells of the epidermis remain attached to the basement membrane and form a so-called "row of tombstones." A few neutrophils and eosinophils may infiltrate the epithelium. There is a variable lymphocytic and plasmacytic lichenoid reaction in the propria. The presence of suprabasilar clefts and bullae due to acantholysis is considered to be diagnostic of pemphigus vulgaris. However, extensive erosion and ulceration of the mucosa and secondary bacterial infections frequently obscure these clefts and bullae. Several biopsies from different areas of the oral mucosa may be required to demonstrate the characteristic lesions. A presumptive histologic diagnosis should be supported by direct immunofluorescence tests that show autoantibodies (usually IgG) and complement in the intercellular spaces of stratified squamous epithelium.

Bullous pemphigoid is a term that has been applied generically to superficial autoimmune vesiculobullous or ulcerative disease of mucous membranes (including the oral mucosa) and skin, characterized by subepithelial clefting; acantholysis is not a feature. It has been reported in humans, horses, dogs, and cats. It is now recognized that there is a *complex of autoimmune subepidermal blistering diseases*, varying in their target antigen, clinical manifestations, and prognosis. Those involving the oral cavity of cats and dogs include bullous pemphigoid, mucous membrane (cicatricial) pemphigoid, and canine epidermolysis bullosa acquisita. All are characterized by circulation of IgG and IgE autoantibodies against specific basement membrane antigens. The characteristic microscopic lesions of all are transient subepidermal blisters, which may contain fibrinocellular exudates with variable numbers of neutrophils and eosinophils. Diagnosis of each is confirmed by the detection of circulating antibody directed at appropriate antigens, using enzyme-linked immunosorbent assay (ELISA) or immunofluorescent tests, or by identification of immunoglobulin fixed to basement membrane. Paraneoplastic bullous stomatitis characterized by subepithelial clefting has been reported in a horse with a hemangiosarcoma.

Bullous pemphigoid is retained as the name for the second most common autoimmune subepidermal blistering disease in dogs and cats. The lesions mainly occur on haired skin, and a minority of cases involve the mucocutaneous junctions or mucosae, including the mouth, which is affected about a third of the time. Microscopically, there is a rich neutrophilic and eosinophilic dermal infiltrate adjacent to and sometimes spilling into the subepidermal bullae. The targets for the autoimmune response are epitopes on canine collagen XVII, a component of the basement membrane.

Mucous membrane pemphigoid is the most common autoimmune subepidermal blistering disease of small animals, causing about half of all cases. Adults are predominantly affected, and among dogs, German Shepherds are overrepresented. Typically, subepidermal vesicles in mucous membrane pemphigoid are associated with a relatively sparse inflammatory infiltrate. The antigen targeted by autoantibodies is collagen XVII or laminin-5, and basement membrane-fixed immunoglobulin is detected by direct immunofluorescent or immunoperoxidase staining of formalin-fixed paraffin-embedded tissue.

Epidermolysis bullosa acquisita is a rare disease of dogs, representing about 25% of cases of autoimmune basement membrane diseases, with a poor prognosis. The associated autoantibodies are directed against collagen VII. The lesions are most common on skin, and advance rapidly to erosions at points of friction, but the oral epithelium often sloughs extensively. Intact subepidermal vesicles may contain no inflammatory cells, or neutrophils may accumulate at the basement membrane, sometimes forming subepidermal microabscesses. The results of serum or cutaneous immunofluorescent tests resemble those in bullous pemphigoid or mucous membrane pemphigoid, but the autoantibodies may be recognized binding to the lower part of the basement membrane.

The oral lesions of pemphigus vulgaris and of the subepidermal blistering diseases must be differentiated from lesions due to trauma, toxic epidermal necrolysis, drug eruptions, chronic uremia, mucocutaneous candidiasis, and lymphoreticular malignancies.

Feline calicivirus causes mainly a respiratory infection in cats. The disease is complicated by *lingual and oropharyngeal ulcers*, which start out as vesicles. They are 5–10 mm in diameter, smooth, and well demarcated from the surrounding normal mucosa. They occur mainly on the rostrodorsal and lateral surfaces of the tongue and each side of the midline of the hard palate. The palatine lesions are apparently more severe in cats fed dry food. Microscopically, the earliest lesions consist of foci of pyknotic cells in the stratum corneum and superficial stratum spinosum. They progress to foci of necrosis with vesicle formation and subsequent erosion and ulceration of the mucosa. Regeneration of the oral mucosa in the ulcerated areas generally occurs within 10–12 days. A single layer of squamous epithelial cells extends from the margins of the ulcer beneath a layer of exudate. Active viral replication also takes place in the tonsillar crypt epithelial cells, and virus may be recovered from these areas for weeks postinfection. Viral inclusions have not been observed in oral epithelial cells. The virus is isolated from a high percentage of cats with chronic stomatitis. Concurrent infection with *Felid herpesvirus 1* may also occur.

Erosive and ulcerative stomatitides

This form of stomatitis is characterized by local epithelial defects of the oral mucosa and nasolabium and is usually associated with acute diffuse stomatitis and pharyngitis. *Erosions* are circumscribed areas of loss of epithelium which leave the stratum germinativum and basement membrane more or less intact. They are usually associated with acute inflammation in the underlying propria. The erosions vary in size and shape. Although they are often a nonspecific development in a wide variety of conditions, they are also an essential part of a number of important diseases. They heal cleanly and quickly, but if secondarily infected or complicated, may develop into ulcers.

Ulcers, in contrast to erosions, are deeper deficiencies that extend into the substantia propria. They too vary greatly in size and shape;

the edges tend to be elevated and ragged, and when they heal, it is with scar formation.

The causes of ulcerative stomatitis are in general those of erosive stomatitis. There are, however, a number of recognized syndromes and specific diseases in which the predominant change is ulceration. *Phenylbutazone* intoxication in horses may cause oral ulcers in concert with ulcers of the stomach, intestine, and colon; the syndrome is discussed with ischemic diseases of the gut (p. 99).

Feline ulcerative stomatitis and glossitis, or **lymphocytic-plasmacytic stomatitis**, is an ulcerative and chronic inflammation of the mucosa of the fauces, the angle of the jaws and, less commonly, the hard palate, gingiva, and tongue. Microscopically, there is chronic active inflammation of the oral mucosa and submucosal connective tissues, dominated by lymphocytes and plasma cells. The syndrome is more common in older cats and may accompany periodontitis. The cause is unknown, but is probably multifactorial, involving imbalance in the oral microbial flora, with predominance of gram-negative anaerobes and spirochetes. Some have reported the isolation of *Feline calicivirus* and *Felid herpesvirus 1* from more cats with lesions of chronic stomatitis compared to those without, but the role of these viruses in the etiology is unresolved. *Feline calicivirus* can persist as a sequel to previous disease episodes and in the face of prior vaccination. *Feline leukemia virus* and *Feline immunodeficiency virus* may predispose some cats to chronic stomatitis because of their immunosuppressive effects, but evidence of infection is not consistently found.

Feline plasma cell gingivitis-pharyngitis or **feline chronic gingivostomatitis** is characterized by raised erythematous, proliferative lesions, mainly in the glossopalatine arches, extending caudally to the palatopharyngeal arch and rostrally to the gingiva. The lesions may involve Eustachian tubes and also can affect the conjunctiva. Histologically, the mucosa is hyperplastic and frequently ulcerated, with a marked submucosal inflammatory cell reaction, mainly plasmacytes, including binucleate cells and cells containing Russell bodies. Neutrophils, lymphocytes, and histiocytes are scattered among the plasma cells. Affected cats have elevated polyclonal serum gamma-globulin levels. The polyclonal gammopathy and the plasmacytic, lymphocytic reaction are suggestive of an immune-mediated lesion, and differentiation from mucosally associated lymphoid neoplasia may be challenging. The etiology and the relationship of this syndrome to feline ulcerative stomatitis and glossitis (see above) are unclear; the two syndromes probably form a continuum, although the plasma cell predominance and the hypergammaglobulinemia attributed to plasma cell gingivitis-stomatitis are distinguishing. Similar stomatitis occurs in dogs.

Eosinophilic ulcer (eosinophilic granuloma, lick granuloma, labial ulcer, rodent ulcer) is a chronic, superficial ulcerative lesion of the mucocutaneous junctions of the lips, and, to a lesser extent, the oral mucosa and skin, in cats of all ages. The cause is unknown but the lesions may respond to corticosteroid, oral progestagens, cryosurgery, or radiation therapy, although recurrences are common. Typically, well-demarcated, red-brown, shallow ulcers, often with elevated margins, occur on the *upper lip on either side of the midline*. They are usually a few millimeters wide and several centimeters long. Occasionally, ulcers are present elsewhere in the mouth, such as on the gums, palate, pharynx, and tongue. Skin lesions are located in those areas that are frequently licked, such as the neck, lumbar area, and abdomen. Microscopically, the squamous mucosa is ulcerated, with large areas of necrosis of the underlying connective tissues and accompanied by a marked inflammatory cell reaction. The cellular reaction consists predominantly of neutrophils at the periphery of the ulcers, with a mainly mononuclear cell reaction (plasma cells and mast cells) in the propria, eosinophils and histiocytes being only occasionally seen. In some cases, the eosinophils and mast cells may predominate, but this difference may be a reflection only of the evolution of the lesion.

Eosinophilic ulcer is one of the three different types of lesions that have been associated with the so-called *eosinophilic granuloma complex*. The other two conditions, eosinophilic plaque and linear granuloma, cause mainly skin lesions, which are different clinically and morphologically from eosinophilic ulcer (see Vol. 1, Skin and appendages).

Oral eosinophilic granuloma (linear granuloma) in dogs occurs as a familial disease in young Siberian Huskies. Sporadic cases have been reported in other breeds, especially Cavalier King Charles Spaniels. Affected dogs have single or multiple firm, often ulcerated, raised plaques, which are covered by yellow-brown exudate, on the *lateral or ventral surfaces of the tongue*. Lesions on the soft palate are less common, and here they tend to be oval to circular ulcers with slightly elevated borders. Cytologic preparations made from scrapings of the oral lesions show many eosinophils, a few neutrophils, occasional macrophages, and epithelial cells.

Microscopically, *foci of collagenolysis* (necrobiosis) in the mid and deep zones of the lingual submucosa are surrounded by a mainly histiocytic granulomatous inflammatory reaction, with giant cells, lymphocytes, plasma cells, and mast cells. *Eosinophils* are a constant feature, but their numbers vary from few to many. The lesions are identical to those seen in linear granuloma of cats.

The cause is unknown, although the morphology of the lesion and the response to corticosteroid therapy suggest hypersensitivity. The familial tendency in Siberian huskies indicates that hereditary factors are involved. *Eosinophilic granuloma must be differentiated from oral mast cell tumors*, which also affect the tongue in dogs. Necrobiosis of collagen fibers is often a feature of mast cell tumors; however, in mastocytoma, the characteristic mixture of mast cells and eosinophils infiltrates the tongue and connective tissues more diffusely. The mast cells may be in various stages of degranulation, and inflammation is minimal or absent in mast cell tumors.

Horses with **eosinophilic epitheliotropic disease** (see Vol. 1, Skin and appendages and section on Eosinophilic enteritis in cats and horses, below) may also have eosinophilic stomatitis and lingual ulceration.

Feline viral rhinotracheitis is a common upper respiratory tract infection of cats caused by *Felid herpesvirus 1* (see Vol. 2, Respiratory system). This virus may cause ulcerative lesions in the mouth, especially on the tongue. Rarely, oral and skin ulcers may occur, without evidence of concurrent respiratory tract infection. Microscopically, foci of cytoplasmic vacuolation in squamous epithelium evolve into areas of necrosis and ulceration. The ulcers are often covered by a layer of fibrinocellular exudate. Herpetic inclusions may be present in epithelial cells at the periphery of the ulcers.

Uremia associated with chronic renal disease often causes *fetid ulcerative stomatitis* in dogs, and less commonly in cats. Dirty gray-brown ulcers occur on the gums, lateral surface, and margin of the tongue, and on the inner surface of the lips and cheeks, often adjacent to the openings of salivary ducts. The margins of the ulcers are swollen and hyperemic.

The pathogenesis of the oral lesions in uremia is still poorly understood. Elevations in blood and salivary urea in combination with urease-producing bacteria, normally present in the oral microflora, may generate ammonia from salivary urea. Ammonia has a caustic effect on the oral mucous membranes. Experimental antibody production against urease renders some intestinal bacteria nonpathogenic and prevents uremic colitis, providing evidence of the importance of urease. However, there is poor correlation between the levels of blood urea and the development of uremic stomatitis, suggesting other important factors. Uremic vasculitis and impaired microvascular perfusion may contribute to the pathogenesis of uremic stomatitis.

Salivary glucose levels may be elevated in dogs and cats with *diabetes mellitus*, resulting in an imbalance of the oral microflora and predisposing to chronic gingivitis in diabetic animals.

Ulcerative glossitis and stomatitis in **swine** is commonly part of **exudative epidermitis** (greasy pig disease) of preweaning pigs (see Vol. 1, Skin and appendages). In addition to the characteristic skin lesions, about a third of the piglets may develop ulcers on the dorsum of the tongue. Erosions and ulcers of the hard palate occur in a small number of piglets. Microscopically, there is ulceration of the squamous mucosa with coagulative necrosis, and vesicle and pustule formation in the superficial epithelium over the rete pegs. A pleocellular inflammatory reaction is evident in the connective tissue below the ulcers.

Oral erosions and ulcers have been reported in pigs with *congenital swinepox*. Microscopically, there is swelling and degeneration of squamous epithelial cells with numerous eosinophilic intracytoplasmic viral inclusions. The central areas of the lesions are necrotic. There is a mixture of lymphocytes, neutrophils, eosinophils, and histiocytes in the submucosa. Poxvirus may be demonstrated by electron microscopic examination of the lesions.

Deep stomatitides

Lesions of the oral mucosa may permit the entry of pyogenic bacteria, often normal oral flora, into the connective tissues of the submucosa and muscle. Purulent inflammation or cellulitis may develop in the lips, tongue, cheek, soft palate, and pharynx. Abscesses may form and may fistulate through the mucosa or skin. Abscesses in the wall of the pharynx may result from necrosis of retropharyngeal lymph nodes. Necrotic stomatitis with simple necrosis of the epithelium and lamina propria may be produced by thermal or chemical agencies, but in animals, it is usually caused by *Fusobacterium necrophorum* and other anaerobes.

Oral necrobacillosis *Fusobacterium necrophorum* is the principal cause of **oral necrobacillosis** or **necrotic stomatitis** in animals. It is also associated with necrotizing lesions elsewhere in the upper and lower alimentary tract, and liver. Wherever it occurs, it is usually a *secondary invader* following previous mucosal damage. The organism produces a variety of exo- and endotoxins; among the latter are leukocidins, hemolysins, and a cytoplasmic toxin, all of which probably enhance the necrotizing ability of the organism. Once established in a suitable focus, *F. necrophorum* proliferates, causing extensive coagulative necrosis.

The best-known form of necrobacillary stomatitis is **calf diphtheria**, an acute necrotizing ulcerative inflammation of the buccal and pharyngeal mucosa, and also of the laryngeal mucosa (**necrotic laryngitis**). The predisposing lesions may include trauma, infectious bovine rhinotracheitis, and papular stomatitis. Necrosis of palatine and pharyngeal tonsils may be seen. The incidence of diphtheria in slaughtered beef cattle may be as high as 1.4%. The same syndrome is rather common in housed lambs as a complication of contagious ecthyma. The infection may also be initiated in the gums about erupting teeth in any species, and by the trauma produced in baby pigs by removing the needle teeth (Fig. 1.9A). It is frequently fatal in young animals, in which extension often occurs to other organs. In adults, oral necrobacillosis tends to remain localized to the oral cavity, where it may complicate vesicular and ulcerative stomatitides. It is not unusual, however, for the infection to spread down the alimentary tract.

The early lesions are large, well-demarcated, yellow-gray, dry areas of necrosis, surrounded by a zone of hyperemia (Fig. 1.9B). They are found on the sides or dorsal groove of the tongue, on the cheeks, gums, palate, and pharynx, especially the recesses beside the larynx. Primary foci may occur in the laryngeal ventricles. Death may be associated with asphyxia. The necrotic tissue projects slightly above the normal surface and is friable but adherent and is not easily detached. In time it may slough and leave deep ulcers, which may heal by granulation. The necrotic tissues are histologically structureless and are surrounded at first by a zone of vascular reaction, later by a dense but narrow rim of leukocytes, and finally by thick encapsulating granulation tissue. The bacteria are arranged in long filaments, particularly at the advancing edge of the lesions. The submucosal extension of the lesions may take them deeply into the underlying soft tissues and bone.

Spread from the oral foci occurs down the trachea (causing aspiration pneumonia), down the esophagus, and via blood vessels. Death may occur acutely in septicemia with only multiple small serosal hemorrhages as evidence, or metastases may occur in other tissue. Venous drainage from the face to the vascular sinuses of the meninges may lead to pituitary and cerebral abscessation.

Fusobacterium necrophorum has also been associated with a *syndrome of necrotic stomatitis, enteritis, and granulocytopenia in calves.* Affected calves have nonregenerative anemia, leukopenia, neutropenia, hypoproteinemia, and increased fibrinogen levels. In addition to the characteristic oral lesions, there is marked depletion of lymphoid tissues and necrotic enteritis. *Fusobacterium* organisms are present in large numbers in a variety of organs, including the bone marrow. Possibly very virulent strains of *F. necrophorum* produce enough leukotoxins, especially in immunodeficient calves, to suppress bone marrow activity. However, granulocytopenia associated with exposure to bracken or treatment with nitrofurans may also facilitate the development of calf diphtheria.

A gross diagnosis of oral necrobacillosis is ordinarily possible, but may be confirmed by a smear from the margin of the lesion. The organism is difficult to cultivate because it is a *strict anaerobe*.

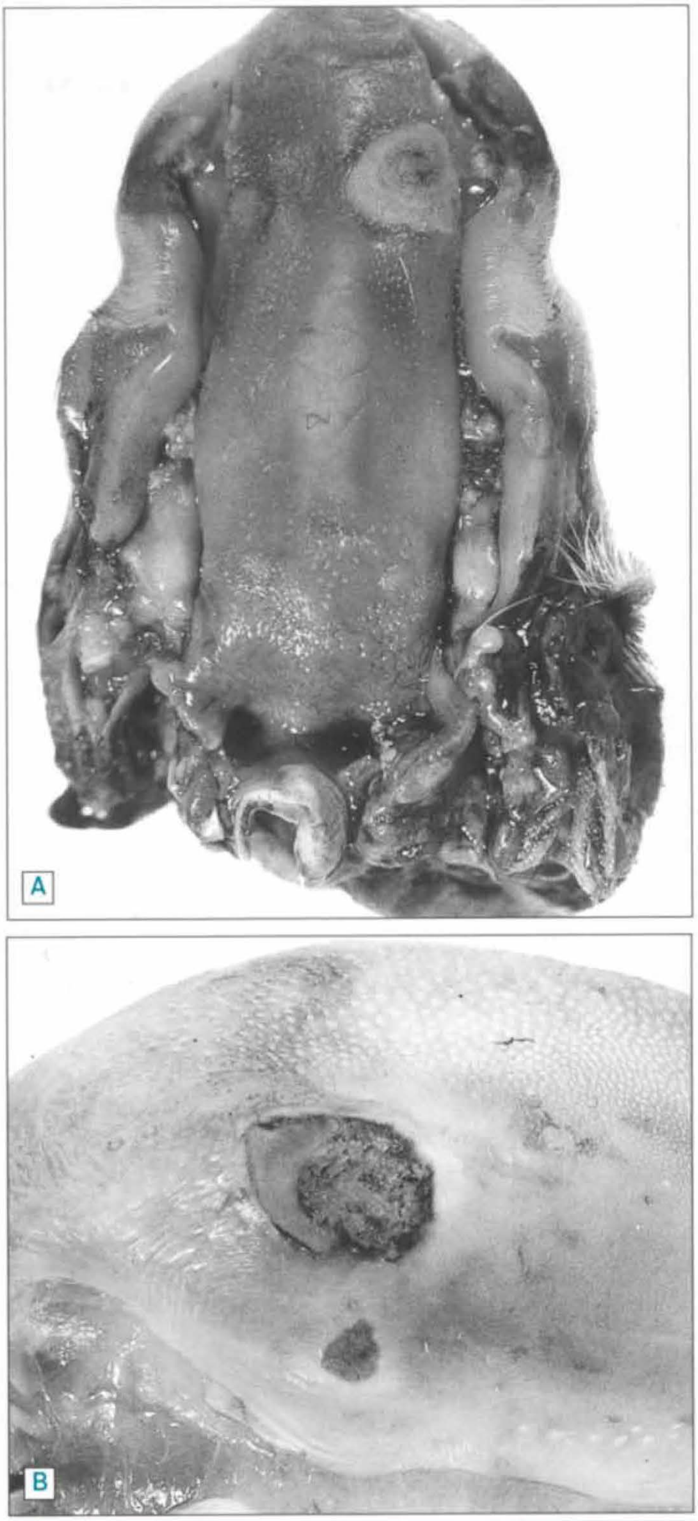

Figure 1.9 A. Necrotic **glossitis and stomatitis** in a pig, subsequent to trauma by needle teeth and *Fusobacterium necrophorum* infection. **B. Oral necrobacillosis** in a calf.

Noma Noma (cancrum oris) is a rapidly spreading *pseudomembranous or gangrenous stomatitis*; it is not caused by a specific pathogen but is associated with tissue invasion by the normal oral flora, particularly fusobacteria and spirochetes. The predisposing factors are unknown, but they are probably nonspecific and associated with mucosal trauma and debility. The disease, which is occasionally observed in horses, dogs, and monkeys, is in many respects similar to oral necrobacillosis. In the lesions, the spirochetes can be found in large numbers at the advancing margins as well as in peripheral viable tissue. In the deep layers of necrosis, fusiforms predominate, and toward the surface, there is a variety of other organisms, chiefly cocci. The initial lesion is a small tattered ulcer of the cheek or gum, which spreads rapidly and may involve much of the buccal surface of the gums and the mucosa of the cheek. It is intensely fetid and consists of a dirty necrotic pseudomembrane surrounded by a zone

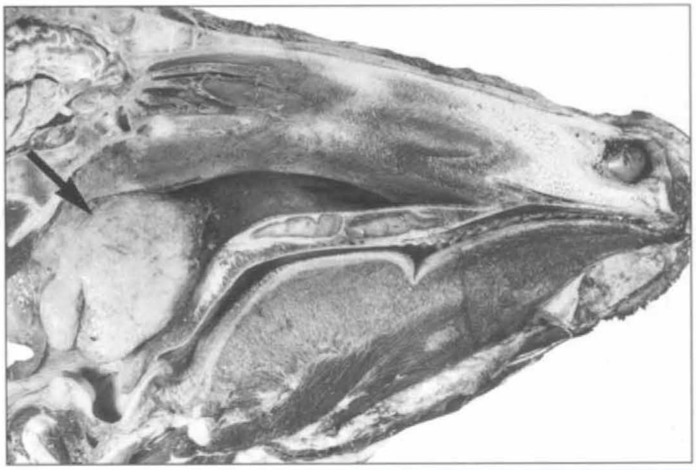

Figure 1.10 Pharyngeal actinomycosis in a cow. Fleshy mass in pharynx (arrow) that resembles actinobacillosis.

of acute inflammation. The necrotic tissue may slough to leave deep ulcers; the cheek may be perforated to leave a gaping defect, or gangrene may supervene.

Actinobacillosis This is a disease mainly of cattle, sheep, and pigs, leading to stomatitis, glossitis, lymphadenitis, and sometimes pyogranulomas in the wall of the forestomachs of ruminants. *Actinobacillus lignieresii* is part of the normal oral flora, and in cattle is associated with deep stomatitis. When introduced into the submucosa, it causes pyogranulomatous inflammatory foci centered on club colonies containing gram-negative coccobacilli. Morphologically similar lesions may be caused by a variety of organisms (Fig. 1.10). *Arcanobacterium pyogenes* may be isolated from lingual ulcers and granulomas in lambs. Microscopic examination of these lesions reveals well-demarcated submucosal granulomas with plant fibers in the center, surrounded by a marked neutrophilic reaction. The organisms most likely gain entry after the mucosa is damaged by hard fibrous plant fibers from the weed lambsleeve sage (*Salvia reflexa*), present in the bedding. *Actinomyces bovis*, a gram-positive filamentous organism, causes pyogranulomatous mandibular and maxillary osteomyelitis in cattle, and mastitis in sows. Staphylococci may cause pyogranulomatous lesions (botryomycosis) in any species, especially mastitis in sows. Less common causes of similar microscopic lesions include *Nocardia* and the various agents associated with mycetomas (see Vol. 1, Skin and appendages).

Actinobacillosis is typically a *disease of soft tissue*, spreading as a *lymphangitis* and usually involving the regional lymph nodes. This distinguishes it from actinomycosis, which causes bone lesions. The tongue is often involved in actinobacillosis, and the chronic condition produces clinical "*wooden tongue.*" Entry of actinobacilli to the tongue may be gained through traumatic erosions along its sides, but often the primary lesion is in the lingual groove. Here, trapped grass seeds and awns may provoke the initial trauma. Lesions elsewhere in the soft tissue of the mouth may be attributed to disruption of the mucosa by similar types of insults, and eruption of, or abrasion by, teeth.

Microscopically, the lesion is a *pyogranuloma*, centered on a mass of coccobacilli, surrounded by radiating eosinophilic clubs made up of immune complexes (Fig. 1.11). The *club colonies*, in turn, are surrounded by variable numbers of neutrophils, and are invested by macrophages or giant cells. Lymphocytic and plasmacytic infiltrates are present in the surrounding reactive fibrous stroma or granulation tissue. An individual inflammatory focus appears grossly as a nodular, firm, pale, fibrous mass a few millimeters to 1 cm in diameter, containing in the center minute yellow "sulfur" granules, which are the club colonies.

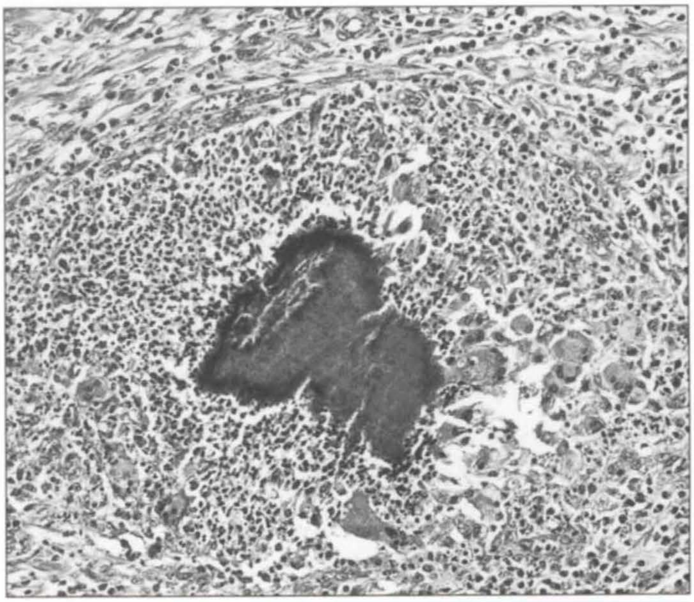

Figure 1.11 Pyogranulomatous focus containing club colony of *Actinobacillus lignieresii* in **actinobacillosis** in a cow.

Lymphogenous spread is common. Affected lymphatics are thickened, and nodules are distributed along their course. This distribution is best seen beneath the mucosa of the dorsum and the lateral surface of the tongue and often can be traced through to the pharyngeal lymphoid tissue (Fig. 1.12). Some of these more superficial nodules erode the overlying epithelium, and coalescence may produce quite large ulcers. The most common form of lingual actinobacillosis consists of granulation tissue in which are embedded many small abscesses surrounded by a dense connective tissue capsule. The epithelium overlying these large granulomas may be intact or ulcerated. Diffuse sclerosing actinobacillosis of the tongue (wooden tongue) is firm, because of extensive proliferation of connective tissue, which replaces the muscle fibers. Granulomatous nodules are sparsely scattered in the fibrous stroma.

Although actinobacillosis in cattle is best known as a disease of the tongue, the infection may occur in any of the exposed soft tissues, especially those of mouth and esophagus; occasionally it involves the wall of the forestomachs, the skin, or the lungs. Lesions in these sites resemble those described in the tongue.

Actinobacillosis causes *regional lymphadenitis*. The cut surface of the node reveals small, soft yellow or orange granulomatous masses, which project somewhat above the capsular contour and which contain "sulfur" granules. There is also sclerosing inflammation of the surrounding tissues, which may cause adhesion to overlying skin or mucous membranes. The retropharyngeal and submaxillary nodes are most often affected, as well as the lymphoid tissues of the submucosa of the soft palate and pharynx. Involvement of the pharynx and the retropharyngeal lymph nodes may cause dyspnea and dysphagia.

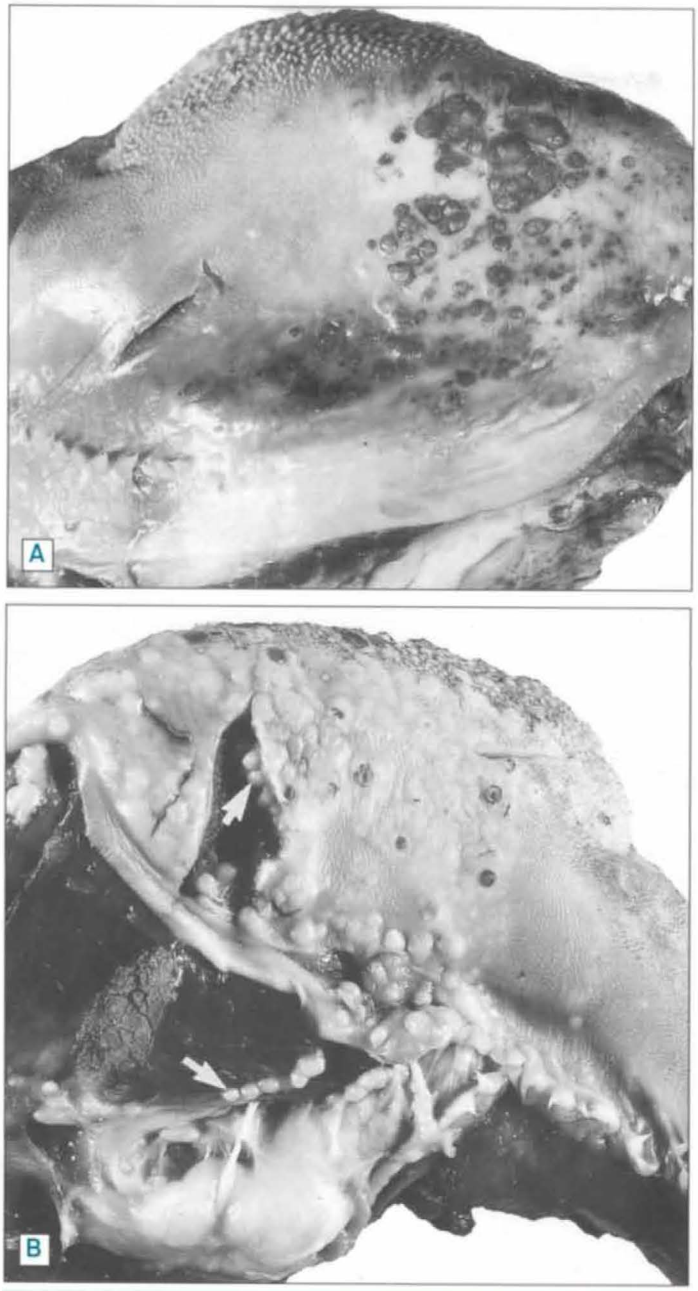

Figure 1.12 Actinobacillosis in a cow. **A.** Granulomas bulging on lateral surface of tongue. **B.** Granulomatous nodules (arrows) along course of lymphatics.

Oral actinobacillosis in *swine* causes lesions similar to those in cattle, including glossitis. Actinobacillosis may also occur sporadically or as outbreaks in *sheep*, but in this species the tongue seems to be exempt. The characteristic lesions in sheep occur in the subcutaneous tissue of the head, especially of the cheeks, nose, lips, and submaxillary and throat regions, and on the nasal turbinates. They may also occur on the soft palate and pharynx as complications of wounds received at drenching. The organism has been isolated from a *horse* with a greatly enlarged tongue.

Oral dermatophilosis of cats This is caused by *Dermatophilus congolensis*, a bacterium that commonly causes exudative dermatitis in a wide variety of species (see Vol. 1, Skin and appendages). In cats, the organism is uncommonly associated with oral granulomas, especially affecting the tongue and tonsillar crypt. Large numbers of gram-positive, filamentous, branching organisms, with longitudinal and transverse divisions, may be demonstrated in the necrotic centers of submucosal granulomas. The organisms probably enter through damaged mucosa. The lesion must be differentiated from the more common squamous cell carcinomas of the tongue. In cattle, *cutaneous streptothricosis* involving the muzzle may extend into the oral cavity.

Parasitic diseases of the oral cavity

These are of minor significance. Sarcosporidiosis and cysticercosis occur in the striated muscles of the tongue and produce the same lesions as they do elsewhere (see Vol. 1, Muscle and tendon). *Trichinella spiralis* may be found in muscles of the tongue and mastication. *Gongylonema* spp. are found in the mucosal lining of the tongue, especially in swine allowed to graze, and less commonly in cattle and sheep. They evoke little or no inflammation of the mucosa, but a mild-to-moderate lymphocytic and eosinophilic reaction may be evident in the underlying lamina propria.

The larvae of *Gasterophilus* spp. in the horse and of *Oestrus ovis* in sheep are found attached to the pharyngeal mucosa, where they may cause focal ulceration and excite mild inflammation. The larvae of *G. nasalis* migrate from the lips and invade the gums around and between the teeth and behind the alveolar processes to cause small suppurating pockets.

Halicephalobus gingivalis has been observed in proliferative granulomas of the mandibular gingiva as well as bone, skin, kidney, central nervous system, mammary gland, and eye of horses.

Parasitic leeches of the genus *Myxobdella* may infect the oral cavity of cattle and humans, leading to minor dysfunction and hemorrhage. Known colloquially as the "tongue worm," the pentastome *Linguatula serrata* infects the nasal cavity and nasopharynx of dogs and humans.

Diseases of the tonsils

The tonsils are normally prominent and protrude slightly from the tonsillar fossa in the dog and cat. In these species tonsils are compact, fusiform structures with a finely stippled, pale pink mucosal surface. In swine, tonsillar lymphoid tissue is concentrated in the caudal soft palate, and forms a plaque of raised and pitted thickened mucosa. In horses tonsillar tissues are dispersed over pharyngeal and epiglottic mucosal surfaces and consist of a series of plaques and nodules in the mucosa. In other species, the tonsils are diffuse. They are subject to the usual conditions involving lymphoid tissue, and undergo progressive atrophy with age.

Tonsils are constantly exposed to antigenic stimuli, by virtue of their function in immune surveillance in the oropharynx. As a result, they are a site of functional lymphoid hyperplasia and physiologic inflammation. Many bacteria native to the oropharyngeal mucosa probably inhabit the tonsillar crypts. Consequently they may serve as portal of entry for a variety of bacterial agents and viruses. A significant percentage of swine may carry *Erysipelothrix rhusiopathiae* and *Salmonella* spp. in the tonsils, and *Streptococcus suis* type 2 can be cultured from tonsils.

Desquamated epithelium, bacteria, necrotic debris, and neutrophils may normally be present to moderate degree in *tonsillar crypts*. This reaction is exaggerated, and may be associated with ulceration of the crypt and suppuration of involuted tonsillar lymphoid tissue, in certain bacterial infections, causing the formation of visible yellow nodules. Conditions in which such bacterial tonsillitis may occur include pasteurellosis in sheep and pigs, *Actinomyces* and *Tonsillophilus* in tonsils of swine, and necrobacillosis in all species (see Fig. 1.8). In porcine anthrax, hemorrhagic necrotizing tonsillitis is reported.

Scrapie-associated prion protein is consistently detected by immunohistochemistry in the center of primary and secondary lymphoid follicles of sheep with clinical and histologic lesions of scrapie, and this may be a useful antemortem diagnostic approach in this and other prion-associated diseases of animals.

The tonsil is the site of primary virus multiplication in pseudorabies (Aujeszky's disease) in swine. The virus causes necrotizing tonsillitis, and intranuclear viral inclusions may be seen in cryptal epithelial cells.

Involution of B-dependent tonsillar lymphoid follicles due to viral lymphocytolysis may occur during the early phase of a number of lymphotropic diseases such as feline panleukopenia, canine parvoviral enteritis, canine distemper, bovine viral diarrhea, rinderpest, and swine vesicular disease. Numerous karyorrhectic nuclei, lymphocyte depletion, and prominent histiocytes signal such damage. In distemper, involuted tonsils are susceptible to secondary bacterial invasion and suppuration. Compensatory lymphoid hyperplasia may occur during the postviremic phase of parvoviral infections and distemper. The tonsil often appears to be the preferred organ of viral persistence in a symptomatic carrier infected with *Feline calicivirus*. In *Porcine circovirus 2* infections (postweaning multisystemic wasting syndrome), involution of lymphoid tissue and accumulation of macrophages and giant cells containing basophilic cytoplasmic circoviral inclusions occur, as they do in other lymphoid organs.

Inflammatory polyps of the tonsils occur infrequently in old dogs. They are flat to pedunculated rubbery masses (1–3 cm in length), attached to the tonsillar sinus, with a smooth to verrucous surface. Histologically, the lesions are composed of mature, sometimes edematous, highly vascularized connective tissue that is covered by squamous epithelial cells. Aggregates of lymphocytes and plasma cells are scattered throughout the connective tissue. The lesions are probably the result of chronic recurrent episodes of subclinical tonsillitis. They are usually asymptomatic but may cause gagging and retching.

Tumors, especially lymphosarcomas and squamous cell carcinomas, are common causes of tonsillar enlargement in dogs. Bilaterally enlarged and soft, pale swollen tonsils are usual with lymphosarcoma, and these may become clinically obvious prior to the development of peripheral lymphadenopathy.

Neoplastic and like lesions of the oral cavity

Some of the lumps, bumps, and cysts that develop in and around the oral cavity are malformations, hyperplasias, and neoplasias originating in tooth germ or teeth. Malformations of dental origin have been considered previously under developmental anomalies of teeth. Gingival masses of all types, many of which are of tooth germ origin, are common in dogs, but occur much less frequently in other species. In this discussion we follow revisions in the nomenclature of lesions that formerly were included with epulis, placing those that clearly are of dental origin with other such tumors, and consigning the remainder to hyperplastic and reactive lesions. Prognostic implications for such masses have not changed, despite some reclassification.

Epulis *is a generic clinical term for tumor-like masses on the gingiva.* Epulis has, in the past, been used to describe developmental, inflammatory, and hyperplastic lesions, as well as several neoplastic lesions of tooth germ origin, which are numerous in dogs, and develop occasionally in cats. It has no specific pathologic connotation, and preferably, *the term should not be used in a morphologic diagnosis, except in the context of fibromatous epulis of periodontal ligament origin*, discussed with Tumors of dental tissues, below.

In evaluating lesions of the gums and jaws, a potentially confusing element is the nature of the epithelium and of the hard tissues that are often found in the stroma. In interpreting these, it is important to recall the inductive pattern of tooth development. Epithelial remnants from tooth organogenesis occur commonly in the gingiva and the periodontium, and nests of dental epithelium can be found incidentally in any proliferative lesion in this region. Characteristically, dental epithelial cells show reverse polarity, their nuclei being located at the apex of the cell, distal to the basement membrane. Often the cell nests are surrounded by a relatively clear halo that contains a few strands of collagenous tissue. Also, gingival epithelium commonly proliferates extravagantly in response to irritation, and may form complex plexiform patterns. Unless there is neoplastic change; the epithelial component is not of primary significance. Similarly, many stromal masses in the regions of the jaws include mineralized tissues or amorphous, apparently mineralizable tissues, which may develop by metaplasia of fibrous tissue or by de novo cellular differentiation. It is often difficult to determine whether this is bone, cementum, dentin, or their precursors, but in any case this is prognostically irrelevant, as is the abundance of such tissues themselves. *In describing lesions of the gums and jaws, the adjective "peripheral" refers to an origin in the gingiva, while "central" implies a deeper origin in the jaw bone.*

The oral and pharyngeal mucosa is a common site of malignant tumors in the dog, as it is in cats. Malignant oral tumors account for ~6% of all canine and ~7% of all feline neoplasms. Large domestic animals have a low prevalence of malignant oral tumors, and when they do occur in ungulates, they are usually relatively nonaggressive.

There are regional geographic differences in the prevalence of certain oral tumors, especially in dogs and cattle. Such differences may be related to the distribution of carcinogens in the environment, and warrant further investigation from the point of view of comparative oncology.

The most common types of malignant oral tumors in dogs and cats are squamous cell carcinomas, fibrosarcomas, and, in dogs only, malignant melanomas. They vary somewhat in their behavior depending on the species in which they occur, and the type and location of the tumor. Dogs and cats with mean ages over about 6 or 7 years of age are mainly affected. The canine population with fibrosarcomas has a mean age of about 8 years. Melanomas in dogs tend to occur in a notably older age class than the other tumors, with the mean of the distribution at about 11–12 years. Typical clinical signs, determined by the location, behavior, and stage of the tumor, are drooling, halitosis, pain, dysphagia, anorexia, weight loss, loose teeth, mandibular fractures, oral bleeding, noisy respiration, coughing, and a change in voice.

Boxers, Cocker Spaniels, German Shorthaired Pointers, Weimaraners, and Golden Retrievers apparently have a higher prevalence of malignant oral tumors than other breeds of dogs, while Dachshunds and Beagles apparently have a very low prevalence. The male-to-female ratio has been reported to be as high as 6:1 for melanomas, 3:1 for tonsillar carcinomas, and 2:1 for fibrosarcomas. The ratios have to be interpreted with some caution since they may be partly related to differences in the ratio of males to females in the general population.

All types of malignant oral tumors in dogs and cats tend to progress rapidly, and regardless of the type of malignancy, the prognosis is generally poor, unless the lesion is completely resected early in its clinical course, prior to metastasis.

Reactive and hyperplastic lesions

Pyogenic granuloma *is a bright red or blue mass on the gums of dogs.* It is composed of extremely vascular granulation tissue covered by gingival epithelium, and is not genuinely granulomatous, despite the name. It ulcerates and bleeds easily. Pyogenic granuloma is probably an exaggerated response to local irritation and infection. In horses, exuberant granulation tissue of periodontal origin sometimes develops at the site of extracted teeth to produce a tumor-like mass in the dental arcade. Epithelial remnants and proliferative bone may be associated with the granulation tissue in such cases.

Peripheral giant cell granuloma (*giant cell epulis*) occurs in dogs and cats as *gingival masses*, often red, that may be smooth and sessile, or pedunculated. Very occasionally, similar lesions, described as *central giant cell granulomas*, occur more deeply in the jaw. The gingival epithelium is hyperplastic or ulcerated and extends deeply into the underlying mass, which is well vascularized and often contains hemosiderin-laden cells. Characteristic of the tumor are numerous giant cells, with multiple central nuclei and abundant eosinophilic cytoplasm, which are located in a densely cellular stroma. Foci of hard tissue may be present. Giant cell granulomas are regarded as hyperplastic or granulomatous lesions, and have occurred at the site of tooth extraction.

Fibrous hyperplasia (formerly part of fibrous or fibromatous epulis, *gingival hypertrophy*) is common in dogs, and may be generalized and diffuse, or focal, localized to one or more teeth. When focal, it is a discrete tumor-like mass and, whether local or general, may cover part of the crown (Fig. 1.13). The stromal component of the mass consists of mature fibrous tissue with low cellular density. Foci of hard tissue and epithelial nests may be present. Local enlargement may be promoted by chronic, probably painless, inflammation. It may be associated with periodontal disease, in which case it is often accompanied by a more-or-less extensive chronic or chronic-active inflammatory

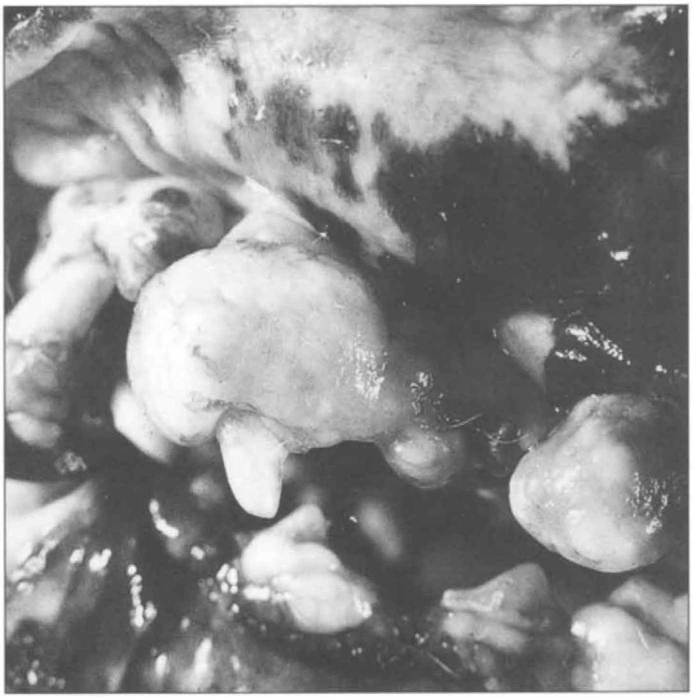

Figure 1.13 Fibrous hyperplasia in a Boxer dog.

reaction. Characteristically there is a band of mononuclear cells, predominantly plasma cells, in the gingival stroma adjacent to the epithelium, which is often hyperplastic, sometimes markedly so. Where the epithelium is ulcerated, neutrophils may be prominent, marginating in vessels, in the stroma, and migrating through the epithelium.

Diffuse fibrous hyperplasia is familial in Boxer dogs, and a more severe overgrowth, termed *hyperplastic gingivitis*, occurs as a recessive inherited disease in Swedish silver foxes. In the foxes, both jaws are affected and the lesion causes displacement and malalignment of teeth, eventually reaching such proportions that the mouth cannot be closed.

Oral papillomatosis

These benign epithelial tumors ("warts") in dogs, cats, and cattle are caused by papillomaviruses.

In **dogs**, they are caused by *Canine oral papillomavirus* (COPV), in genus *Lambdapapillomavirus*, and mainly occur in young animals, although older dogs in close contact may become infected. The lesions are unsightly, and may be traumatized and bleed, but only unusually heavy infections that interfere with swallowing or respiration cause other than cosmetic problems.

The virus is host- and fairly site-specific. Infection of basal epithelium of the squamous mucosa stimulates increased mitosis, while viral genome replicates in the differentiating keratinocytes of the stratum spinosum and granulosum, which degenerate, with viral assembly and expression in superficial squamous layers. The incubation period is generally about 2 months. Spontaneous recovery, mediated by CD4 and CD8 T cells, usually occurs within 1–2 more months, followed by *solid antibody-mediated immunity to reinfection.* The warts first develop as single, smooth papular elevations which are pale or the color of the mucosa. These lesions progress to multiple, proliferative cauliflower-like, firm, white to gray growths (Fig. 1.14). They develop on the lips, gingiva, buccal mucosa, tongue, palate, and walls of the pharynx. The esophagus and the skin of the muzzle also may be involved. Persistent and progressive infections, which may also involve haired skin remote from the mouth, are attributable to immunocompromise of the host, rather than an unusually virulent strain of virus.

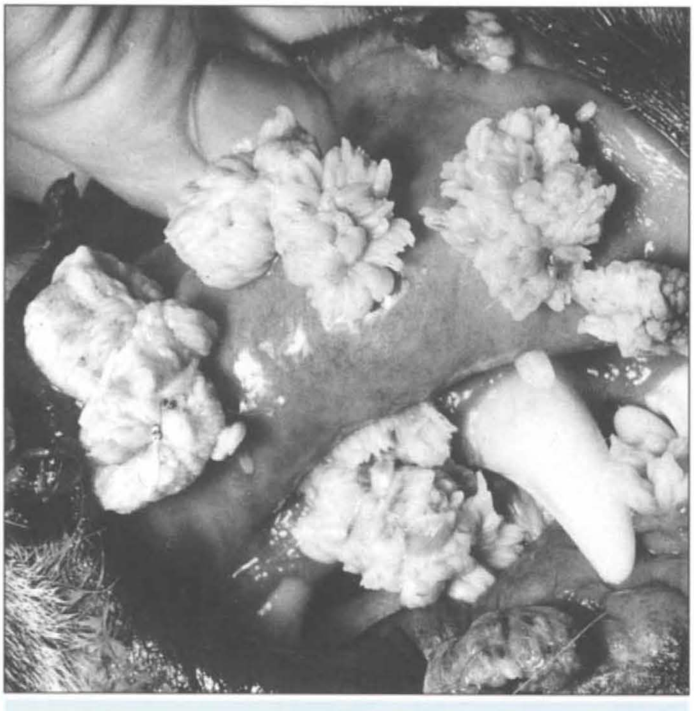

Figure 1.14 Oral papillomatosis in a dog. (Courtesy of WR Kelly.)

The *microscopic structure* of fully developed lesions is typically verrucous, with very thick keratinizing squamous epithelium covering thin, branching, often pedunculated cores of vascularized proprial papillae. There is also marked acanthosis. Individual epithelial cells or small groups in the upper areas of the stratum spinosum and granulosum degenerate, developing koilocytic atypia, with clear cytoplasm around or adjacent to an often somewhat condensed nucleus, and large cytoplasmic granules or inclusions, with loss of intercellular bridges. *Basophilic intranuclear viral inclusions* may be found in cells in the outer spinose layers, but they can be rare. Regressing lesions are infiltrated by moderate numbers of T lymphocytes. Viral antigen can be demonstrated in nuclei of koilocytes and in intranuclear, but not cytoplasmic, inclusions by specific immunohistochemistry. Electron microscopy reveals intranuclear 50–55 nm viral particles, sometimes forming paracrystalline arrays.

Malignant transformation of infected papillomavirus-infected epithelium to produce squamous cell carcinomas can apparently occur, but its importance in the etiology of canine oral squamous cell carcinomas is unclear. Injections of live COPV vaccine into the skin of dogs may result in a spectrum of lesions, including epidermal hyperplasia, papillomas, epidermal cysts, basal cell tumors, and squamous cell carcinomas, and some cutaneous squamous cell carcinomas in dogs contain COPV genetic material.

In domestic and wild species of **cats**, oral and cutaneous papillomas and fibropapillomas are very occasionally identified. In the oral cavity they are most common on the ventral aspect of the tongue, and typically they are multifocal, pink, and more sessile than verrucous. Microscopically, raised areas of thickened mucosa are comprised of hyperplastic keratinocytes with occasional fibrovascular stalks. Typical degenerative changes are seen in infected keratinocytes, and papillomavirus antigen can be detected by immunohistochemistry in a high proportion of such cases.

In **cattle**, oral papillomas, caused by *Bovine papillomavirus type 4* (a strain of *Bovine papillomavirus 3*, genus *Xipapillomavirus*), can occur commonly in endemic areas. Their morphology and distribution in the oral cavity are similar to the papillomas of dogs, but since they infect the esophagus and forestomachs extensively, they are considered more fully in the section on neoplasia of the esophagus and forestomachs, below.

Tumors of dental tissues

Tumors of dental tissues are classified either as epithelial (with or without odontogenic mesenchyme) or mesenchymal neoplasms, and malformations. Tooth development provides the classic example of epithelial–mesenchymal interactions, and inductive influences appear to be active in some tumors. Familiarity with dental embryology assists an understanding of the origin, appearance, and classification of the tumors discussed below.

Tumors of dental tissues, other than fibromatous epulis of periodontal ligament origin, and canine acanthomatous ameloblastomas (acanthomatous epulides), *are rare. All are nonmalignant, and infiltrative or expansive.* However, their location predetermines destruction of bone and displacement of teeth, and they are difficult to remove.

Ameloblastoma is a slowly progressive invasive but nonmetastatic tumor, consisting of proliferating odontogenic epithelium in a fibrous stroma. The proportions of epithelium and stroma vary widely. The terms "adamantinoma" and "enameloblastoma" are obsolete synonyms. These tumors are more common in dogs than in cats and horses, and seem to occur more often in the mandible than the maxilla. Tumors formerly described as ameloblastomas in young cattle are now considered to be ameloblastic fibromas, discussed below.

Ameloblastomas occur at any age. They originate from the dental lamina, the outer enamel epithelium, the dental follicle around retained unerupted teeth, the oral epithelium, or odontogenic epithelium in extraoral locations. They are *predominantly intraosseous* and, because of their location, they may destroy large amounts of bone, and extend into the oral cavity or sinuses. Large tumors may undergo central degeneration and become cystic.

Odontogenic epithelium, which is the criterion for diagnosis of ameloblastoma, may form any one of several patterns (Fig. 1.15). Follicular and plexiform patterns are most common, consisting of discrete islands, or irregular masses and strands of epithelium, respectively. Many tumors contain both patterns. In both, central masses of cells, often resembling the stellate reticulum of the enamel organ, but sometimes with an acanthomatous appearance, are surrounded by a single layer of cuboidal or columnar cells that resemble inner enamel epithelium. Cysts originate from degeneration of the centers of epithelial islands, or from stromal degeneration. Small cysts may coalesce to form grossly evident cavities. Ameloblastomas occasionally undergo keratinization. In some, stromal osteoid and bone develop, which may be an epithelial inductive effect.

Amyloid-producing odontogenic tumors are rare tumors that occur as unencapsulated gingival masses in dogs and cats. They are characterized by dental epithelium, with deposits of amyloid, and sometimes prominent trabeculae of osteoid/dentinoid. The epithelium may be arranged in strands, nests, or masses and may contain areas of stellate reticulum. Occasionally there is mineralization of epithelium or stroma, in the form of small nodules or amorphous masses. The amyloid may also be nodular or amorphous and may be intermingled with the mineral. Distinguished histologically, but not prognostically, from ameloblastomas by the presence of amyloid, these tumors are cured by surgical excision.

Acanthomatous ameloblastoma (acanthomatous epulis, peripheral ameloblastoma, adamantinoma, basal cell carcinoma) *is a common tumor arising from the mucosal epithelium or epithelial rests of the gingiva of dogs*; it does not occur in other species. It is easily confused clinically with the benign stromal masses found in the canine gingiva, but *it often behaves aggressively*, invading local alveolar bone (Fig. 1.16), causing tooth loss, and recurring in many animals following conservative treatment. Grossly they are gray-pink papillary to sessile gingival masses in the vicinity of the alveolus

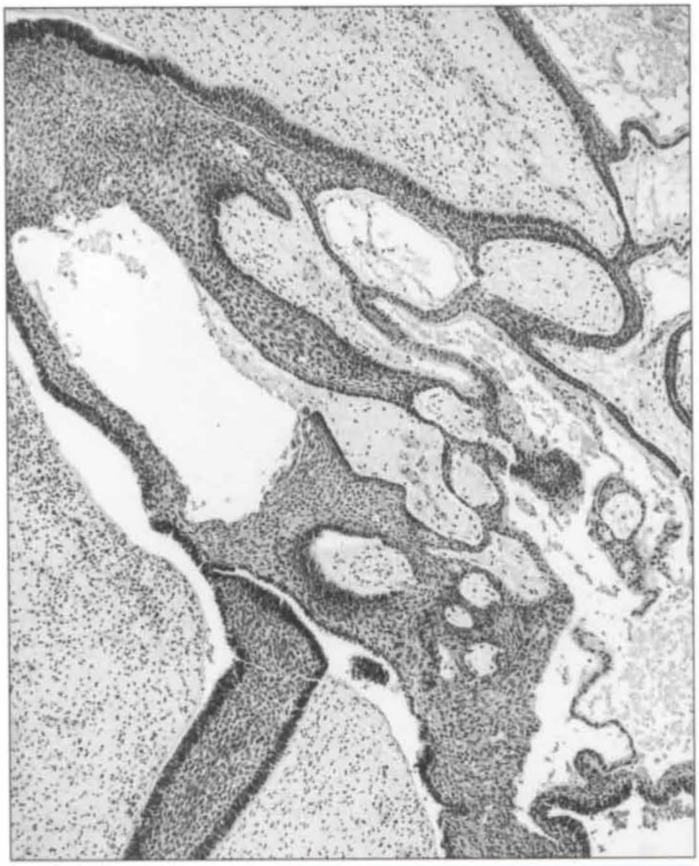

Figure 1.15 Ameloblastoma. Tall enamel-type epithelium and cyst formation.

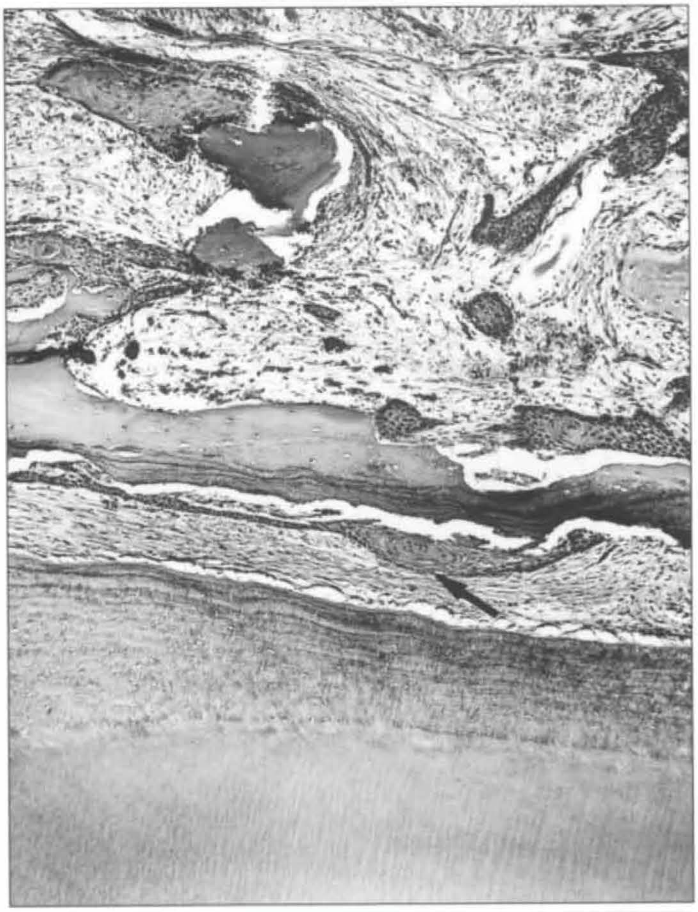

Figure 1.16 Acanthomatous ameloblastoma invading periodontal ligament (arrow) and resorbing alveolar bone (center). Cementum and dentin (below).

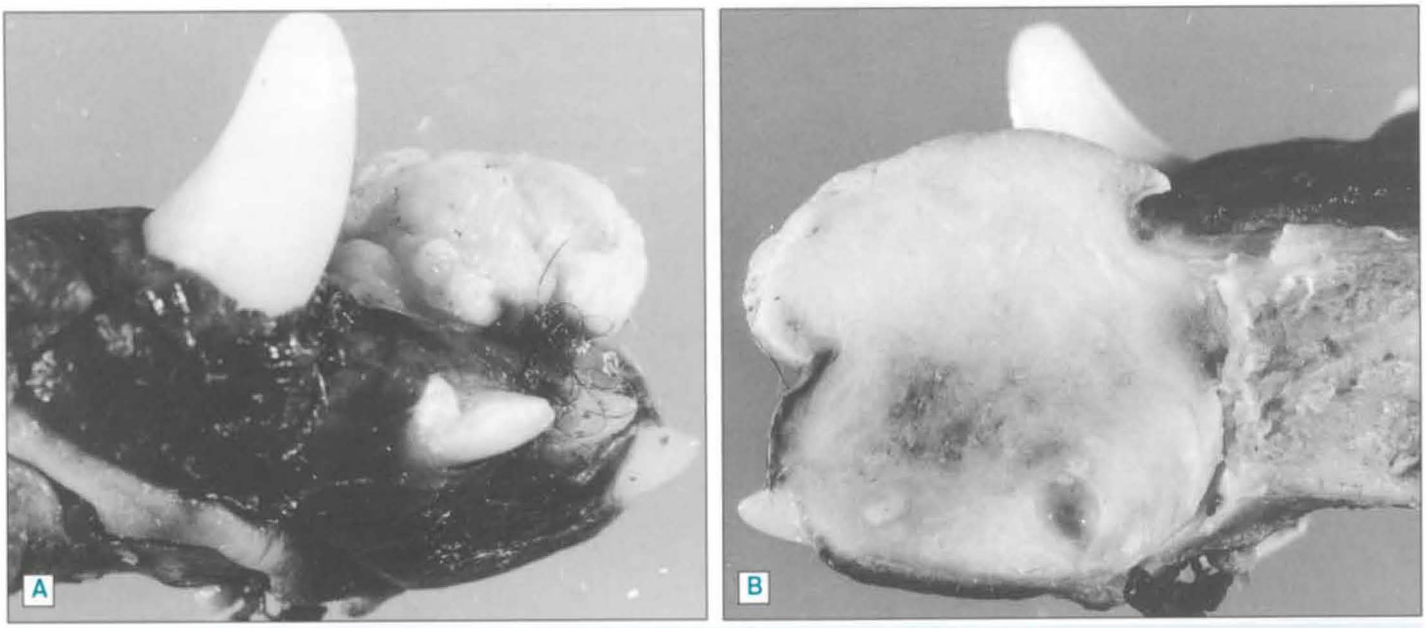

Figure 1.17 Acanthomatous ameloblastoma in a dog. **A.** Lateral view. Exophytic tumor that is also invading and destroying mandibular symphysis and displacing teeth. **B.** Medial view, with the symphysis split.

(Fig. 1.17). Histologically the tumor is composed of sheets, nodules, and anastomosing cords of polyhedral epithelium bordered by a row of cuboidal to columnar cells with round to oval nuclei and moderate amounts of cytoplasm. *Prominent intercellular bridges*, the defining feature of the lesion reflected in the name, are present between many of the central polyhedral cells. In some tumors, intraepithelial cysts contain vacuolated, otherwise structureless, eosinophilic material and cellular debris (Fig. 1.18). These cysts probably form from degenerate epithelium. Small masses of hard tissue may develop in the stroma between the epithelium.

It is sometimes difficult to distinguish an acanthomatous ameloblastoma developing in the gingiva from the epithelial proliferation accompanying gingivitis. Besides the usual prudence required when identifying neoplastic cells in areas of inflammation, other criteria for differentiation include the *predominance of broad sheets of epithelium and the mitotic figures sometimes present in the acanthomatous ameloblastoma*. Evidence of invasion of bone is clearly relevant to the diagnosis, care being taken to differentiate alveolar bone from stromal hard tissues.

Some acanthomatous ameloblastomas show characteristics of squamous cell carcinoma when they escape the influence of the subgingival stroma and invade bone, but metastases are not recorded, and complete surgical resection is curative. Squamous cell carcinoma, and occasionally fibrosarcoma or osteosarcoma, have been reported from the site of irradiated acanthomatous epulides, several months to many years after treatment.

Among the rare tumors containing both dental epithelial and mesenchymal tissue, the **ameloblastic fibroma** (fibroameloblastoma) occurs in horses, and dogs, often in young animals, but is the *commonest odontogenic tumor of cattle*, where it is found in the vicinity of the mandibular incisors of calves. It consists of cords of epithelium resembling dental lamina, intimately associated with spindle cells resembling dental pulp. Where the epithelium is well differentiated, resembling the enamel organ, it may be associated with

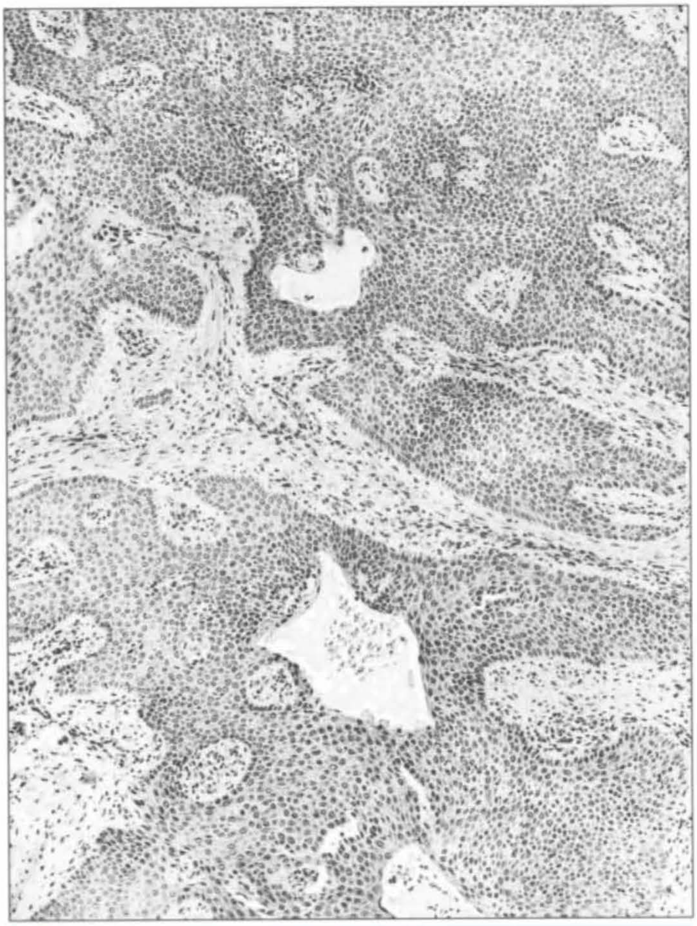

Figure 1.18 Acanthomatous ameloblastoma in a dog, illustrating invasive cords of cells.

enamel and dentin; such variants are termed **ameloblastic fibro-odontomas**, in contrast to ameloblastic fibromas, which contain no mineralized tissue. These tumors generally behave like ameloblastomas, although malignancy has been reported once in a dog.

Feline inductive odontogenic tumor is a rare tumor specific to cats, but the commonest odontogenic tumor in kittens, where they occur as osteolytic masses in the rostral maxilla, causing tooth loss or facial distortion. They are distinguished by the presence of aggregates of neoplastic dental epithelium partially enveloping somewhat spherical masses of cellular mesenchyme, forming structures resembling the cap stage of tooth development, when dental epithelium invests the dental papilla but odontoblasts have not yet differentiated.

Complex and compound odontomas are malformations in which fully differentiated dental tissues are represented. In *complex odontomas*, the tissues are disorganized, and in dogs, cementum is not evident, though it is in horses. In *compound odontomas*, tooth-like structures (denticles) are present, each containing enamel, dentin, cementum, and pulp, arranged as in a normal tooth. Distinction of the two may be arbitrary. Separate areas of ameloblastic epithelium are not present in complex and compound odontomas. A tumor that contains ameloblastic epithelium and separate areas of complex or compound odontoma is an **odontoameloblastoma**.

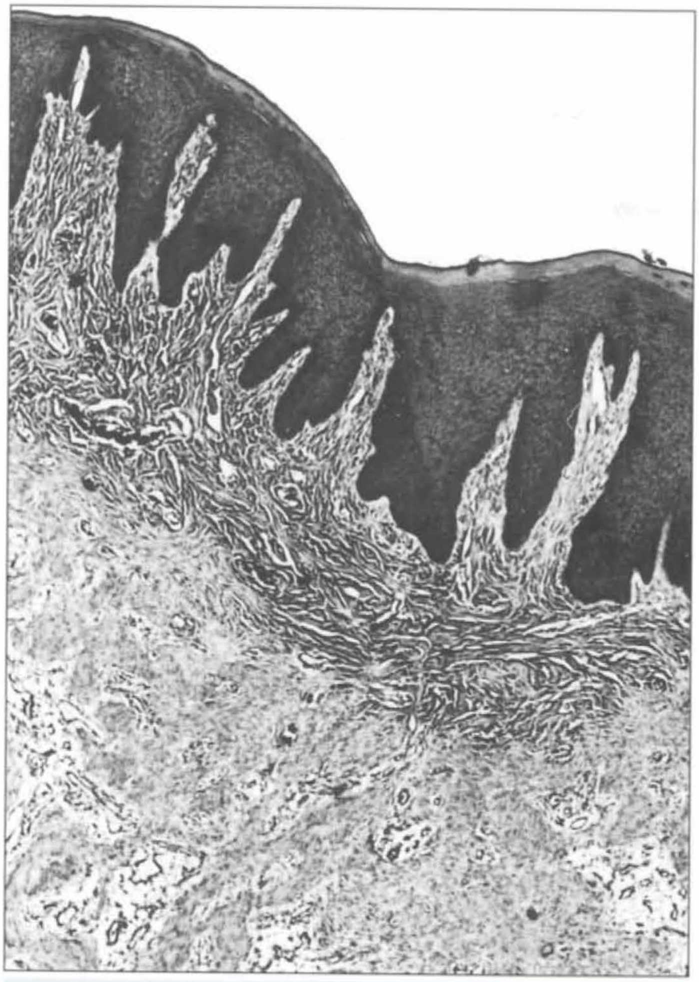

Figure 1.19 Fibromatous epulis of periodontal ligament origin in a dog. Note demarcation between tumor (below) and gingival stroma.

Odontomas are usually located in the mandibular or maxillary arch, and are less rare in cattle and horses than in other species. They are connected with existing dental alveoli and are detected when they bulge the contour of the host bone or interfere with other teeth. They may originate from normally or abnormally placed dental anlagen as well as from a supernumerary dental anlage.

Fibromatous epulis of periodontal ligament origin *is a peripheral odontogenic neoplasm, indistinguishable clinically from fibrous hyperplasia, and most common in dogs.* The distinction is academic since prognosis following surgical removal is good for both lesions. Fibromatous epulis of periodontal ligament origin is a neoplasm, however, comparable to the rare human tumor called peripheral odontogenic fibroma. Similar tumors occur rarely in cats. Fibromatous epulides of periodontal ligament origin are firm to hard, gray-pink neoplasms, often projecting from between the teeth or from the hard palate near the teeth. Often they are mushroom-shaped and have a smooth, lobulated surface. They are attached to the periosteum, and may displace teeth mechanically, but do not invade bone. Fibromatous epulides are most common around the carnassial and canine teeth of brachycephalic breeds, and usually occur in dogs over about 3 years of age.

Fibromatous epulides of periodontal ligament origin are *stromal tumors* consisting of interwoven bundles of cellular fibroblastic tissue that is often well vascularized (Fig. 1.19). They are distinguished from fibrous hyperplasia by the immaturity of this stroma, which is comprised of small stellate to fusiform fibroblasts dispersed in a dense collagen matrix, and by their tendency to contain less inflammatory tissue and more hard tissue, which may resemble bone, cementum or dentin. About 60% contain branching cords or islands of epithelium which may be continuous with the gingiva, or originate in epithelial rests of Malassez. The epithelium is bordered by a row of cuboidal cells somewhat resembling odontogenic epithelium (Fig. 1.20). Though

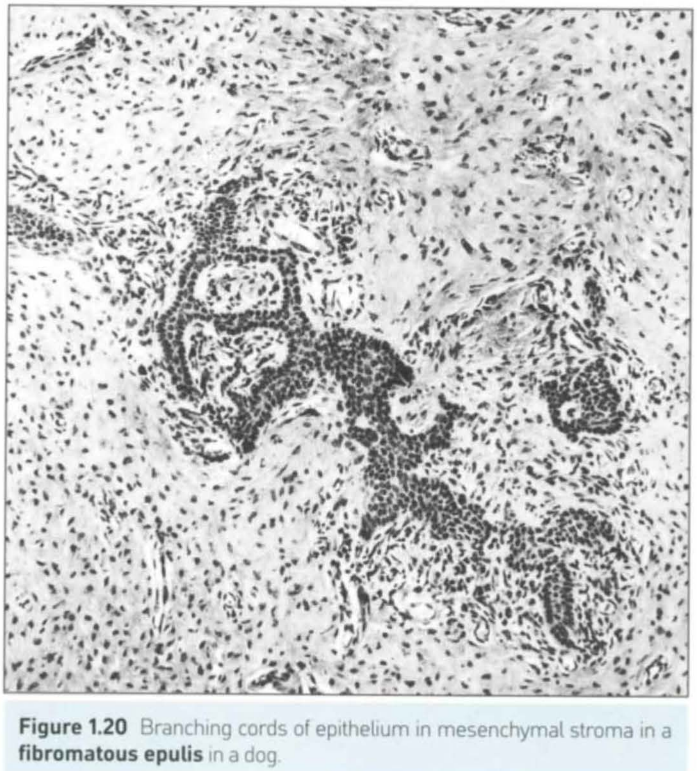

Figure 1.20 Branching cords of epithelium in mesenchymal stroma in a **fibromatous epulis** in a dog.

such masses are sometimes categorized as fibromatous or ossifying, depending on the abundance of the hard tissue, there is no prognostic value in this distinction, since these are all benign tumors that are cured by excision.

Squamous cell carcinomas

Squamous cell carcinoma (SCC) is by far the most common oral malignancy of **cats**, and, although there seems to be some geographic variation, it is generally most frequently located on the ventral surface of the tongue, on the midline near the frenulum. The gingiva is the next most common site, and other locations, including the tonsils, are generally much less frequently involved. In the early stages gingival SCCs are often mistaken for gingivitis. Oral SCCs in cats are generally advanced at presentation. *The tumor is locally invasive*, especially into bone and local soft tissues, but at presentation is less frequently metastatic to regional lymph nodes, and rarely to the lungs, although the survival rate of animals following surgical resection alone is only about 20%. Larger tumors at presentation signal a poorer prognosis. Paraneoplastic hypercalcemia has been reported. Grossly, these tumors are irregular, slightly nodular, red-gray, friable masses, often with an ulcerated surface that bleeds easily. Microscopically the tumor is a conventional SCC in appearance. Infection with *Feline immunodeficiency virus, Feline leukemia virus* or *Feline sarcoma virus* is not clearly a factor in the etiology, which is presumably multifactorial and in some cases may involve exposure to environmental tobacco smoke.

In the **dog**, most studies have found that SCC is second to melanoma in prevalence in the oral cavity. It most frequently involves the tonsils, although the gums are also common sites. Lips, tongue, and other oropharyngeal mucosae are involved much less often. The etiology is likely multifactorial, including epithelial hyperplasia associated with chronic gingivitis, and carcinogens associated with smog and smoke in the case of tonsillar tumors in urban dogs, but, as alluded to above, infection with *Canine oral papillomavirus* may have a part to play in some cases.

Grossly, tonsillar carcinoma usually appears unilateral. The earliest lesion visible is a small, slightly elevated, granular plaque on the mucosal surface, but it is rarely recognized. In the advanced stages, the affected tonsil is replaced by neoplastic tissue, 2–3 times normal size, nodular, firm and white, and the surface often is ulcerated. There is usually extensive infiltration of the surrounding tissues by microscopically typical SCC. Histological examination of the grossly unaffected tonsil may also reveal early carcinoma. SCCs originating in the tonsils of dogs often metastasize early to the regional nodes, initially the retropharyngeal node, and to the thyroid, with distant metastases to many visceral organs, but especially the lungs, and to bone. Tonsillar SCCs must be differentiated from involvement of the tonsil in lymphosarcoma. Those of the tongue may be difficult to resect fully locally, as they infiltrate among muscle bundles, and invade veins and lymphatics. They also tend to metastasize early to regional nodes, though more distant metastases are less common.

Gingival SCCs may be associated with chronic periodontitis in dogs. It is not always clear whether they have predisposed to periodontitis, or resulted from chronic irritation of the gingiva. It is assumed that some originate in the gingiva and others in subgingival or periodontal epithelial rests. They appear as pink or white nodular masses around the mandibular or maxillary dental arcade, often around canine or carnassial teeth, extending to form larger masses or ulcerative plaques; sometimes they involve adjacent hard palate. Their microscopic appearance is conventional, though the degree of keratinization, and formation of keratin pearls, may be lower than in similar cutaneous tumors. They may often be obscured by chronic active inflammation, as well. They are locally invasive, and may invade bone (Fig. 1.21), maxillary tumors sometimes extending into the sinuses and orbit. However, they are much less likely to have metastasized at presentation than SCC of the tonsil.

In **horses**, SCC are found rarely on the gums and hard palate, possibly arising in chronically irritated hyperplastic alveolar epithelium in cases of chronic periodontitis. They are slow-growing, exceedingly destructive, and metastatic mainly to the regional lymph nodes. Such tumors are large when first observed and may project from the palate or gums as gray extensively ulcerated masses, or appear as craterous ulcers. The large ones are extensively necrotic, and the teeth are lost or loosely embedded in the tumor. These tumors of the maxilla rapidly fill the adjacent sinuses and cause bulging of the face and may extend further, into the nasal, orbital, and cranial cavities. The microscopic appearance of the tumors varies considerably, from well differentiated with keratinization of individual epithelial cells and formation of keratin "pearls," to poorly differentiated with little evidence of keratinization.

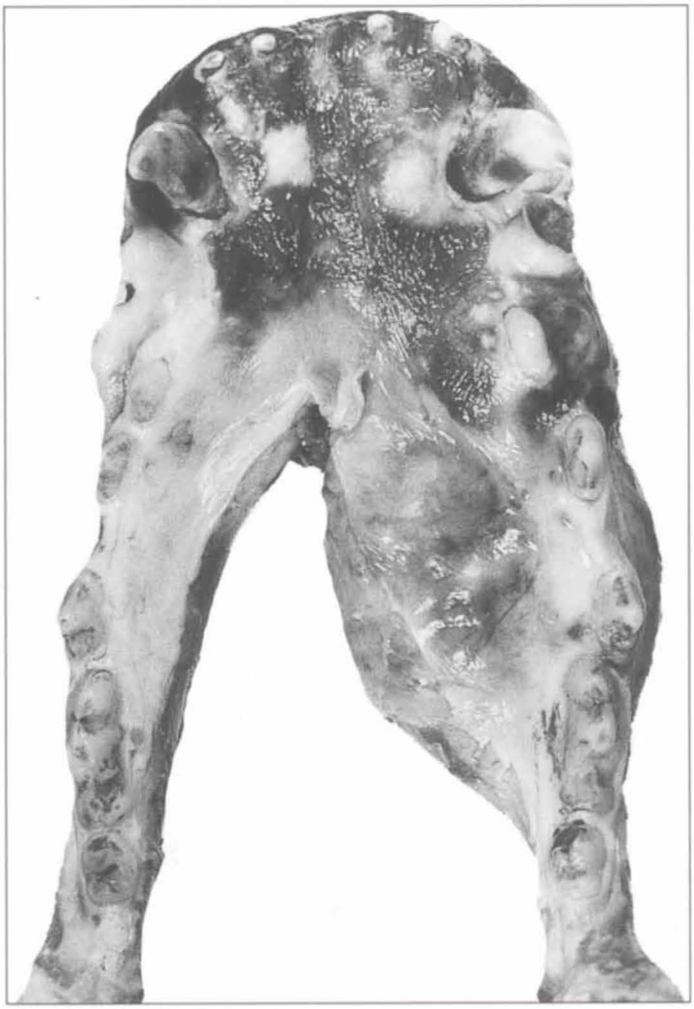

Figure 1.21 Squamous cell carcinoma arising from alveolus of right canine tooth and invading mandible in a dog.

In **cattle**, oral SCCs are very rare, with the exception of a few geographic areas where they are associated with oral papillomatosis and ingestion of bracken fern. A similar association is made in the etiology of SCC of the esophagus and forestomachs in cattle, and is considered more fully in that section. There are sporadic reports of this tumor on the lower lip of **sheep**.

Melanomas

Malignant melanomas *are the most common oral tumors in dogs in many parts of the world.* Although cutaneous melanomas are common in gray horses and certain breeds of swine, these species have no tendency to develop oral melanomas, though rare cases are reported. These tumors are also rare in cattle, sheep, and cats.

Most oral melanomas in **dogs** are malignant, in contrast to cutaneous melanomas, which are usually benign, and the majority have metastasized by the time they are diagnosed. They arise from melanocytes in the mucosa or superficial stroma, mainly on the gingiva and labia, and less often on the buccal mucosa, palate, tongue, and pharynx. There is variation in the outcomes of studies of sex and breed association. Males have been overrepresented in some studies, but not others. Some consider that melanomas are more common in smaller breeds or in those with a dark hair coat and/or pigmented mucous membranes, such as Scottish and Boston Terriers, black Cocker Spaniels, Dachshunds, Miniature Poodles, and Chow Chows, but not all studies have found size or breed associations. *The degree of pigmentation of these tumors varies considerably, and many are at least partially amelanotic, but there appears to be no relationship between the amount of pigment and biological behavior.* Metastases are usually pigmented, but in some cases the primary tumor is pigmented and the metastases are not, and vice versa.

Symptomatic lesions usually are about 3 or 4 cm in diameter when discovered. They grow rapidly; necrosis and ulceration are common (Fig. 1.22A), as is invasion of bone by gingival tumors. Over 70% metastasize to the regional lymph nodes. An approximately equal number spread via hematogenous and lymphatic routes to more distant sites, especially the lungs, where they may be evident at necropsy, but too small to be detected radiographically. The median survival time for untreated dogs is reported as 65 days, and survival following treatment is little better, at about 3 months. The median survival time of dogs with no bone, lymph node or distant involvement detected at diagnosis is about 8 months after surgical resection.

The histological appearance of melanomas varies greatly, from a fairly well-differentiated heavily pigmented type, to a highly anaplastic amelanotic type. The diagnosis of the latter is often difficult. However, certain features are evident in most of these tumors. *Anaplastic melanocytes show*

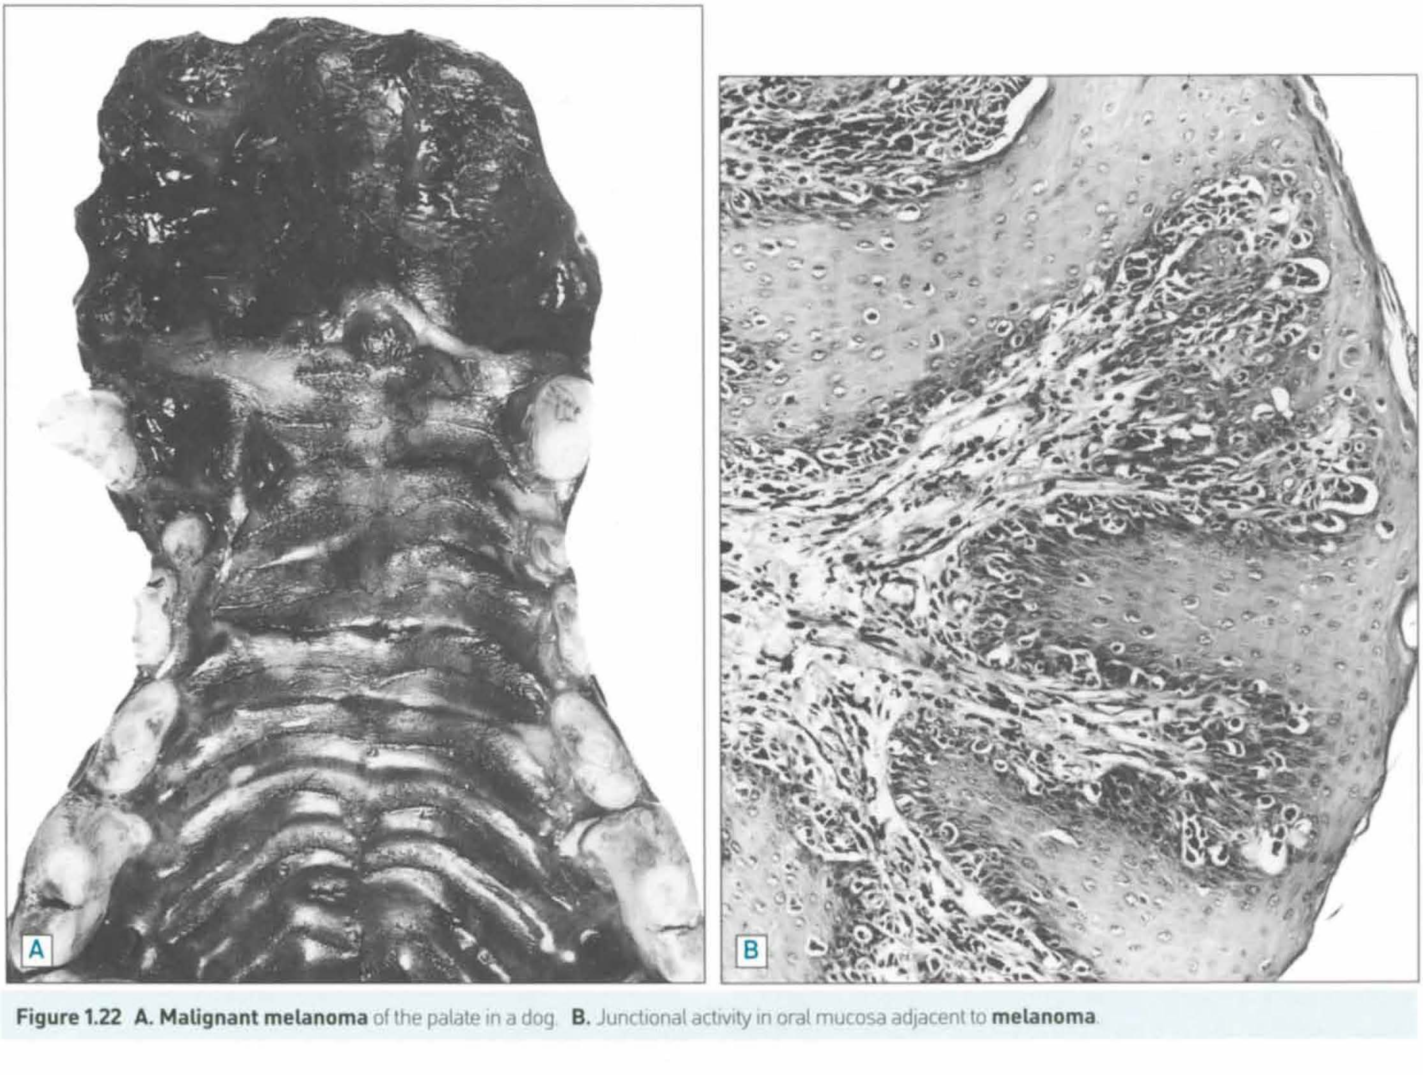

Figure 1.22 A. Malignant melanoma of the palate in a dog. **B.** Junctional activity in oral mucosa adjacent to **melanoma**.

junctional activity, infiltrating the junction between the basilar epithelial cells and the submucosa (Fig. 1.22B). Round or polyhedral cells with a large nucleus and extensive cytoplasm with well-demarcated borders predominate in some tumors. Others are comprised of spindle-shaped cells with oval nuclei containing small nucleoli. Most frequently there is a characteristic mixture of epithelial-like and spindle-shaped cells, which have a marked tendency to form nests supported by a light stroma, extending deep into the submucosa. Multinucleated giant cells may also be present. Osteoid has been reported in the stroma of one canine melanoma. The majority of melanomas have melanin pigment, but detection of this pigment, which may also be concentrated in melanophages, often requires careful examination of individual tumor cells. Cytologic evaluation of melanotic tumors may require bleaching, but any difficulty in interpretation is more likely to involve poorly pigmented variants. They are DOPA-positive (DOPA, 3,4-dihydroxyphenylalanine) in frozen section, and react immunohistochemically (vimentin 100%, melan A >90%). *Melan A is considered sensitive and specific for melanocytes,* differentiating them from melanophages in oral tumors. The mitotic rate and apparent degree of anaplasia may vary throughout the tumor, but since *almost without exception oral melanomas are malignant,* including some that appear benign histologically, all must be considered with suspicion. Prognosis is unrelated to any criterion investigated: demographic; tumor location or mass; pattern or cytologic characteristics.

In **cats**, oropharyngeal malignant melanoma is rare. It occurs in older animals, involves the same regions affected in dogs, resembles the mixed tumor cell phenotype of dogs, and has a short median survival time.

Pigmented basilar epithelial cells are frequently present in superficial areas of the submucosa in a variety of nonneoplastic lesions resulting from irritation to the mucosa. *This so-called "pigmentary incontinence" must be differentiated from malignant melanoma.*

Fibrosarcomas

In **dogs**, fibrosarcoma is the third most common oral malignant tumor, comprising about 15–25% of such lesions, but the most common sarcoma of the oral cavity. It frequently occurs in younger dogs, e.g., one report indicated 25% occurred in dogs less than 5 years of age, and the median age is about 7 years. Larger breeds appear to be predisposed, perhaps especially the Golden Retriever. It occurs mainly on the gums of the maxilla and adjacent palate and the rostral mandible, and less often in the buccal mucosa, lips, and tongue. *Despite a relatively benign histological appearance in large breeds, it grows rapidly, invading maxillary and mandibular bone in the majority of cases, and frequently recurs after surgical removal.* About 20–35% have metastasized to regional nodes, and pulmonary metastases have occurred in about 10–20% at diagnosis.

The tumors are solitary gray to red, firm, irregularly shaped to nodular fleshy masses over about 4 cm in diameter, that may ulcerate and become secondarily infected. They are usually fixed to any underlying bone. Microscopically the submucosa is diffusely infiltrated by densely cellular sheets of pleomorphic fusiform fibroblasts arranged in interwoven bundles with variable, but often relatively small, amounts of collagen. The mitotic index is high in high-grade tumors, and there may be multinucleate giant cells scattered throughout.

In **cats**, this tumor is the second most frequent oropharyngeal malignancy, but it is not common. The gingiva and palate have been reported as sites of predilection by some but others did not observe any specific location. The tumor resembles that in dogs, and invasion of bone is common.

Mast cell tumors

This tumor occurs occasionally in the oral cavity of middle-aged dogs, and, less frequently, in cats. Most commonly they are found on the lip of dogs, but they may arise in the submucosa of the tongue, gum, and hard palate. The tumor is diagnosed using the same criteria as cutaneous mastocytomas, and *all should be considered potentially malignant,* with metastasis to regional lymph nodes a possibility. Mast cell tumor should be considered in the differential diagnosis of oral lesions resembling granulation tissue or eosinophilic granuloma in dogs and cats.

Granular cell tumors

This rare tumor occurs in older (mean age 9 years) **dogs**, mainly in the base of the tongue, but also in the gingiva, lips, and palate. Most granular cell tumors are thought to be derived from neuroectodermal precursor cells. They are elevated, usually less than about 2 cm in size, red, and granular or smooth on the mucosal surface. The cut surface is white and firm. Microscopically, the mass consists of *large, polyhedral to round epithelioid cells that have abundant acidophilic granular cytoplasm.* The cytoplasmic granules are strongly periodic acid–Schiff-positive, and ultrastructurally are *phagolysosomes.* The nuclei are round to oval, centrally or eccentrically located, and have 1–2 nucleoli. Mitotic figures are rare. The tumor cells have a marked tendency to form nests or cords that are separated by a delicate network of reticulin fibers, though some are arranged as sheets of cells. None of these tumors in dogs have recurred after excision, and there is only one record of metastasis, to thoracic organs. There are a few reports of this tumor in the tonsil, tongue, gingival, and palate of **cats**. In **horses**, granular cell tumors are located in the lungs (see Vol. 2, Respiratory system).

Neuroendocrine carcinomas of the oral cavity and pharynx

Neuroendocrine cells of the dispersed neuroendocrine system occur rarely at most levels of the gastrointestinal tract, as well as at other sites, in several mammalian species. In older literature they may be referred to as Merkel cells.

Very rarely, they form tumors of the skin and the oral/nasal pharyngeal mucosa in the dog. In the latter site they tend to be pedunculated, and are located on the gums, lips, and pharynx. *Their behavior is aggressive, with metastasis to local nodes and distant sites,* and local recurrence if margins around the resected tumor are not adequate. Histologically, they consist of well-circumscribed densely packed nests and sheets of polygonal to round cells in the submucosa, resulting in an organoid appearance. The cells have a moderate amount of pale basophilic cytoplasm. The nuclei are pleomorphic, the nuclear membrane is indented, and there are 1–2 centrally located nucleoli. The mitotic index varies from few to 2–3 mitotic figures per high-power field. Multinucleate giant cells are often present. The cells stain negatively with the periodic acid–Schiff stain but have a positive argyrophilic reaction. These are useful features to differentiate this tumor from granular cell tumors. The tumor must also be differentiated from malignant melanoma. Immunohistochemical reactions are usually positive for synaptophysin and neuron-specific enolase, and more variably for chromogranin-A and cytokeratin. Ultrastructurally, the tumor cells contain *cytoplasmic secretory granules characteristic of neuroendocrine cells*.

Plasmacytomas

Extramedullary plasmacytomas are uncommon tumors of the oral mucosa and skin of mainly older dogs (mean age 9–10 years). They arise as primary tumors from plasma cells in the soft tissue, or rarely as metastases from primary osseous myeloma.

This tumor has probably been underdiagnosed in the past, being mistaken for undifferentiated round cell tumor, reticulum cell sarcoma, or a variant of dermal lymphoma. In the oral cavity it has been misdiagnosed as malignant melanoma. Grossly the tumor is a red, lobulated raised mass usually located on the gingiva or lips. It can invade bone, rarely. Plasmacytoma also occurs sporadically in the stomach, colon, and rectum.

Histologically, the tumor is well circumscribed, nonencapsulated, and the overlying mucosa is usually intact, unless it has been traumatized in large tumors. The tumor cells are pleomorphic with variable amounts of amphophilic to basophilic cytoplasm. The nuclei are round to oval and the nuclear membrane is indented. The cells are densely packed into nests and sheets that are divided by scant fibrovascular stroma. Anisokaryosis, bi- and multinucleated cells are frequently present in the center of the tumor, and the most differentiated plasma cells are usually evident at the periphery. The mitotic index varies widely from one tumor to another. Immunoglobulin, especially IgG, can frequently be demonstrated in the neoplastic cells, and AL amyloid is occasionally present among the tumor cells (AL, amyloid immunoglobulin light chain). Electron microscopic examination reveals features typical of plasma cells.

In spite of the anaplastic appearance and the presence of mitotic figures, the biological behavior of these tumors is *benign*, and they are cured by simple resection.

Vascular tumors

Lesions variously considered *vascular hamartomas* or *hemangiomas* have been described in the gums of neonatal **calves**. Hamartomas are focal disorganized overgrowths of mature tissue endogenous to the organ involved. Because of their location, they usually have an inflamed surface, and may resemble, superficially, granulation tissue or pyogenic granuloma. They are pink to red lobulated masses, up to several centimeters in diameter, often pedunculated, on the rostral mandibular gingiva adjacent to the incisors, which may be displaced. They may also be located in the tongue. Microscopically, the tumors consist of irregular thin-walled vascular channels containing erythrocytes or proteinaceous material, and lined by well-differentiated endothelial cells. The vascular spaces are separated by loose fibrous stroma. Vascular hamartomas are benign, but a single hemangiosarcoma in a young calf has been described that involved the palate and gums, as well as distant sites.

Hemangiomas occur rarely in the oral cavity of mature horses, dogs, and cats. Rare hemangiosarcomas have been recorded in the oral cavity of cats and a few dogs, the latter with cutaneous hemangiosarcomas.

Miscellaneous tumors

Various benign and malignant neoplastic and like lesions in the oropharynx have been reported sporadically. In the dog, benign masses include dermoid cysts, histiocytoma, lipoma, lymphangioma, hemangioma, rhabdomyoma, ganglioneuroblastoma, and calcinosis circumscripta (of the tongue). Malignant tumors that have been reported in the oral cavity, mainly in the lip and tongue, are hemangiosarcoma, leiomyosarcoma, histiocytoma, ectopic thyroid carcinoma, hemangiopericytoma, schwannoma, osteosarcoma, rhabdomyosarcoma, and highly malignant undifferentiated tumors.

In cats, benign tumors include hemangioma and fibroxanthoma, and malignant examples are oral and tonsillar lymphosarcoma, schwannoma, and osteosarcoma. Pharyngeal, lingual, and gingival lymphomas have been described in horses.

Salivary tumors are described in the section on salivary glands, below.

SALIVARY GLANDS

Salivary glands are a complex set of secretory structures, present both as large discrete glands in the head and cranial neck region, and as an extensive series of submucosal minor salivary glands in the oral cavity, including the tongue, and in the oropharynx and larynx. Gland structure is variable, depending on whether the gland produces serous or mucous secretion, or both. Common *acute reactions* to injury include hypersecretion, acute necrosis, edema, and inflammation. Gland atrophy, ductular fibrosis and obstruction, and squamous metaplasia may develop following *chronic injury*. A lesion associated with increasing *age* may be oncocytic metaplasia of salivary duct epithelium.

The most common conditions of the salivary glands are functional, *ptyalism* being an increased secretion of saliva and *aptyalism* being a reduced or ceased secretion. Ptyalism (to be differentiated from failure to swallow) is seen as abnormal accumulation of saliva in the mouth. It occurs in a variety of conditions, including heavy-metal poisoning, poisoning with organophosphates, encephalitis, and, most often, stomatitis. Decreased secretion of saliva is less common, but accompanies fever, dehydration, and salivary gland disease.

Ptyalism in cattle and horses may be an expression of a mycotoxicosis. *Rhizoctonia leguminicola* infestation of legumes is associated with "slobbers syndrome." On well-cured legume hay, the mycelial growth is not visible grossly. The fungus has a wide geographical distribution. *Rhizoctonia leguminicola* produces two biologically active alkaloids, *slaframine* and *swainsonine*. Slaframine, a parasympathomimetic alkaloid, induces excessive salivation, as well as anorexia, excessive lacrimation, diarrhea, frequent urination, and bloat. Milk production is reduced and there is loss of body weight. No specific lesions have been associated with slaframine toxicosis. Guinea pigs are extremely sensitive to the toxin. Presumptive diagnosis may be based on feeding trials in that species, if chromatographic analysis for slaframine is not readily accessible.

Ptyalism may be associated with *neurointoxication*, particularly those agents that affect the trigeminal nuclei. Known causes include ingestion of *Paspalum destichium* and *Prosopis glandulosa* (honey mesquite), poisoning with cholinergic stimulants, neurotropic viruses especially *Rabies virus*, and in dogs exposure to the toad *Bufo marinus* will cause neurologic abnormalities and ptyalism.

Foreign bodies are occasionally present in the ducts, usually the parotid duct, but sometimes the submaxillary. They are usually plant awns or fiber. They invariably cause some degree of inflammation with secondary infection; if the duct epithelium is destroyed, local cellulitis occurs. **Salivary calculi** (*sialoliths*) may also cause obstruction and inflammation. They are more common in horses than other species. Calculi are composed largely of calcium carbonate, and are white, hard, and laminated. They are thought to originate from microliths, which are formed routinely and undergo regular turnover. Secretory inactivity can cause microliths to accumulate more material, leading to calculi that may be obstructive. Calculi are usually single and cylindrical, and they may be quite large. Most of them lodge at the orifice and cause some degree of salivary retention, glandular atrophy, and predisposition to infection and further inflammation.

Dilations of the duct are due to stagnation of flow, and this in turn results from obstruction due to congenital atresia or by foreign bodies, calculi, and inflammatory strictures. The dilated ducts appear as fluctuating cords, sometimes with local diverticula. **Ranula** *is the term* *applied to a cystic distension of the duct in the floor of the mouth.* These present a smooth rounded prominence with a blue tinge and fluctuations, and the lining epithelium is more or less intact. The contents may be serous or thick tenacious mucus. Rupture of a duct or a gland to an epithelial surface results in a permanent fistula as the continued flow of saliva prevents normal restoration, the duct epithelium fusing with that of the surface.

Salivary mucocele or sialocele *is an accumulation of salivary secretions in single or multiloculated cavities in the soft tissues of the mouth or neck.* These cystic formations do not have an epithelial lining. Sialoceles can occur in dogs of any breed, where they may become large enough to require surgery. There may be a history of an antecedent ranula-like swelling in the mouth. Many sialoceles are probably the result of trauma to the duct. They may be located anywhere from the mandibular symphysis to the middle of the neck, the latter due to gravitational displacement. Most are ventrolateral, sometimes bilateral or midline, at the angle of the mandible. They arise most commonly from the sublingual salivary gland, either from individual units of the polystomatic portion or from the duct of the monostomatic portion. Zygomatic salivary mucoceles also occur, associated with local swelling and exophthalmos. Most sialoceles are subcutaneous and may be up to 10 cm in diameter, the larger ones being pendulous. The wall is of soft pliable connective tissue, well vascularized, with a glistening lining. The contents are brown and mucinous, becoming progressively inspissated and tenacious with time.

Small sialoceles, seldom exceeding 0.5 cm in size, are occasionally observed on the side of the bovine tongue. They presumably originate from rupture of the fine tortuous ducts of the dorsal part of the sublingual gland.

The histological appearance of sialoceles varies greatly, apparently depending on the stage of development. Initially, the wall consists of an outer, highly vascularized layer of immature connective tissue and an inner zone of loosely arranged fibroblasts. A pleocellular inflammatory reaction, which may be very mild, is evident in the central area, which also contains much amorphous amphophilic material. More mature fibrous connective tissue forms the wall in later stages when inflammation is mainly mononuclear, and plasma cells often predominate, and the material in the center becomes progressively more basophilic.

Cysts of other origins do occur in this region. Cysts of the **thyroglossal duct** are midline and readily distinguishable when they contain thyroid follicles. Cystic salivary adenomas are rare. **Branchial pouch cysts** may be located ventrolaterally, as are the salivary cysts, or dorsolateral on the neck. Their distinction is probably valid when no demonstrable connection occurs with a salivary duct and a pseudostratified or stratified squamous or columnar lining epithelium is present.

Sialoadenitis, *inflammation of the salivary glands,* is uncommon in animals, but it is, after sialoceles and malignant neoplasms, the most frequently diagnosed lesion involving salivary glands of dogs and cats. The submandibular gland is usually affected. Inflammation of the zygomatic gland in dogs is a cause of retrobulbar abscess. The infection usually gains entrance via the excretory duct, although it may be hematogenous or locally traumatic. Inflammation of the duct results in its obstruction by exudate, desquamated epithelial cells, and mucus. Some of this may be expressed from the ductal orifice as pus; the orifice is usually acutely inflamed. Obstruction of the duct, whether partial or complete, produces secondary atrophic changes in the glands, although there is initial enlargement due to the combined effects of retained secretion and inflammation. The ducts throughout the gland dilate and leukocytes infiltrate the lumen and stroma. The acini undergo compression atrophy or swell and rupture from retained secretion. In acute infections this often leads to suppuration, and in chronic ones only remnants of atrophic epithelium remain in a mass of inflamed scar tissue.

Specific inflammations of the salivary glands in domestic animals are unusual. Examples include rabies, where there is often focal lysis of acinar cells, mononuclear infiltration and, uncommonly, Negri bodies in the ganglionic neurons; strangles in horses; and distemper in dogs. *Eosinophilic sialoadenitis* is found in an eosinophilic epitheliotropic syndrome in horses discussed in the section on Eosinophilic enteritis in cats and horses, below. *Sjögren's-like syndrome* has been diagnosed in cats and dogs, with plasmacytic infiltrates in the salivary glands. Sialoadenitis occurs in **vitamin A deficiency** in calves and pigs and in cattle poisoned with highly chlorinated naphthalenes. In these conditions, inflammation, often purulent, is secondary to squamous metaplasia of the ducts, with stasis of flow and secondary infection; *squamous metaplasia of interlobular ducts is an early and rather specific lesion of vitamin A deficiency.*

Necrotizing sialometaplasia is a distinct, rare disease of dogs and humans, characterized by ischemic necrosis of salivary gland lobules with inflammation and squamous metaplasia of the ducts. The underlying reason is thought to be vascular compromise induced by trauma, although immune-mediated destruction of blood vessels or infection have also been hypothesized. In dogs, the disease is seen in a number of small breeds, primarily terriers. The mandibular gland is affected preferentially. Dogs with this condition are presented in extreme pain, with enlarged hard salivary glands and with recurrent vomition. The reasons for vomition are unclear; however it may be centrally mediated, as administration of anticonvulsants is effective in controlling this clinical sign.

Neoplasms of salivary glands

Neoplasms of the salivary glands are rare in all species; they have been reported in cattle, sheep, goats, horses, dogs, and cats, but apparently not in swine. Only in dogs and cats do salivary tumors occur often enough to permit generalization. They may arise from either the major or the minor salivary glands, involvement of the major glands being three times as frequent; the parotid and mandibular are the most susceptible. The tumors develop almost exclusively in aged animals; the majority are epithelial, malignant at diagnosis, grow rapidly, and become fixed to the overlying skin. Signs are related to swelling, pain, halitosis, dysphagia, and exophthalmia. Metastasis to regional nodes and distant sites, especially the lungs, is common.

Salivary tumors express the phenotype of ductular or glandular epithelium, either because they arise in these structures, or because they derive from pluripotential stem cells. Duct neoplasms are generally papillomatous if benign, and squamous or mucoepidermoid carcinomas if malignant. Tumors with glandular phenotype are usually adenomatous, their malignant potential sometimes only manifest by carcinomatous areas at the periphery of the neoplasm (Fig. 1.23).

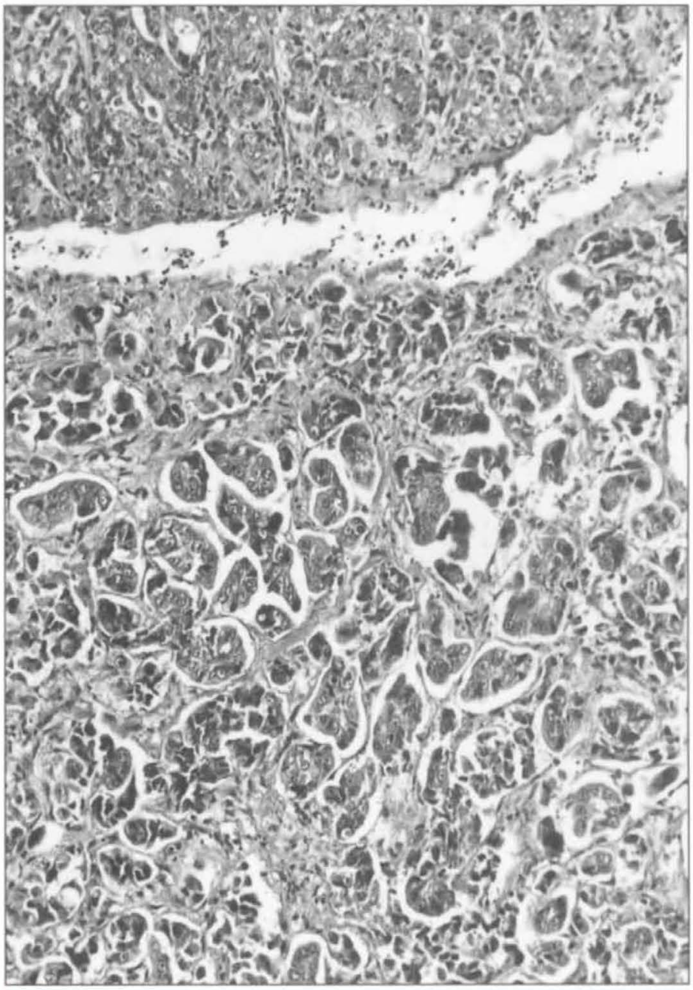

Figure 1.23 Salivary adenocarcinoma of glandular origin in a cat.

The histological structure of salivary tumors in animals is as diverse as in humans and the accepted classifications apply. However, the phenotype of salivary tumors has little bearing on prognosis, with the exception of acinic cell tumors, which are less aggressive, and pleomorphic adenomas, which are benign with potential for malignant transformation. Adenocarcinomas that have metastasized to the nodes or beyond at diagnosis have a worse prognosis than those with tumor localized to the gland. In one study, adenocarcinomas in cats seemed more aggressive than those in dogs.

The most frequent variety in dogs is *adenocarcinoma*, and although there are various structural patterns, sometimes within the same tumor, an acinar or nested arrangement is usually evident somewhere, embedded in an often extensive fibrous stroma. Some adopt a mucoepidermoid pattern, containing squamous epidermoid cells, mucus-producing cells, and intermediate phenotypes, which may line cysts, sometimes in a papilliform pattern. The rupture of such cysts initiates a granulomatous response, including giant cells. Salivary carcinomas infiltrate locally at the periphery, and metastasize via lymphatic and vascular invasion.

Acinic cell carcinomas are less common than adenocarcinomas, occurring mainly in dogs and sporadically in the cat, horse, and sheep. They are at least partially encapsulated masses with potentially infiltrative margins, composed of usually well-differentiated epithelial cells with a low mitotic index, that form a pronounced acinar pattern, or resemble cells of the intercalated duct, including clear cells. The presence of cells of normal acinar salivary epithelial phenotype is an essential criterion for diagnosis of this tumor. They are locally invasive; metastases to the regional nodes are rare.

Pleomorphic adenomas, or mixed tumors, have been described, rarely, in the dog, cat, bovine, and horse. They are similar to the comparable mammary tumors, with areas of myoepithelial cells embedded in a mucinous matrix that also contains neoplastic epithelial cells. Bone and cartilage form in these areas. These tumors grow by expansion, and may develop malignant foci, usually carcinomatous rather than carcinosarcomatous.

Rarely, mesenchymal malignancies, including fibrous histiocytoma, osteosarcoma, and fibrosarcoma, appear to arise in the salivary glands.

ESOPHAGUS

The esophagus is comprised of an inner circular layer and an outer longitudinal layer of skeletal muscle for much or all of its length. In the pig, there is a short segment near the cardia that is comprised of smooth muscle, and in horses and cats, smooth muscle is found in the distal third of the esophagus. The esophagus is lined by a stratified squamous mucosa, with a variable number of submucosal mucous glands, depending on the species and location along the esophagus. Esophageal protection against aggressive insults resides mainly in mucus and bicarbonate in salivary secretion and is produced by esophageal submucosal glands.

The esophagus merits particular attention during the examination of animals with inadequate growth rate, cachexia, ptyalism, dysphagia, regurgitation, vomition, and aspiration pneumonia. In the ruminant, tympany may be a sequel to esophageal disease. The presence of a "*bloat line*" in the esophagus at the thoracic inlet may indicate a condition causing increased intra-abdominal pressure such as gastric dilation or ruminal tympany. The squamous mucosa is frequently eroded or ulcerated in viral diseases that cause similar lesions elsewhere in the upper alimentary tract. Conditions of striated muscle, such as nutritional myodegeneration and eosinophilic myositis in the ruminant, or polymyositis, systemic lupus erythematosus, and trypanosomiasis in the dog, will involve the esophageal muscle. Envenomation following snake bite may lead to myopathy of the esophageal musculature in dogs. Diseases of the neuromuscular junction, as in myasthenia gravis, and peripheral neuropathies, such as giant axonal neuropathy and polyneuritis, will result in esophageal disease.

Anomalies, epithelial metaplasia, and similar lesions

The mucosa of the distal portion of the feline esophagus normally has a herringbone pattern of superficial folds. **Hypertrophy of the smooth muscle** of the distal esophagus, most commonly the circular layer, occurs in horses. It is usually found incidentally at autopsy, although some cases also have concurrent terminal ileal muscular hypertrophy. Speculatively, defects in the pacemaker cells normally found in smooth muscle at these sites may be the basis for these lesions.

Congenital anomalies of the esophagus are very rarely recorded in domestic animals, and their interpretation as such can be difficult, since similar defects may develop as sequelae of esophageal trauma or inflammation.

Congenital duplication of the esophagus is rare in domestic animals. It may result in a cystic mass, usually in the vicinity of the esophagus, lined by variably columnar to squamous epithelium, and with a double muscle layer in the wall; such cysts may become manifest as space-occupying lesions as they fill with cellular debris and secretion. Tubular duplications of the esophagus are usually clinically silent; they are contiguous with the wall of the true esophagus, with which they communicate.

Rare **segmental aplasia** of the proximal esophagus may be apparent in the neonate. A short blind pouch communicates with the pharynx, and a thin fibrous band connects it to the distal patent esophagus which follows a normal course to the stomach. Esophageal atresia and congenital esophagorespiratory communications result from anomalies occurring when the respiratory primordium buds from the embryonic foregut.

Esophagorespiratory fistulae without esophageal atresia are more commonly recognized in animals; in calves and dogs strong circumstantial evidence suggests that some of these are congenital. Short fibrous bands with a narrow mucosa-lined lumen, connecting an esophagus of normal diameter with the trachea or bronchus, are reported, as are small apertures connecting the lining of esophageal diverticula with the respiratory tree. The lining of such defects changes from stratified squamous to columnar respiratory epithelium in the fistula or wall of the diverticulum. Gastric distension by air in calves, and pneumonia due to aspiration, have been associated with esophagorespiratory fistulae.

Esophageal diverticula are irregular outpouchings or herniations of the esophageal mucosa through the muscularis. They communicate with the esophagus by variously sized, often slit-like, apertures. Most are probably acquired, and they are commonest in the lower cervical esophagus, or in the distal thoracic esophagus, just cranial to the diaphragm. Increased intraluminal pressure, associated with foreign bodies, obstruction or stenosis, is considered the cause of "*pulsion*" *diverticula*, in which the mucosa is forced out through the distended or ruptured muscularis. Such diverticula may be large spherical structures, with a narrow neck. They are most common in the horse and dog. The rare "*traction*" *diverticulum* is the result of contraction of a paraesophageal fibrous adhesion, following perforation and inflammation, drawing with it a pouch of esophageal mucosa that is usually small and inconsequential. In contrast to pulsion diverticula, which have a layer of epithelium lining the inner aspect of a wall of fibrous connective tissue, traction diverticula have a wall comprised of all layers of the esophagus. Ingesta and foreign bodies may accumulate in diverticula, causing gradual enlargement, with the potential for local esophagitis, ulceration, and perforation or formation of a fistula.

Rare *anomalies* of the mucosa include epithelial inclusion cysts, the presence of papillae resembling those of the rumen in the distal esophagus of cattle, and gastric heterotopia.

Hyperkeratosis and thickening of the epithelium may be signs of vitamin A deficiency, common in birds and also seen in herbivores, or with chlorinated naphthalene toxicity. Squamous metaplasia in the ducts of submucosal esophageal mucous glands, and in ducts and glands elsewhere, should be sought. Mild hyperkeratosis may be difficult to assess since in herbivores some degree of keratinization may be normal, and anorexia or failure to swallow results in loss of the abrasive effect of food passage, with accumulation of keratinized squames. Parakeratotic thickening and basal hyperplasia of the epithelium should be considered indicative of response to epithelial injury, and in the distal esophagus of pigs is a concomitant of ulceration of the pars esophagea of the stomach. Hyperkeratosis and thickening of the epithelium leading to raised striations in the distal esophageal mucosa occur following repetitive injury through reflux of gastric acid, usually accompanied by linear erosions. Parakeratosis of the esophagus occurs in pigs with cutaneous parakeratosis caused by zinc deficiency.

Esophagitis

Erosive and ulcerative esophagitis is a common finding associated with viral diseases causing similar lesions in the oropharynx or reticulorumen. Bovine viral diarrhea, rinderpest, bovine papular stomatitis, infectious bovine rhinotracheitis, and calicivirus in cats may produce necrotizing esophageal lesions. Healing esophageal ulcers repair by granulation. Local epithelial proliferation and thickening produce an opaque pearly appearance of the margin of the lesion or surface of the scar.

Caustic or irritant chemicals, ionizing radiation, electrochemical reactions, and hot ingesta may cause mucosal injury, the severity of which depends on the nature of the insult and duration of exposure. Mild acute insult may result in diffuse or local reddening of the mucosa. Deep sloughing of the mucosa, liquefactive necrosis associated with alkalis, and coagulative necrosis following acid and toxins (paraquat, oak toxicosis) reflect more severe insult and may result in ulceration extending to deeper layers of the esophagus.

Superficial epithelial damage heals uneventfully, though repeated insult may cause thickening of the epithelium with the development of prominent rete pegs. Ulcerated mucosa will granulate, and raised islands of surviving pearly proliferative epithelium may be present over the surface. The inflammatory reaction in ulceration frequently involves muscularis and adventitia. The ultimate development of a contracted fibrous scar causes stricture or stenosis, if the original mucosal defect involved a significant portion of the esophageal circumference.

Reflux esophagitis results from the action on the esophageal mucosa of gastric acid, pepsin, probably regurgitated bile salts, and possibly pancreatic enzymes (Fig. 1.24A). Stratified squamous epithelium appears more susceptible to the corrosive effects of gastric secretion than other types of mucosa in the lower gastrointestinal tract. Relatively short duration of exposure to refluxed gastric content

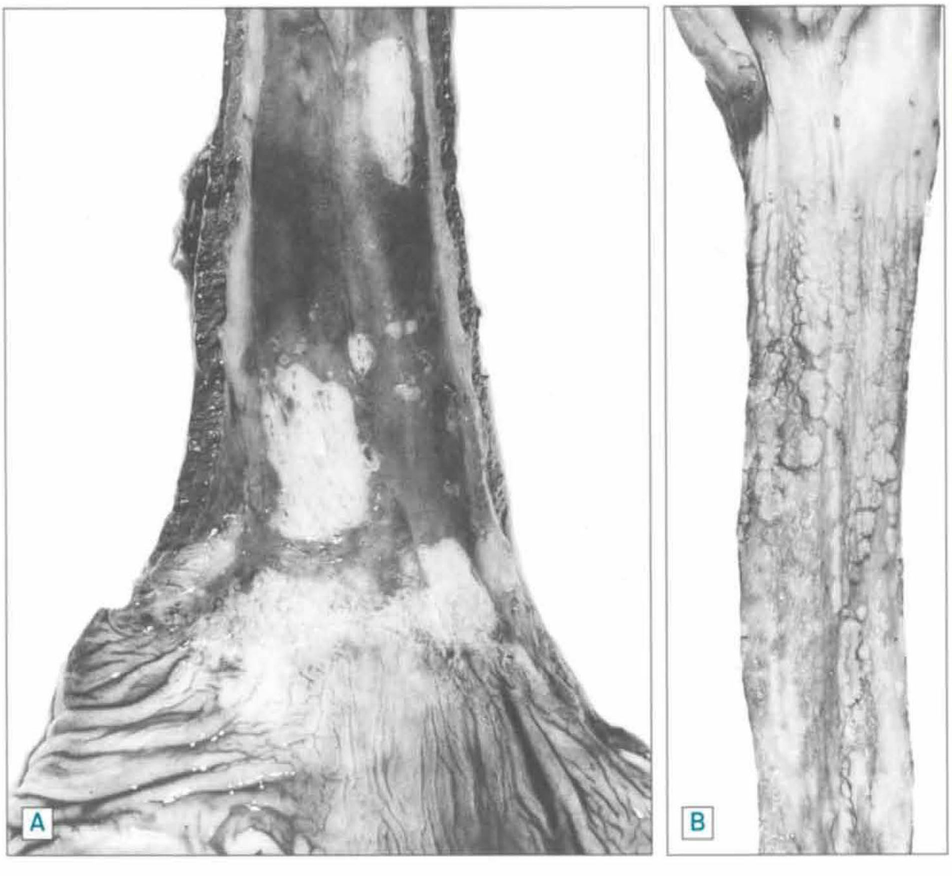

Figure 1.24 A. Reflux esophagitis following chronic vomition in a dog. Islands of squamous epithelium remain surrounded by ulcerated mucosa. **B. Reflux esophagitis** in a pig, secondary to esophagogastric ulceration.

is required to induce epithelial damage, which is signaled by hyperemia or linear erosions and ulcers, perhaps with superficial fibrinonecrotic debris, and erythematous margins. Such damage is most common in the distal esophagus, but may extend well forward, in some instances nearly to the pharynx. The expected microscopic basal epithelial activation, rete peg elongation, and epithelial transmigration by neutrophils occur in response to mild superficial epithelial necrosis. A thinned epithelium following recent moderate insult, or granulation of an ulcerated surface, may be evident. Re-epithelialization with a columnar mucous cell type may occur in distal esophagus adjacent to the cardia. *Papillomatous esophagitis* of unknown etiology has been reported in the distal esophagus of the cat, which normally has a somewhat corrugated or herringbone pattern to the mucosa.

Functional integrity of the lower esophageal sphincter may be compromised or overwhelmed by airway occlusion and increased intra-abdominal pressure, the pharmacologic effects of preanesthetic agents, or abnormality of the hiatus. Reflux esophagitis is thus most common in dogs and cats as a sequel to surgery involving general anesthesia, though it may follow chronic gastric regurgitation or vomition for any cause. In swine and horses, it may be associated with ulceration of the squamous esophageal portion of the stomach (Fig. 1.24B). In dogs, it is associated with rare hiatus herniation.

Hiatus hernia usually involves sliding herniation of all or part of the abdominal esophagus, cardia, and stomach into the thoracic esophagus, rather than periesophageal herniation. It is generally self-reducing, and its effect is usually lower esophageal sphincter failure and reflux, rather than gastric herniation and obstruction. *Gastroesophageal intussusception* is a rare event, most reported in puppies of large breeds of dogs, and is associated with recurrent vomition that may lead to aspiration pneumonia.

Thrush, or mycotic esophagitis caused by *Candida albicans*, is seen in piglets and weaner swine, where the lesions may involve squamous mucosa of the entire upper alimentary canal. The condition is probably secondary to other intercurrent problems, including antibiotic therapy, inanition, and esophageal gastric reflux, and is considered more fully in the section on Mycotic diseases of the gastrointestinal tract, below. Similarly, secondary *phycomycotic* granulomatous involvement of the esophagus is a rarely recorded complication of debilitating systemic disease states and heavy use of glucocorticoids and antibiotics.

Esophageal obstruction, stenosis, and perforation

"*Choke*," obstruction, or impaction of the esophagus occurs when large or inadequately chewed and lubricated foods, masses of grain or fibrous ingesta, or medically administered boluses, lodge in the lumen of the esophagus (Fig. 1.25). This often occurs where the esophagus deviates or is slightly restricted normally, at the area over the larynx, the thoracic inlet, the base of the heart, and immediately cranial to the diaphragmatic hiatus.

Complications of obstruction include *pressure necrosis and ulceration of the mucosa*, which may progress to perforation. Sharp objects, such as bones, are most liable to cause *perforation*. Usually fatal cellulitis of the periesophageal tissue ensues, which may involve the

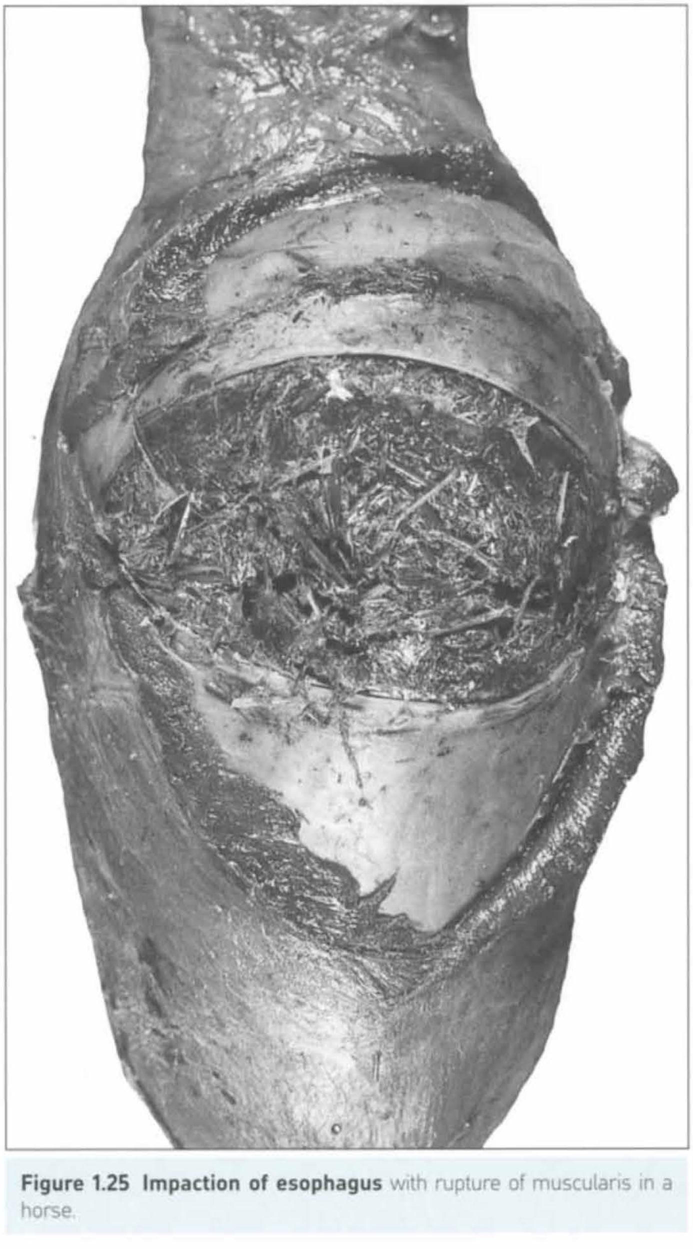

Figure 1.25 Impaction of esophagus with rupture of muscularis in a horse.

mediastinum directly, or by extension along fascial planes from the cervical region, depending on the site of perforation. Alternatively, perforation of the thoracic esophagus may lead to pleuritis.

Sharp objects, such as needles, quills, grass seeds, and awns, may penetrate and track from the esophagus through adjacent tissues. Diverticula, and esophagorespiratory or esophagoaortic fistulae, may also ensue following obstruction by foreign bodies.

Removal or dissolution of an obstructing object may be followed by *scarring* of the segmentally ulcerated esophagus, resulting in narrowing of the lumen, stricture, or stenosis. Esophagitis, especially due to gastric reflux, may have a similar sequel. Although hypertrophy of internal and external muscle layers is seen occasionally in the distal esophagus of cattle and horses (in which species the distal esophageal muscle is normally relatively thick), it is usually not clearly the result of obstruction.

Stenosis may also result from rare intramural or intraluminal neoplasia, or commonly by external compression. Among causes of external compression may be enlarged hyperplastic or neoplastic thyroids, and neoplasia of the thymus and of cervical and mediastinal lymph nodes.

"Vascular ring" anomalies, seen in dogs, occasionally in cats, and rarely in other species, are the most common causes of external constriction of the esophagus. *Dextroposition of the aorta*, the development of the aortic arch from the right, instead of the left, fourth arch, is the most common of these anomalies. This results in entrapment and constriction of the esophagus between the heart and pulmonary artery ventrally, with the anomalous aortic arch on the right, and the ligamentum arteriosum or remnant of the ductus arteriosus dorsally on the left. *Other vascular anomalies* that may constrict the esophagus, and reported only in the dog, are persistence of both right and left aortic arches; persistent right ductus arteriosus; aberrant left subclavian artery, in association with persistent right aortic arch; and aberrant right subclavian artery arising distal to the left subclavian artery, and passing dorsally over the esophagus. The Irish Setter, German Shepherd, and Boston Terrier are the breeds most commonly afflicted with vascular ring anomalies.

Esophageal deviation and stenosis have been associated in English Bulldogs with "thoracic shortening" due to hemivertebra and esophageal compression between the left subclavian artery and the brachiocephalic artery. The site of stricture, with its narrowed esophageal lumen, is readily identified at necropsy.

Constricting mural fibrosis or other causative internal or external obstructive lesions will be obvious. The mucosa at the site of stricture may be ulcerated, as the result of impaction of ingesta, or as a sequel to antecedent esophagitis, pressure necrosis, or neoplasia. The esophagus proximal to the stenotic area is dilated, may contain retained ingesta, and itself may have evidence of esophagitis.

Dysphagia

Swallowing is a complex and highly coordinated physical act, which may be conveniently divided into three phases – oral, pharyngeal, and esophageal. **Oral-phase dysphagias** are the product of painful physical lesions of the oral cavity and tongue, such as stomatitis, glossitis, gingivitis, or lesions such as hyoid damage that limit movement of the tongue or delivery of the bolus to the pharynx. Loss of hypoglossal nerve function associated with hydrocephalus, trauma, or myasthenia gravis impairs lingual function. Cleft palate results in nasal regurgitation at this phase.

Pharyngeal dysphagia may be associated with painful pharyngitis, tonsillitis, retropharyngeal abscesses, and granulomas. Abscesses, granulomas, and neoplastic processes involving the tonsils and regional lymph nodes may physically intrude on the pharyngeal space. Encephalitis involving the medulla oblongata and the nuclei or tracts of the major cranial nerves involved in pharyngeal contraction and lingual function (V, IX, X, XII) should be sought in pharyngeal dysphagia, unexplained on physical grounds. Rabies and brain abscess in all species, infectious bovine rhinotracheitis and listeriosis in ruminants, are candidate central causes of pharyngeal paralysis. Retropharyngeal abscesses and lesions of the equine guttural pouch may cause peripheral nerve damage and paralysis. Idiopathic myodegeneration and myasthenia gravis have been reported as causes of impaired pharyngeal muscle function. Dysphagia is reported in Bouviers in association with muscular dystrophy.

Cricoesophageal incoordination, or **achalasia** (failure to relax), may impede the first stage of the esophageal phase of swallowing – the opening of the upper esophageal sphincter to accept the approaching bolus. This condition is recognized in dogs. The underlying deficit is unknown but may be muscular as removal of part of the cricopharyngeal muscle is curative.

Megaesophagus, or *esophageal ectasia*, is the result of atony of the esophageal muscle, flaccidity, and luminal dilation (Fig. 1.26). This is the product of segmental or diffuse motor dysfunction of the body of the esophagus. This results in failure of peristaltic propulsion of the food bolus to, and through, the lower esophageal sphincter to the stomach. Ingesta accumulates in the esophageal lumen, with eventual regurgitation of undigested food. Retention of some ingesta in the esophagus may lead to putrefaction and esophagitis in dilated or dependent areas. The volume of the dilated thoracic and cervical esophagus may greatly exceed that of the stomach, and the intrathoracic trachea and heart may be displaced ventrally. Animals with esophageal hypomotility or megaesophagus may have signs of marked malnutrition, including emaciation, dehydration, and osteopenia, often in association with rhinitis and aspiration pneumonia resulting from regurgitation.

Congenital idiopathic megaesophagus (CIM) is relatively common in dogs; it may improve functionally to some extent with time. CIM has its highest prevalence in Great Danes, German Shepherds, and Irish Setters, and appears to be *heritable*, with a pattern in Miniature Schnauzers compatible with a simple autosomal

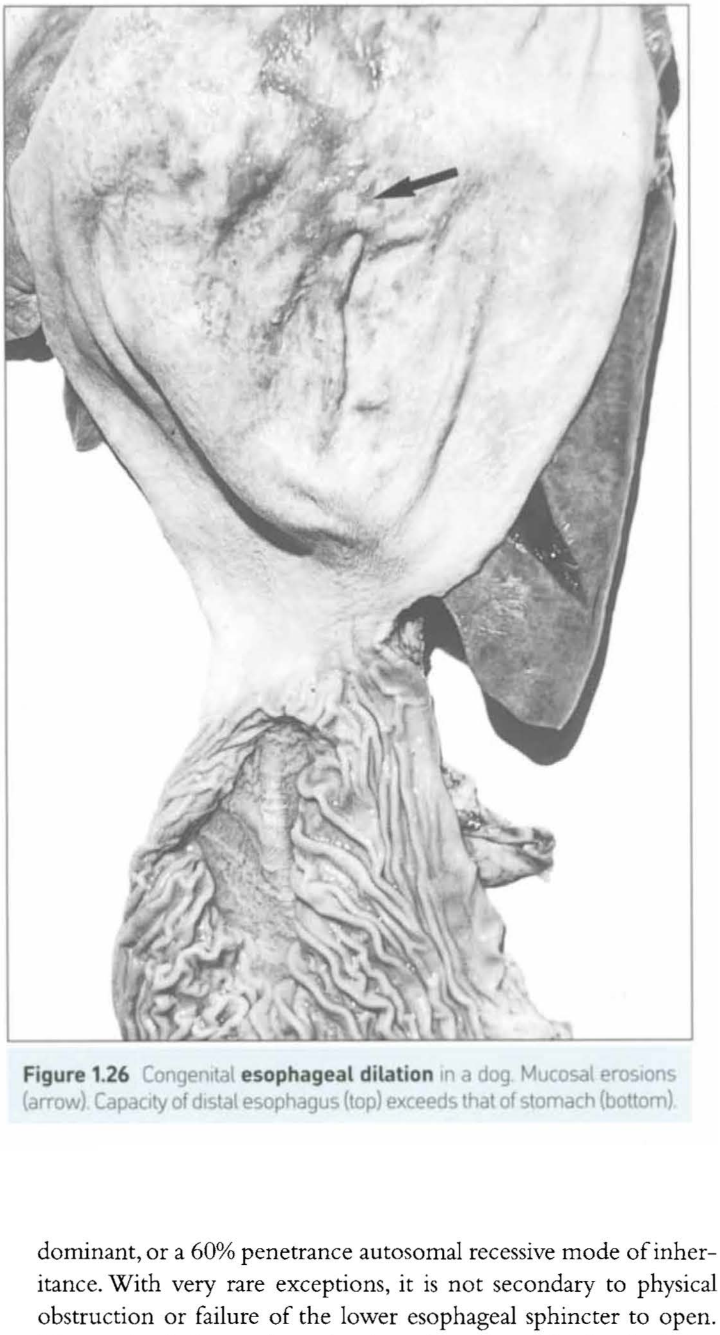

Figure 1.26 Congenital **esophageal dilation** in a dog. Mucosal erosions (arrow). Capacity of distal esophagus (top) exceeds that of stomach (bottom).

dominant, or a 60% penetrance autosomal recessive mode of inheritance. With very rare exceptions, it is not secondary to physical obstruction or failure of the lower esophageal sphincter to open. Motor stimulation to the striated esophageal muscle, despite being carried in the vagus, is not autonomic, and seems intact. There is strong evidence that CIM results from a selective defect in the distension-sensitive afferent autonomic arm of the reflex that coordinates esophageal function.

Most cases of idiopathic megaesophagus in dogs are not comparable to **esophageal achalasia** (failure of the gastroesophageal sphincter to relax) in humans. One case of true esophageal achalasia without esophageal motility disorder has been reported in a dog.

Idiopathic megaesophagus may also develop in *mature dogs*, in which, in some studies, the majority of cases of megaesophagus are reported to occur. In addition, megaesophagus may be acquired secondary to glycogen storage disease in Lapland dogs, myasthenia gravis, administration of cholinesterase inhibitors, hypoadrenocorticism, canine giant axonal neuropathy, immune-mediated polymyositis, polyradiculoneuritis, canine distemper, systemic lupus erythematosus, lead poisoning, Chagas disease, and snake envenomation.

Megaesophagus in the **cat** may be congenital, with signs appearing about weaning, and it seems most common in the Siamese breed. The pathogenesis is unclear. Neuronal degeneration or neurogenic atrophy of muscle is not recognized in the esophageal wall. Megaesophagus in cats has also been associated with functional pyloric stenosis, hiatus hernia, and lead poisoning.

Several **foals** have been reported with esophageal dilation or ectasia, apparently congenital. Dilation of the proximal portion, with a normal or thickened distal thoracic esophagus, was found in two cases. Examination of the wall, which is smooth muscle in the distal half, revealed equivocal muscle abnormalities, and no anomalies of the autonomic ganglia in those animals. However, aganglionosis has been implicated in megaesophagus in a third case. Megaesophagus may also be acquired in foals with ulceration and fibrosis of the cardia and lower esophagus, associated with ulceration of the pars esophagea of the stomach.

Acquired megaesophagus in **cattle** has been associated with hiatus hernia, and with pharyngeal trauma presumably causing vagus nerve damage. Segmental megaesophagus is reported in the cervical region, in one case associated with marked fatty replacement of esophageal myofibers. Megaesophagus is rarely reported in small ruminants.

Parasitic diseases of the esophagus

Sarcosporidiosis occurs in the striated esophageal muscle of sheep. Esophageal sarcocysts appear as ovoid white thin-walled nodules ~1 cm long projecting from the esophageal muscle. *Sarcocystis gigantea*, the species producing large esophageal cysts and similar large cysts in skeletal muscle, is spread by cats. Microscopic sarcocysts of other species may also be encountered in esophageal striated muscle of a variety of hosts (see section on protistan infections, below, and Vol. 1, Muscle and tendon). Sarcocysts in esophageal muscle normally incite little or no local inflammatory reaction and are only of significance in meat inspection. However, lesions of *eosinophilic myositis*, possibly associated with rupture of cysts, are found in the esophageal muscle, and megaesophagus has been reported in a sheep with esophageal myositis associated with sarcocysts.

Larvae of ***Gasterophilus*** spp. may be temporarily attached to the caudal pharyngeal and cranial esophageal mucosa, and to the mucosa cranial to the cardia, in horses. Insignificant focal ulceration may occur at the sites of attachment.

The larvae of the warble fly ***Hypoderma lineatum*** reside for some time in the submucosa or adventitia of the bovine esophagus before they migrate to the dermis of the back. The easily overlooked translucent larvae may be only 2–4 mm long, but instigate local hemorrhage and neutrophil infiltration. *Hypoderma* assume significance in a small proportion of animals treated with systemic organophosphate insecticides while larvae reside in the esophageal wall. Acute inflammation, probably an allergic response to products of dead larvae, develops in the esophageal submucosa. This leads to swelling, hemorrhage, and necrosis, causing fatal esophageal obstruction, tympany, and esophageal perforation.

Spirurid nematodes of the genus ***Gongylonema*** may be encountered in the stratified squamous mucosa of the upper alimentary tract, including the esophagus, in ruminants and swine. These white threadlike worms up to 10–15 cm long burrow in the epithelium, and occasionally the propria, of the esophageal wall. They usually produce white or red blood-filled zigzag tracks in the mucosa (Fig. 1.27). Their presence is inconsequential to the host.

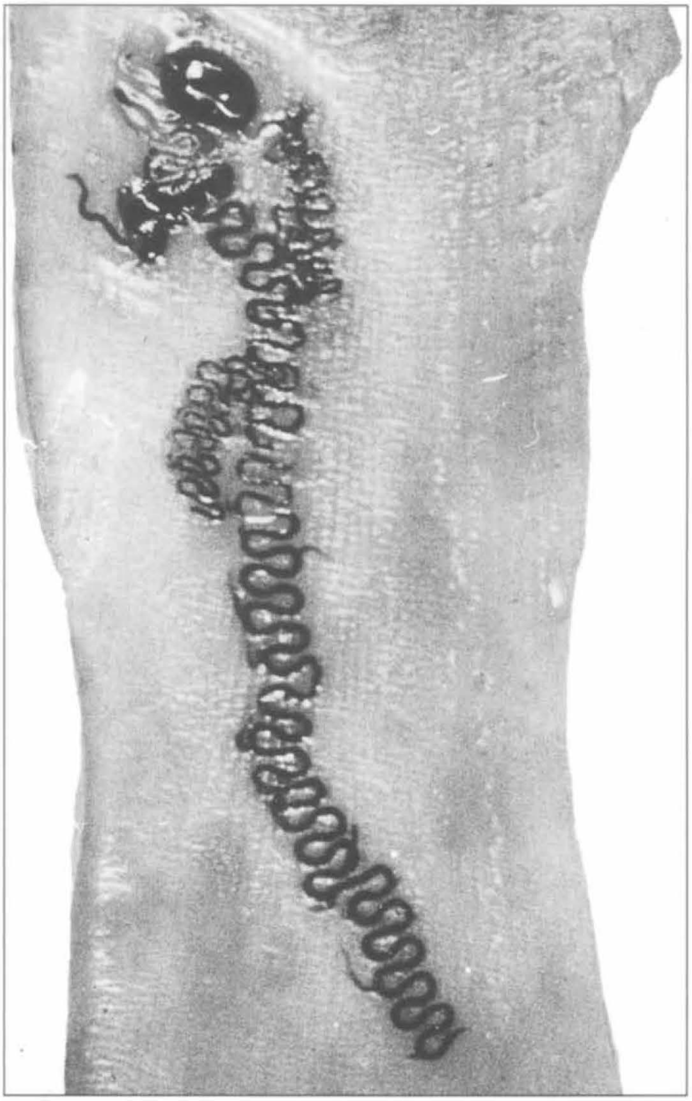

Figure 1.27 Blood-filled tracks and small hematoma in esophageal mucosa caused by ***Gongylonema pulchrum*** migration in a cow.

Spirocerca lupi is a spirurid nematode that parasitizes the esophageal wall of Canidae and some other carnivores. It is most common in warm climates where appropriate species of dung beetles act as intermediate hosts, and where the opportunity for dogs to obtain access to larvae in vertebrate transport hosts is high. The normal site for the adult nematode is in large, thick-walled cystic granulomas in the submucosa of the distal portion of the esophagus or gastric cardia, where one or more pink worms, surrounded by purulent exudate, are found. A fistula leading to the esophageal lumen is usually present, through which the tail of the female worm may protrude, and which provides the outlet for ova to the gastrointestinal tract (Fig. 1.28).

Third-stage larvae of *Spirocerca*, ingested with dung beetles or encysted in the insectivorous transport hosts, penetrate the gastric mucosa and move along arteries to the aorta. Here they migrate, often subintimally, forward to the caudal thoracic area, which they attain within several weeks of infection. Following 2–4 months in an inflammatory granuloma in the aortic adventitia, worms migrate to the subjacent esophagus where they develop to adulthood in the submucosa and perforate the epithelium. Larvae that adopt aberrant migratory pathways may be found in granulomas in sites such as the subcutis, bladder, kidney, spinal cord, as well as stomach and intrathoracic locations.

Aortic lesions associated with *Spirocerca* are described in Vol. 3, Cardiovascular system, but include intimal and medial hemorrhage and necrosis, with eosinophilic inflammation; intimal roughening with thrombosis; aneurysm with rare aortic rupture; intimal and medial mineralization and heterotopic bone deposition. The presence of persistent aortic lesions in the dog, even in the absence of esophageal granuloma, is evidence of prior infection with *S. lupi*. Spondylosis of the ventral aspects of vertebral bodies T5–10 occurs in some cases. Exostoses or bony spurs arise from one or both ends of the vertebral bodies, and are presumably instigated by the local irritant effects of migrating worms.

In some animals with *S. lupi*, *mesenchymal neoplasms* develop in the wall of the esophageal granuloma (Fig. 1.29), and pulmonary fibrosarcoma has been associated with an ectopic worm. The granulomas around *Spirocerca* contain highly reactive pleomorphic fibroblasts with large open nuclei and numerous mitotic figures. Neoplasms arising from such lesions have cytologic characteristics typical of

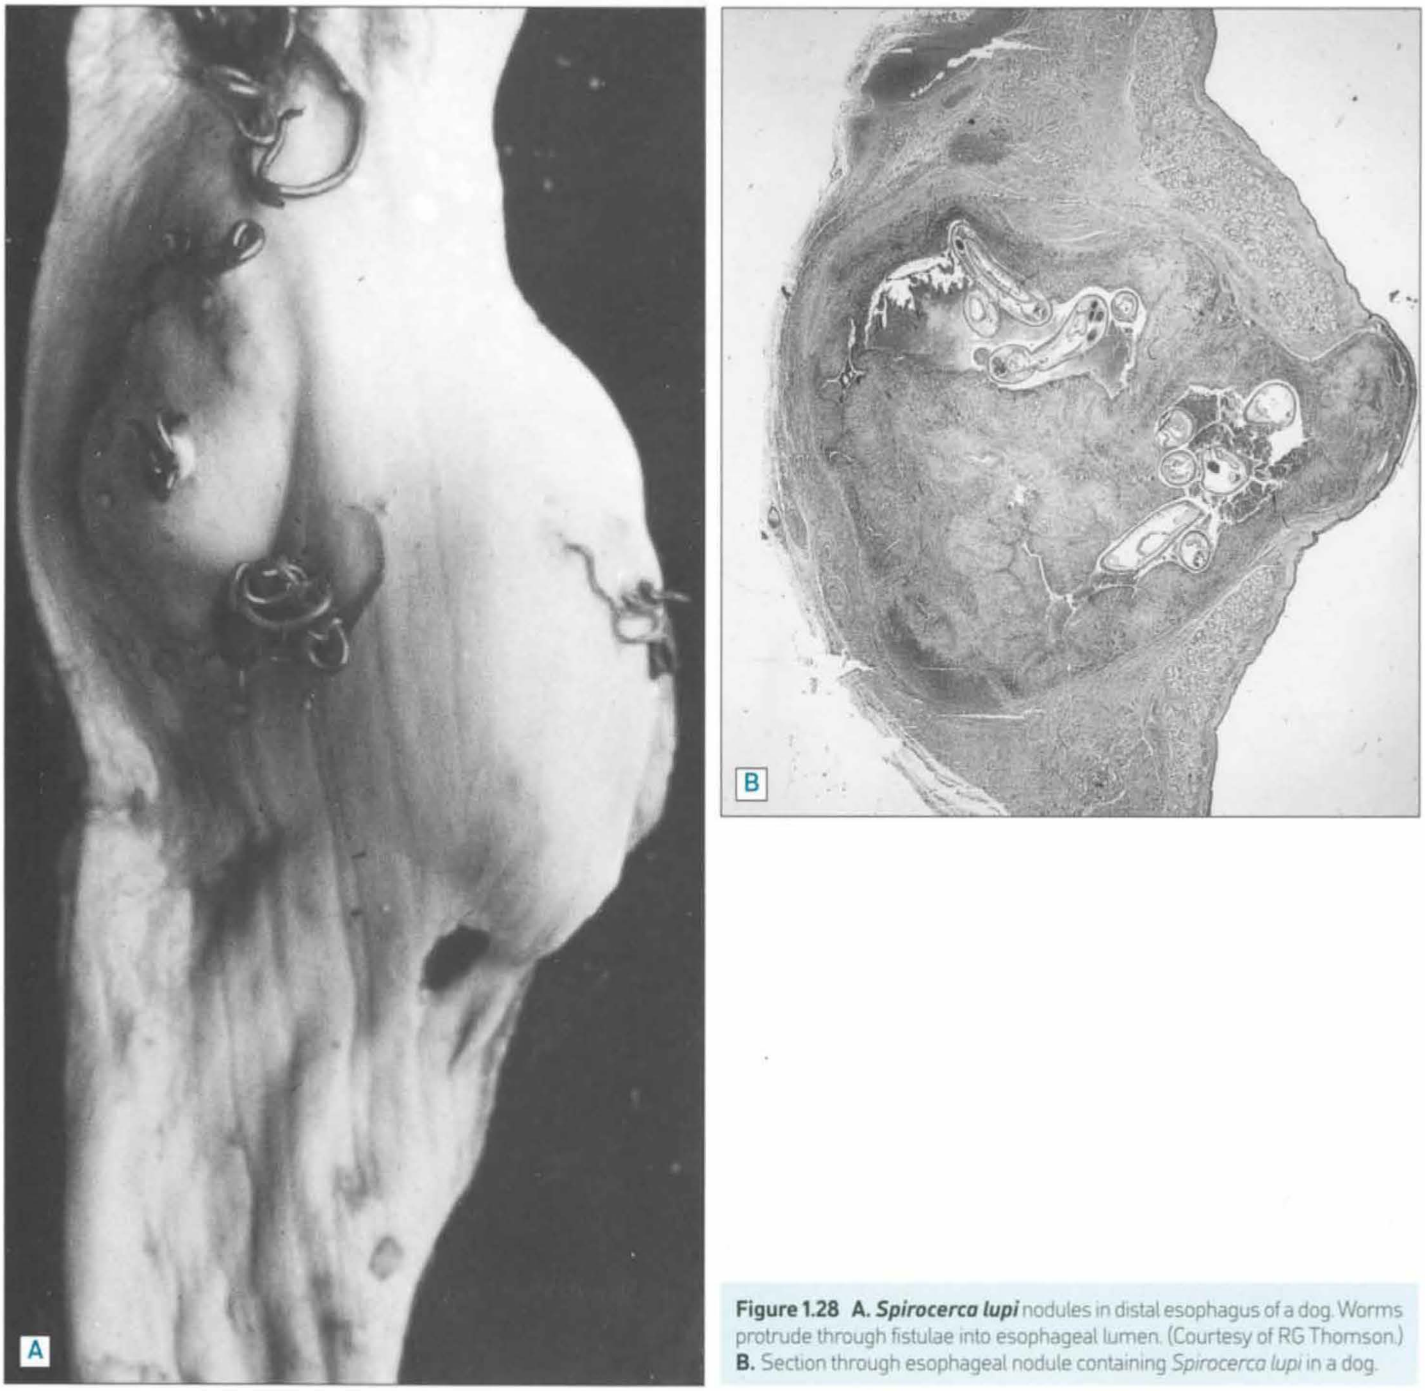

Figure 1.28 A. ***Spirocerca lupi*** nodules in distal esophagus of a dog. Worms protrude through fistulae into esophageal lumen. (Courtesy of RG Thomson.) **B.** Section through esophageal nodule containing *Spirocerca lupi* in a dog.

fibrosarcoma and osteosarcoma, with local tissue invasion, and in many cases, pulmonary metastasis. The carcinogenic stimuli associated with the development of these tumors are unknown. Hypertrophic pulmonary osteopathy is occasionally found in animals with *Spirocerca*-associated sarcoma and, rarely, granuloma.

FORESTOMACHS

The rumen represents the central processing unit for ingesta and as such is critical to the animal's well-being. However, since most of this occurs as a chemical process with minimal morphologic

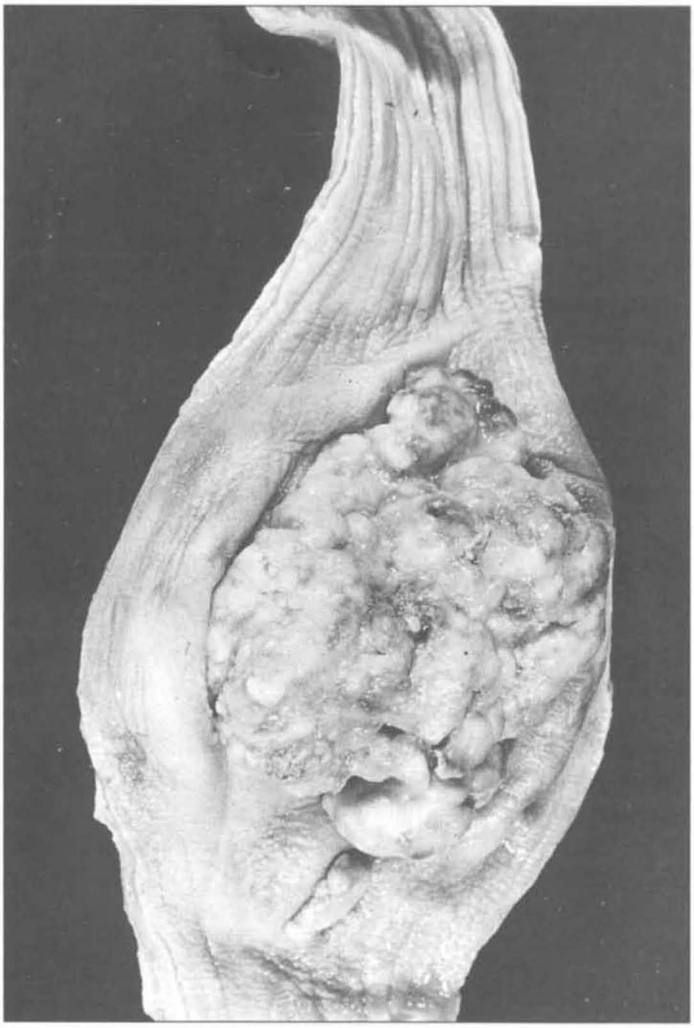

Figure 1.29 Ulcerating **fibrosarcoma** associated with ***Spirocerca*** granuloma in the distal esophagus of a dog. (Courtesy of RG Thomson.)

correlates, it is an organ that often seems to be overlooked by pathologists. Examination of ruminal contents may provide critical cues with respect to general metabolic states. Overly dry contents are an excellent indicator of dehydration. Voluminous frothy contents occur with primary bloat. Urea toxicity can be detected by an ammoniacal odor and alkaline pH. An odor of cooked turnips or a pungent insecticidal smell is suggestive of organophosphates. In grain overload, contents have a fermentative odor and pH may be less than 5.0. With putrefaction and release of toxic amines into the rumen, pH in cases of acidosis may return to near-normal levels. In these animals, the ruminal epithelium remains adherent to the submucosa despite any intervening postmortem changes, and it is an important clue to mucosal disease. Vagus indigestion, often associated with dysfunction of the esophageal groove, leads to accumulation of large volumes of watery fluid within the forestomachs. *Taxus* spp. toxicity will have an aromatic odor like cedar oil and needles will be present in the ingesta. Recognition of characteristic foliage in rumen content may lead to a diagnosis of poisoning by cyanogenic plants of the genus *Prunus*. Motor oil, paint flakes, or metallic lead present in the rumen would help to support a diagnosis of lead poisoning.

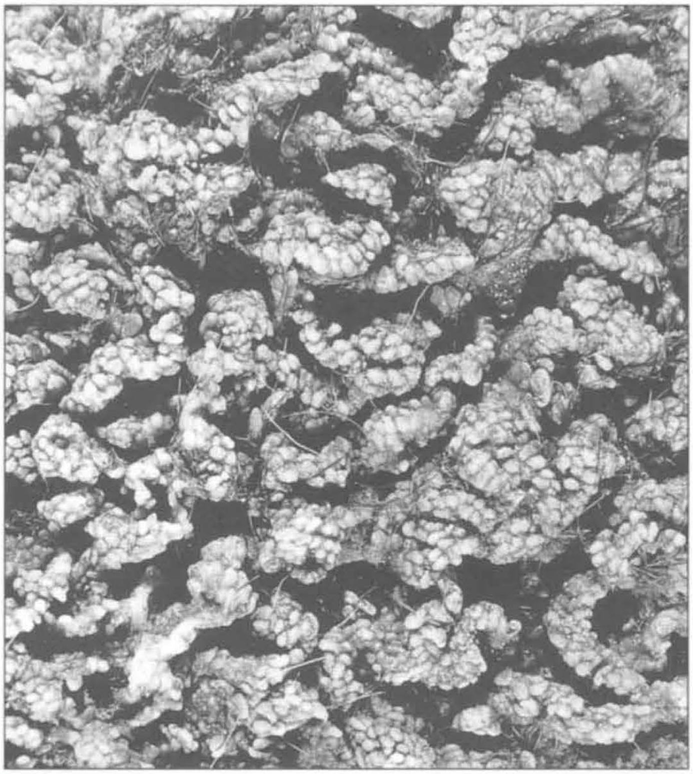

Figure 1.30 Clubbing and adhesion of rumen papillae with parakeratotic epithelium, associated with feeding a ration high in **barley**. Plant fibers and hairs are among the matted papillae.

Dystrophic and hyperplastic changes in the ruminal mucosa

The ruminal mucosa is unique in that it is a stratified squamous epithelium that functions in absorption as well as protection from the vat of fermenting bacteria contained within. Langerhans cells are distributed within the mucosa throughout all compartments of the rumen. T lymphocytes are found individually, and in aggregates, in both intraepithelial and subepithelial locations, with most in the cranial sac and relatively few dorsally.

Ruminal papillae in newborn calves are rudimentary and their subsequent development is dependent on diet, possibly as a consequence of stimulation by insulin-like growth factor-1. The end products of ruminal carbohydrate fermentation, propionate and butyrate, stimulate papillary growth. Papillae can take a variety of shapes, including long and flat, conical, spade-shaped, or hair-like. High-concentrate rations, which provide abundant propionate and butyrate, tend to produce papillae that are club-shaped, clumped, and may be dark. Microscopically, these papillae are covered with epithelium displaying acanthosis, hyper- and parakeratosis, and hyperpigmentation. Secondary papillae may be hyperplastic as well, creating the clumped appearance or rosette-like configurations. Rumens in animals fed barley rations have similar changes. Hairs from the rachilla of the barley adhere to the mucosa, especially in the interpapillary areas, giving it a distinct matted appearance (Fig. 1.30). These penetrate the mucosa and lamina propria, where they evoke a leukocytic reaction, often causing microabscesses. A diffuse pleocellular reaction is evident in the thickened fibrotic wall.

Roughage also plays a role. When animals receive adequate levels (approximately 15%) of coarse roughage, propionic and butyric acids decrease, while acetic acid levels increase, precluding hyper- and parakeratosis.

Hyperkeratosis of the ruminal epithelium also occurs in calves deficient in vitamin A.

Postmortem change

The ruminal mucosal epithelium usually sloughs within a few hours after death. It separates from the lamina propria in large gray patches, which cover the ingesta when the rumen is opened. *Persistent firm attachment of the ruminal epithelium is abnormal.* This undue adhesion occurs in dystrophic changes, described earlier, in acute rumenitis, especially if caused by fungi, and about healed lesions of necrobacillary rumenitis. Adhesion may not occur in the early stages of ruminal acidosis.

Dilation of the rumen

Tympanitic distension of the forestomachs (tympany, hoven, bloat) may be acute, or chronic and recurrent. The acute or primary tympany of cattle fed legumes or high-concentrate rations is characterized by foaming of the rumen contents, which prevents gas from being eructated, whereas in chronic or recurrent (secondary) tympany, the gas is free but retained because of some physical or functional defect of eructation.

Primary tympany is also called *frothy bloat.* Foam production in ruminal contents occurs normally. However, the amount of foam produced is small and unstable. There is apparently a delicate balance between pro- and antifoaming factors. These factors are multiple, and there is considerable controversy as to the extent to which each one influences the production of the foamy, viscous ruminal content so characteristic of frothy bloat, the most common cause of rumen distension.

The formation of foam is dependent on *soluble proteins*, especially fraction I proteins, which are present in high levels (to 4.5%) in bloat-inducing legumes, such as alfalfa and clover, especially in the pre-bloom stage of growth. Other legumes, notably sainfoin, trefoil, and cicer milk vetch, are not associated with bloat. Soluble proteins, released from chloroplasts, are degraded by the rumen microflora, and they rise to the surface where they are denatured, become insoluble, and stabilize the foam. The optimal pH (isoelectric point) for foam production by soluble proteins ranges from 5.4 to 6.0. *Pectins* are considered to increase viscosity of ruminal fluid and may act as foam-stabilizing agents. Plant lipids may act as antifoaming agents by competing for metal ions with the soluble proteins, thus inhibiting the denaturation of these proteins and resulting in decreased foam production.

Excessive foam production causes distension of the rumen because it prevents formation of a free gas cap, and the clearing of the cardia, which is essential for normal eructation to take place. When foam enters the esophagus, it stimulates the swallowing reflex, which also interferes with normal eructation. Gassy froth accumulates in the rumen as a consequence.

The variation among animals in their susceptibility to bloat may be determined in part by variations in the amount and composition of *saliva*. Saliva apparently has properties which may promote or prevent foaming in the rumen. When secretion of saliva decreases, the viscosity of ruminal contents increases, which in turn promotes foaming. Cows that have high susceptibility to bloating produce less saliva than cows that have low susceptibility. Succulent and high-concentrate feeds reduce salivary secretion, thus increasing viscosity of rumen contents. The composition of saliva affects foam production in several ways. Combination of salivary bicarbonate with organic acids such as citric, malonic, and succinic acids, which are present in high levels in legumes, results in the production of large amounts of *carbon dioxide*, enhancing bubble formation. Carbon dioxide accounts for 40–70% of the total gas produced in the rumen.

High and low susceptibility to bloat can be temporarily transferred between animals by exchange of total reticulorumen contents. The understanding of the full role played by these various factors in bloat is still incomplete, and other factors may be involved.

Rations high in concentrate and low in roughage not only reduce saliva secretion, but also change the ruminal microflora. They promote the growth of large numbers of encapsulated bacteria, which increase the concentration of polysaccharides, and these, in turn, increase the viscosity, promoting foam. These bacteria are also often mucinolytic and may destroy salivary mucins. Perhaps this explains the more gradual onset of **feedlot bloat**, since it takes time for the ruminal flora to change. Particle size of the grains fed may be one factor in feedlot bloat, with smaller particle size predisposing more to bloat.

The *cause of death* in bloat is probably a combination of physical and metabolic effects. Increased intra-abdominal pressure on the diaphragm inhibits respiration, and adversely affects cardiac function. Hypoxia may be caused by respiratory embarrassment. Increased intra-abdominal pressure also has a marked effect on the hemodynamics of the abdominal viscera, which are compressed, driving blood out of them. The caudal vena cava is also compressed, decreasing venous return to the heart. Distension also affects mucosal permeability and alters vagosympathetic reflexes.

The bloated animal is often found dead and distended with gas; blood exudes from the orifices, and because of the gaseous distension, the carcass often rolls on its back and assumes a sawhorse posture, with forelegs extended forward and rear legs pointing backward. The blood is dark and clots poorly; both features are indicative of death due to anoxia. Subcutaneous hemorrhages are prominent in the cranial extremities, which are congested. There is marked edema, congestion, and hemorrhage of the cervical muscles and of the lymph nodes of the head and neck. An inconsistent but significant finding is the so-called *bloat line* in the esophageal mucosa (Fig. 1.31A). This lesion is formed due to congestion with petechial and ecchymotic hemorrhages in the mucosa of the cervical esophagus, which changes

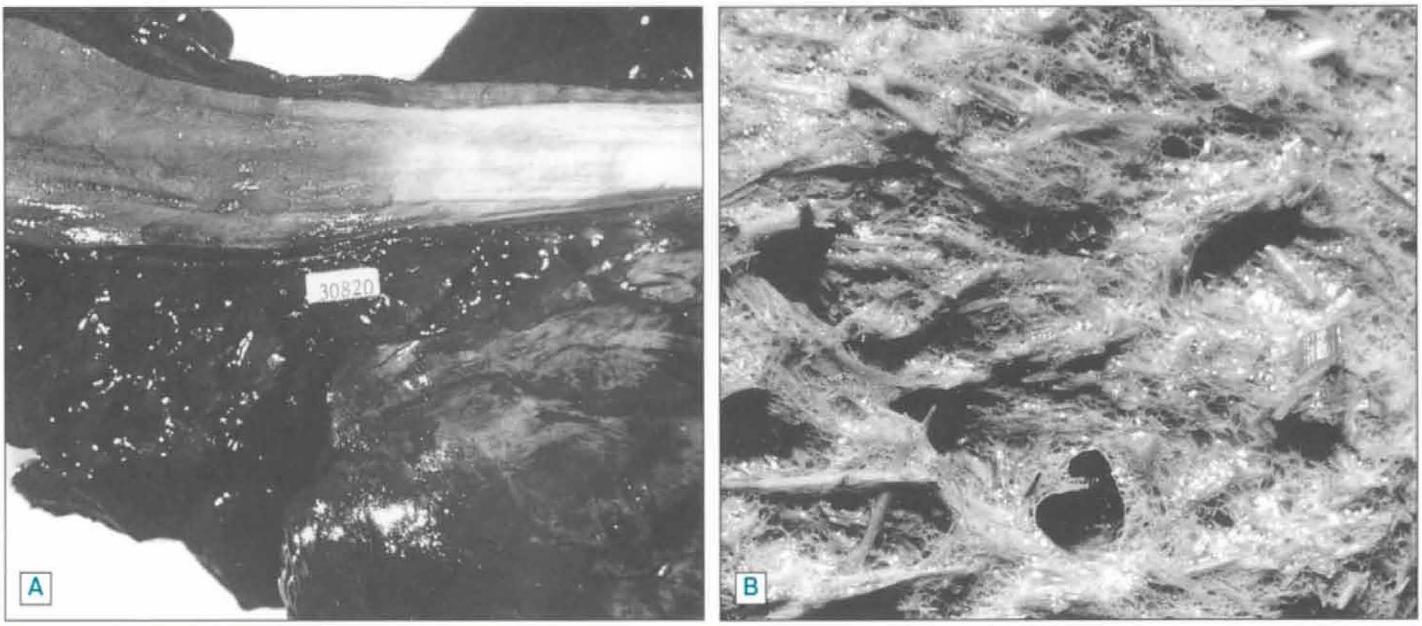

Figure 1.31 **A. "Bloat line"** in the esophagus of a cow with ruminal tympany. Congestion of esophagus and connective tissue cranial to thoracic inlet and blanching of esophagus caudal to thoracic inlet. **B. Frothy bloat** in a cow. Fine bubbles are evident in the rumen content.

abruptly or gradually to a pale mucosa at the level of the thoracic inlet. The tracheal mucosa is hemorrhagic, especially cranial to the thoracic inlet. Blood clots are frequently seen in the bronchi, and paranasal and frontal sinuses. The lungs are pale and compressed into the cranial thorax by the bulging diaphragm. There is pressure ischemia of the abdominal viscera, especially the liver, though the extreme margins of the hepatic lobes may be congested. Lymph nodes and the muscles of the hind legs are pale. There may be marked subcutaneous edema, particularly of the vulva, inguinal region, and perineum, and intestines may herniate through the inguinal canals. If the autopsy is done soon after death, the ruminal contents are bulky and foamy (Fig. 1.31B). The foam gradually disappears after death and is usually absent if the autopsy is delayed for 10–12 hours. Inguinal hernia and diaphragmatic rupture may occur after death.

Secondary tympany (free gas or secondary bloat) may be acute, but is generally chronic, with periods of acute exacerbation. It is usually the result of a physical or functional *defect in eructation of gas* produced by normal rumen fermentation. The more common physical problems include internal or external obstructions of the esophagus or esophageal groove by tumor, papilloma, or foreign body, and esophageal stenosis of any cause. Reticular adhesions, abscesses, peritonitis, or tumor masses that interfere with contractions of the forestomach can result in bloat. Functional causes of secondary tympany include organophosphate intoxication, and vagal damage due to adhesions, lymphosarcomatous infiltrates, or right-sided abomasal displacement and volvulus. It is a component of the syndromes collectively termed *vagus indigestion*. Bloat due to muscular dystrophy of the diaphragmatic muscles has been described in both Meuse–Rhine–Yssel and Holstein–Friesian breeds of cattle.

Secondary tympany, sometimes fatal, occurs in *bucket-fed calves*. They ingest large amounts of milk, which escapes the reticular groove and flows into the rumen, where it putrefies because of digestion by proteolytic bacteria. Failure of the reticular groove to close may be a persistent problem in some veal calves, which are known as *ruminal drinkers*. The clinical signs are characterized by inappetence, unthriftiness, recurrent tympany, abdominal distension, and clay-like feces. The presence of partly digested milk in the rumen results in hyper- and parakeratosis of the mucosa and perhaps mild rumenitis. Casein clot formation in the abomasum is inhibited.

Animals fed rations that have too much undigestible roughage may have recurrent episodes of bloat. Feed must contain adequate portions of protein, starch, and/or sugars, and cellulose to stimulate growth of the cellulytic microflora. Undigestible roughage accumulates in the rumen and reticulum when the intake of digestible nutrients (starches and sugars) is inadequate. As a result, the forestomachs become dilated, which in turn inhibits reticuloruminal contractions that are required for clearance of the cardia and subsequent eructation.

A *diagnosis of secondary bloat* at autopsy is based on physical findings like those described in primary bloat, but without frothy rumen content, and with the addition of any physical causes of impaired eructation. Postmortem distension of the rumen must not be mistaken for antemortem tympany. Extraruminal lesions must be present to establish a diagnosis of bloat.

Foreign bodies in the forestomachs

Cattle are notoriously lacking in alimentary finesse, a deficiency that allows an amazing variety of foreign bodies, prehended with the food, to be deposited in the forestomachs. Sheep are largely immune because of their more selective eating habits. Foreign bodies are rarely found in the rumen of goats, despite their reputation for indiscriminate feeding habits. In consequence, a large proportion of adult cattle, and very few goats or sheep, have metallic, wood, or plastic foreign bodies in the rumen and reticulum, but rarely in the omasum.

Spherical masses consisting largely of hair or wool (**trichobezoars**) or plant fibers (**phytobezoars**) may also form in these compartments. Hairballs are most common in younger ruminants, the hair being swallowed after licking, particularly by animals deprived of dietary fiber. They may have some other foreign body as a nucleus and contain a proportion of plant fibers, the whole mass concreted by organic substances and inorganic salts. The same general comments apply to phytobezoars. Being smooth, neither are important unless regurgitated to lodge in the esophagus or passed on to obstruct the reticulo-omasal orifice, the pylorus, or the intestine, which is very infrequent. Otherwise, these bezoars are an incidental finding.

The important foreign bodies are those (such as lead) that cause *intoxication* when dissolved, and those that (being abrasive or sharp) *penetrate the mucosa*. In calves on diets low in roughage, ingestion of wood shavings or straw may lead to diffuse cellulitis of the forestomachs and sometimes the abomasum. A mixed bacterial flora containing clostridia is responsible, presumably following mucosal trauma. The sequel to penetration by sharp objects in adult cattle is traumatic reticuloperitonitis.

Traumatic reticuloperitonitis and its complications

Perforation of the forestomachs by foreign bodies is virtually always caused by a sharp foreign body, usually a *wire or nail* over 4 cm long, penetrating the reticular wall. Incomplete perforation is usually inconsequential, though in some cases focal suppurative or granulomatous inflammation develops in the wall of the reticulum, with minor overlying peritonitis. There are no adequate answers as to why perforation occurs, but it is probably caused by forceful contraction of the reticulum, and many cases seem to be predisposed by the increased intra-abdominal pressure of late pregnancy and parturition.

The prophylactic use of *magnets* has become common in many herds, and this probably contributes to the marked decrease in fatal cases of traumatic reticuloperitonitis. Frequently, these magnets are found incidentally in the reticulum, completely covered by metal foreign bodies, including nails and wires, which might otherwise have penetrated the reticular wall. The replacement of baling wire with twine is another reason for the apparent decline in the prevalence of this disease.

The outcome of complete perforation is consistent, but variations in the pattern are common. The perforation is usually in the cranioventral direction and is followed immediately by *acute local peritonitis*. If the foreign body is short or bent, it may progress no further, and some foreign bodies are apparently withdrawn with the next reticular movement; in such instances, *chronic local peritonitis* with adhesions develops. The foreign body may advance to perforate the diaphragm and pericardium, resulting in *traumatic pericarditis*, but this advancement may be delayed.

A ventral penetration may result in subperitoneal and subcutaneous abscess near the xiphoid. Rare perforation of one of the larger regional arteries may result in sudden death from hemorrhage, and sudden death may also occur if there is penetration of the myocardium or rupture of a coronary artery. Penetration of the thoracic cavity may occur without perforation of the pericardium, causing pneumonia and pleuritis. Right lateral deviation of the penetrating agent involves the wall of the abomasum. It is unusual for the liver or spleen to be penetrated, but metastatic abscesses in the liver are common.

As soon as the foreign body penetrates the serosa, local fibrinous peritonitis develops, which later leads to dense adhesion of variable extent between the reticulum and adjacent structures. Further progression of the foreign body is ordinarily slow and produces a canal surrounded by chronic granulation tissue and containing, besides the foreign body, ingesta, purulent exudate, and detritus. The bacteria commonly active in the tract are *Arcanobacterium pyogenes*, *Fusobacterium necrophorum*, and a variety of putrefactive types. In many cases, a foreign body cannot be found, perhaps because it has rusted away or been withdrawn into the reticulum.

Traumatic pericarditis is a less common sequel now, perhaps because many of the initial penetrations are diagnosed and the foreign body removed surgically. The pericardial reaction is copious, fibrinopurulent, and putrid. There are usually additional lesions of traumatic pneumonia and pleurisy.

One of the variants in the usual pattern of migration of the foreign body is penetration of the side of the reticulum, leading to suppurative inflammation in the grooves between the reticulum, omasum, and abomasum. The acute local peritonitis causes immediate cessation of ruminal movements; however, persistent ruminal atony or irregular motility with gradual onset of bilateral abdominal distension, inappetence, and decreased milk production may ensue. Clinically this is referred to as **vagus indigestion**, which may also be a sequel to abomasal displacement. At autopsy, there are very characteristic changes in the stomachs with this syndrome. The rumen is distended with enough fluid to cause sloshing if the carcass is jolted. There is no ruminal fermentation or odor, and bits of unmacerated straw and food particles float on the watery fluid; the more-normal ingesta has sedimented. The omasum can be very large and impacted with dehydrated ingesta. The abomasum may be distended and impacted with dry ingesta, presumably because of functional pyloric stenosis or abomasal stasis.

The question of the importance of vagal nerve damage in the pathogenesis of vagus indigestion remains unresolved. The consensus is that this syndrome is associated with mechanical or functional impairment of outflow of ingesta from the forestomachs or abomasum, but in some cases the primary defect appears to reside in flaccidity of the reticular groove and in degeneration of its muscle and intramuscular nerve plexus. The rumen and reticulum are dependent on intact vagi for normal movement, and a minority of cases of vagus indigestion appear to be associated with damaged nerves.

Vagal lesions may be in the pharyngeal and cervical areas, or intrathoracic, such as lymphosarcomatous infiltration, or abdominal. The latter are usually investment of the nerve in adhesions following reticular perforation, or trauma following abomasal volvulus.

In other cases, degeneration of the vagus is not evident. In these, the dysfunction and lesions are more likely to be due to peritonitis and the subsequent abscessation, or adhesions which disrupt the normal tension–receptor activity, or cause a pain response that interferes with normal motility of the forestomachs and abomasum.

In **failure of omasal transport** (*type II vagus indigestion*), there is impairment of movement of ingesta from the reticulorumen to the omasum, associated with abscesses adjacent to the reticulo-omasal orifice. There, lesions probably result in mechanical or neural interference to emptying of the reticulorumen.

A *diagnosis* of vagal indigestion at autopsy is ordinarily dependent on evidence of abnormal abomasal, omasal, or reticuloruminal motility, in association with morphologic lesions of the vagus nerves, adhesions, or neoplasms involving the forestomachs and abomasum.

Rumenitis

Inflammatory lesions in the forestomachs occur in a number of *viral diseases* of the alimentary tract in ruminants. In neonatal calves, necrosis of ruminal mucosa is an important sequel to *Bovine herpesvirus 1* infection. Bovine papular stomatitis and contagious ecthyma rarely cause rumen lesions. Ruminal erosions and ulcers are present in some cattle with acute bovine viral diarrhea and mucosal disease; they are reported to be less common in rinderpest. Extensive hemorrhage and ulceration of the reticuloruminal mucosa may be seen in bluetongue in sheep. Adenoviral infection occasionally causes multifocal fibrinohemorrhagic rumenitis. These conditions are described fully in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter. Mycotic rumenitis can occur subsequent to chemical rumenitis, primary viral rumenitis, sepsis, or intensive antibiotic treatment.

Mild inflammation of the forestomachs occurs in some young calves fed *milk* from a pail, when, because of laxity of the reticular groove reflex, the milk spills into the rumen and reticulum in large quantity. A similar problem occurs with feeding by stomach tube. Putrefaction in these compartments leads to mild rumenitis, with edema and mild neutrophil infiltration of the mucosa.

Accidental consumption of excessive quantities of *urea*, in the form of nonprotein nitrogen supplement, or fertilizer, in liquid or powder form, results in the production of ammonia in the rumen. The toxic effect is accelerated by urease in soy-based rations, and is based on the production of high blood levels of ammonia. Rumen contents smell ammoniacal when the organ is opened; the content is alkaline; and there may be congestion or coagulative necrosis of the cranioventral wall of the rumen. Elevated ruminal and abomasal pH values (7.0), without specific lesions, have been associated with ingestion of boron fertilizer by cattle and goats.

Ingestion of toxic levels of *sulfur* results in chemical rumenitis due to the conversion of sulfur to H_2S, and possibly sulfurous acid, in the rumen. Large amounts of yellow sulfur particles are usually found in the rumen and abomasum. Eructation and subsequent inhalation of H_2S result in acute alveolitis. Absorption of sulfides from the lungs leads to marked depression of the respiratory and cardiovascular centers in the central nervous system. Affected animals also develop acidosis, probably due to the absorption of acids, and impaired renal function associated with the direct toxic effects of sulfur metabolites on tubular epithelial cells.

Inflammation of the forestomachs may be associated with certain *plant toxicoses*, mainly in Australia and Africa. Examples are Kikuyu grass (*Pennisetum clandestinum*), prickly paddy melon (*Cucumis myriocarpus*), and several species of *Bryophyllum*, an ornamental garden plant.

Feeding rations deficient in fiber, which is increasingly the case in developed countries, can alter the microflora, predisposing the animals to metabolic disorders or rumenitis. In addition, acute chemical rumenitis develops after overeating on rapidly fermentable carbohydrate, usually grain.

Rumenitis and acidosis caused by carbohydrate overload

Ruminal acidosis and rumenitis associated with ingestion of excess carbohydrate are problems mainly of *intensive beef and dairy production*. Sheep, and especially goats, are also susceptible to this problem. Its importance lies partly in loss of production and partly in mortality due to the acute disease, in which rumenitis is of minor significance and lactic acidosis is the major cause of morbidity and mortality. Rumenitis assumes significance in subclinical disease or in survivors of acute episodes, by providing a portal for the entry for fungi and *Fusobacterium necrophorum*, which cause secondary infections. These complications are discussed below. Other complications include coexisting primary tympany (frothy bloat), which may be the fatal partner of grain overload in feedlot cattle.

Ruminal acidosis usually follows the *ingestion of excess carbohydrate* in the form of grain, or other fermentable feedstuffs occasionally used, such as root crops, bread, waste baked goods, brewers' waste, and apples. There is wide variation in the amount of carbohydrate necessary to kill an animal, because tolerance to rations high in starch does develop if they are introduced gradually. Sudden increments in the amount of carbohydrate ingested are of more importance than the actual amount. Sudden changes from concentrates with lower energy values to those with higher values may predispose to acidosis. Extreme environmental temperature changes, either hotter or cooler, may result in temporary reductions in feed consumption, and acidosis may develop once such animals return to full feed.

Shortly after the ingestion of a toxic amount of carbohydrate, ruminal pH begins to fall. The decrease in pH during the first few hours is mainly due to an increase in dissociated volatile fatty acids, not lactic acid. The production of the latter increases after there has been a marked change in the ruminal flora, which is very responsive to the substrate available for fermentation. *In cattle and sheep, the normal pH of ruminal fluid varies between 5.5 and 7.5*, depending on the diet fed.

The gram-negative bacteria that predominate in the normal flora, and the protozoa, are very sensitive to changes in the pH; most die at a pH of 5.0 or less. Once the pH of the ruminal contents starts to fall, streptococci, mainly *Streptococcus bovis*, proliferate rapidly, acting as a major source of lactic acid. When the pH reaches 5.0–4.5, the numbers of streptococci decrease, with a concomitant increase in lactobacilli. The pH of rumen content may fall as low as 4.0–4.5 in fatal cases.

As ruminal pH drops, ruminal atony develops, mainly as the result of an increase in the concentration of the nondissociated volatile fatty acids, lactic, propionic, and butyric. They act on receptors that mediate inhibition of reticuloruminal motility via a vagovagal reflex. Loss of forestomach motility in ruminal acidosis is apparently not dependent on the development of systemic acidosis. There is also cessation of salivary secretion, so that the buffering effect of saliva is absent.

The increase in ruminal organic acids, mainly lactate, causes an increase in ruminal osmotic pressure. This results in movement of fluid from the blood into the rumen, producing bulky and liquid ruminal contents and severe dehydration. Plasma volume is reduced; hemoconcentration, anuria, and circulatory collapse follow. Serum protein levels, urea, inorganic phosphorus, lactate, pyruvate, and liver enzymes are all elevated. The osmotic pressure of the intestinal contents also increases when the ingesta with the high lactate concentrations arrives there. Loss of fluid at this level probably contributes further to the dehydration, and it may also play a significant role in the development of the diarrhea that is commonly seen clinically. In addition to the osmotic effects, there is acidosis due to the absorption of lactate from the rumen, and possibly from the intestine.

The low ruminal pH is lethal to much of the normal flora and fauna. The protozoa appear to be particularly sensitive, but many types of bacteria are also lost. In those animals that survive the acute phase of ruminal acidosis, recovery is not complete until a normal ruminal flora is re-established through contact with other animals. Temporary recovery may be followed by what appears clinically to be a relapse in acidosis, but which is a developing mycotic rumenitis. If treatment of the initial fluid imbalance is delayed, death may occur in a week or so from ischemic renal cortical necrosis.

The **gross findings** in this metabolic disease are not specific, and a practical diagnosis requires knowledge of access to fermentable carbohydrate and a clinically observed circulatory failure. At autopsy, the eyes are sunken, the blood may be thick and dark due to dehydration and hypoxia, and there is general venous congestion. The appearance of the ruminal contents varies with the time interval between ingestion of the carbohydrate and the autopsy. In the early stages, there is a copious amount of porridge-like rumen content, which has a distinct fermentative odor. The amount of grain, corn, or other source of starch varies considerably and is an unreliable indication of acidosis, and the presence of finely ground concentrate may be overlooked. Ruminal pH is only helpful when it is low (<5.0), since it may rise in later stages of the disease. Although the ruminal contents may appear relatively normal in more advanced cases of acidosis, intestinal contents tend to remain very watery. Absence of protozoa is consistent with chemical rumenitis, but is also influenced by the interval between death and the postmortem examination.

The **diagnosis** of ruminal acidosis at autopsy can be difficult. The most suggestive abnormality is the *rumenitis*. It is probably chemical and dependent on the low pH, and is not readily discerned grossly. There may be a slight poorly defined blue coloration in the ventral sac of the rumen and reticulum and in the omasum, visible through the serosa. When the epithelium is detached, the lamina propria is seen to be hyperemic in patches. In some cases, the epithelium appears to have undergone fixation due to low pH, and is difficult to peel.

Microscopic examination of the ruminal mucosa is the most reliable way of confirming a diagnosis of chemical rumenitis. The ruminal papillae appear enlarged. There is marked cytoplasmic vacuolation of the epithelial cells, often leading to vesiculation. A mild to marked neutrophilic reaction is evident in the mucosa and submucosa (Fig. 1.32). Focal areas of erosion and ulceration may or may not be present.

Fusobacterium necrophorum is a normal inhabitant of the anaerobic ruminal environment. This bacterium is commonly responsible for complications of ruminal acidosis, producing characteristic lesions in the forestomachs (Fig. 1.33A, B) and in the liver. Invasion of the wall of the rumen takes advantage of the foothold provided by the superficial necrosis and inflammation of acidosis. Inflammatory changes favor the adherence of *F. necrophorum* to ruminal lining cells.

Necrobacillary rumenitis is common in feedlot cattle, probably a product of mild acidosis following a too-rapid introduction to a high-concentrate ration. It affects the papillated areas of the ventral sac and occasionally the pillars. On the mucosal surface, the early lesions are visible as multiple irregular patches 2–15 cm across, in which the papillae are swollen, dark, slightly mushy, and are matted together by fibrinocellular inflammatory exudate. Affected papillae are necrotic, but ulceration may be delayed if there is ruminal atony and stasis. If the animal recovers from the immediate effects of overeating, the necrotic epithelium sloughs, the ulcer contracts, and epithelial regeneration begins from the margins. The regenerated epithelium is flat and white, and the papillae do not return completely. A stellate scar often remains, but many of the smaller lesions

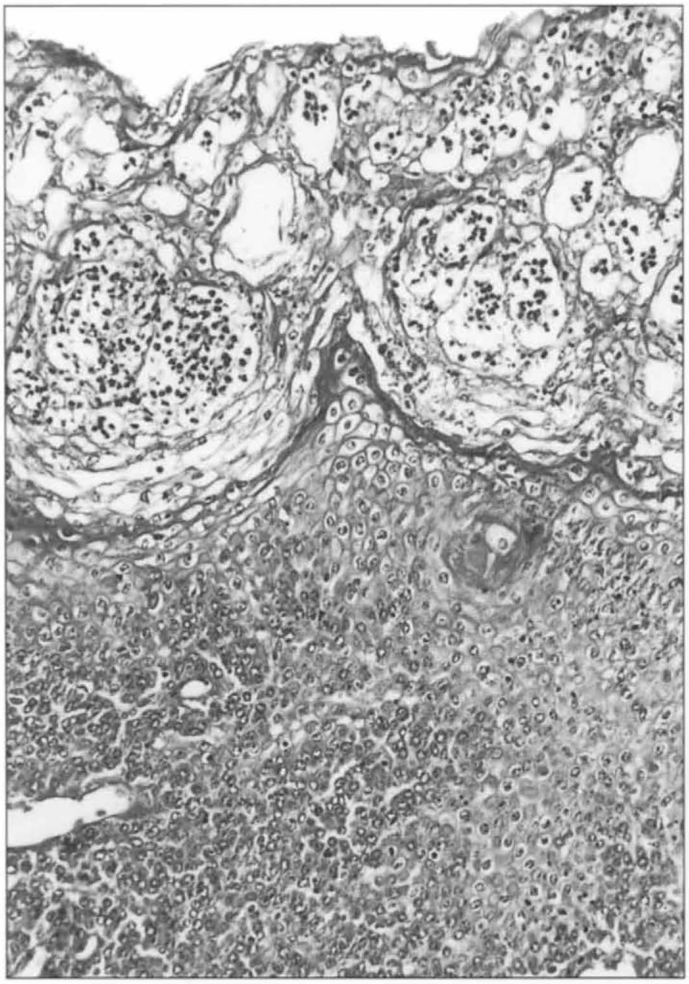

Figure 1.32 Vacuolation and neutrophil infiltration into superficial epithelium of rumen papilla in **chemical rumenitis** (ruminal acidosis) due to excess carbohydrate intake.

may disappear completely (Fig. 1.33C). *Hepatic lesions* are initially the typical coagulative necrosis of necrobacillosis, but in time they liquefy to form abscesses, and these often persist long after the initial ruminal lesions have cicatrized or disappeared.

It is unusual for ruminal necrobacillosis in cattle to be more than a superficial infection, and although the muscle layers are involved in the inflammation, they are not ordinarily invaded by the organism. However, perforation of the omasal leaves is common. In sheep, the infection is more aggressive than it is in cattle.

Mycotic infection should be suspected when inflammation in the wall of the forestomachs extends to the serosa and is *hemorrhagic.* The fungi, which, like *F. necrophorum*, are opportunists, are usually zygomycetes of the genera *Mucor*, *Rhizopus*, and *Absidia*, which cannot be differentiated from each other in histologic sections.

Mycotic rumenitis is much more severe and extensive than necrobacillary rumenitis, and is often fatal. *The basis for the lesion is submucosal venular thrombosis due to fungal invasion*, causing venous infarction of the tissue field involved. The inflammation extends to the peritoneum, causing hemorrhagic and fibrinous peritonitis that mats the omentum to the rumen. In fatal cases, most of the ventral sac and parts of the reticulum and/or omasum are involved. The lesions are very striking and suggest on initial inspection that the walls have been massively infarcted, which in part they have (Fig. 1.34A). The margins are well demarcated, usually by a narrow zone of congestive swelling. The affected areas are red to black, thickened to 1 cm or more, firm and leathery. There is acute fibrinohemorrhagic inflammation of the overlying peritoneum, and beneath it in the grooves there is blood-stained, inflammatory edema.

On the inner surface of the rumen, the lesions are more hemorrhagic than those of necrobacillosis, and more irregular in outline (Fig. 1.34B), and the necrotic epithelium is difficult to detach. Histologically, the rumenitis is characterized by hemorrhagic necrosis of all structures in the wall; by copious fibrinous exudate; and by rather scant leukocytic reaction. *Fungal hyphae* are readily visible in the necrotic tissues and the lumina of the thrombosed blood vessels. More chronic cases are characterized by granulomatous inflammation in the deeper parts of the mucosal lesion.

Mycotic rumenitis and omasitis may occur in cows that do not have a history of acidosis. It has been suggested that these cases may be a sequel of sepsis, with reflux of abomasal fluid into the forestomachs, and therapy with broad-spectrum antimicrobials acting as predisposing factors for mycotic infections. It can also be a sequel to ruminal damage in survivors of *Bovine viral diarrhea virus* infection.

Metastases sometimes occur in the liver and cause necrotizing thrombophlebitis of the portal radicles visible as small irregular tan areas of infarction surrounded by a deep red margin (Fig. 1.35).

Other conditions which have been associated with ruminal acidosis are *laminitis* and an *encephalopathy* which morphologically resembles the lesions of early polioencephalomalacia (see Vol. 1, Skin and appendages; and Vol. 1, Nervous system).

Parasitic diseases of the forestomachs

Gongylonema spp. occur in the epithelium of the rumen. They appear as described in the esophagus, and are not pathogens.

More important parasites are the conical **flukes** belonging to the family Paramphistomatidae. They are found in cattle and sheep in warm temperate, subtropical, and tropical regions. These red, plump, droplet-shaped flukes are about the size of the papillae between which they reside in the rumen, where they are usually nonpathogenic (Fig. 1.36). If present in very high numbers, they can cause atrophy of papillae and excessive cornification of the stratum corneum and granulosum. Larval paramphistomes in the duodenum

can cause disease. The biology and pathogenicity of paramphistomes are discussed in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Myiasis of the rumen caused by larvae of the **"screwworm" fly** *Cochliomyia hominivorax* is occasionally a cause of mortality in young calves in South America. The larvae are presumed to be licked from cutaneous wounds and swallowed. They lodge in the rumen and perforate it.

Neoplasia of the esophagus and forestomachs

Neoplasia of the esophagus and reticulorumen is, with the exception of papilloma, rare in domestic animals.

Papillomas of the esophagus in **dogs** are uncommon and may be associated with oral papilloma. In **cattle**, papillomata of the esophagus and reticulorumen are common in some areas. They are caused by *Bovine papillomavirus type 4* (BPV-4), which infects only squamous mucosa of the mouth, pharynx, and upper alimentary tract. Bovine alimentary papillomata are usually solitary, though a minority of infected animals may have multiple lesions. Most are small (<1 cm), broadly pedunculate tapering acuminate masses. They are composed of a number of closely packed fronds of squamous epithelium, each supported by a light core of fibrous stroma, and arising from a common fibrous base. Viral replication and the microscopic changes in infected epithelium are typical, as described earlier for canine oral papillomas, although the characteristic koilocytes and intranuclear inclusions can be sparse.

Fibropapillomas, limited to the esophagus, esophageal groove and rumen, are caused by *Bovine papillomavirus type 2* (BPV-2), normally associated with cutaneous papillomas and fibropapillomas. Alimentary fibropapillomas are smooth nodular pearly white masses, usually about 0.5–1.0 cm in diameter, but occasionally up to 3.0 cm and plaque-like. They are comprised of fibromatous stroma covered by acanthotic epithelium, which may occasionally be ulcerated. No evidence of expression of BPV-2 is found in alimentary fibropapillomas, the viral genome being identified by molecular probes.

Papillomas and fibropapillomas are normally asymptomatic, though large lesions of the reticular groove and esophagus may interfere with eructation and deglutition, causing bloating or loss of condition.

Malignant neoplasms of the esophagus and forestomachs in ruminants are ordinarily extremely rare. However, in several localities, **squamous cell carcinoma** is relatively common in **cattle**, associated with BPV-4-induced papilloma (but not with fibropapilloma due to BPV-2). However, BPV-4 viral antigens or genome are not detected in these carcinomas. An interaction between papillomavirus and ingestion of carcinogens in bracken fern predisposes to the development of squamous cell carcinomas of the esophagus and forestomachs in the hill country of Scotland and northern England. Immunocompromise due to bracken fern intoxication is permissive of chronic papillomatosis, and a cofactor in neoplastic transformation to squamous carcinomas. In Brazil and Bolivia, a similar association is made with carcinomas of the oropharynx and esophagus. A high prevalence of carcinoma of the esophagus and forestomachs has also been reported from a single valley in Kenya, in association with papillomata, not confirmed as viral, and with a carcinogen apparently ingested with or derived from native forest plants.

Esophageal and ruminal carcinomas are associated with dysphagia or difficult deglutition, ruminal tympany, and apparent abdominal pain with progressive cachexia. Concurrent papillomas, carcinomas, and hemangiomas of the bladder, like those causing enzootic hematuria, but associated with BPV-2, are often found in cattle with esophageal or ruminal cancer. In Scotland, intestinal adenomas or adenocarcinoma also occur in many cases.

Esophageal and ruminal carcinoma may be seen developing from recognizable papillomas; as brown irregular roughened hyperplastic epithelium; or as ulcerated or irregular proliferative fungating lesions. Distal esophagus, reticular groove, and the adjacent ruminal wall are the sites most commonly affected with carcinoma. Microscopically, they are typical squamous cell carcinomas, and invade locally, their scirrhous nature causing induration of the wall of the organ. They may metastasize to local lymph nodes, and to distant sites such as liver and lung.

In **sheep**, papillomas and squamous cell carcinomas are rare, and little is known of their etiology.

Squamous cell carcinomas may also be encountered rarely in the esophagus of aged **cats**, where they develop in the mid-thoracic portion, forming proliferative plaques of neoplastic cells that eventually ulcerate and invade the wall of the esophagus and adjacent mediastinum. In **horses**, squamous cell carcinoma of the stomach may also involve the adjacent terminal esophagus. Rare squamous cell carcinoma, and adenocarcinomas arising from the esophageal glands, are reported in **dogs**. Invasion of, or metastasis to, the canine esophagus by thyroid, respiratory, and gastric carcinomas is also reported.

Mesenchymal tumors of the esophagus, with the exception of the *Spirocerca*-associated fibrosarcomas and osteosarcomas in **dogs**, referred to previously in the section on parasitic diseases of the esophagus, are very rare. However, leiomyoma, osteosarcoma, and plasmacytoma have been reported in dogs. Connective tissue tumors of the **ruminant** forestomachs are similarly rare, though fibromas of the reticular groove have been reported. Occasional involvement of the rumen, omasum, and reticulum may occur in cattle with lymphosarcoma, usually also involving the abomasum and more distant sites.

STOMACH AND ABOMASUM

Normal form and function

The stomach should be carefully examined in animals of any species with a history of inappetence or anorexia, cachexia, hypoproteinemia, diarrhea, regurgitation, or vomition. Abdominal distension may be associated with gastric dilation or displacement. Hematemesis, melena, or anemia may signify gastric bleeding. Many infectious diseases, with major systemic or alimentary tract signs elsewhere, produce gastric lesions. Systemic states such as uremia and endotoxemia cause characteristic gastric lesions in some species.

In the horse and pig, an obvious smooth white or yellow **esophageal region** is present. It is covered by stratified squamous epithelium, with susceptibility to insult and reparative capacity similar to that of the esophageal lining. Chronic inflammatory infiltrates and lymphoid follicles are normally present in the lamina propria and submucosa of the **cardiac gland mucosa** abutting the esophageal region, especially in the pig. The cardiac gland zone is gray and is particularly well developed in this species, lining the gastric diverticulum, fundus, and about half the body of the stomach. In the dog, cat, and ruminant, cardiac glands are limited to a narrow zone at the cardia or omasal opening. Cardiac glands are branched tubular structures, lined almost exclusively by columnar mucous cells.

The **fundic, or oxyntic, gland acid-secretory mucosa** in the horse and pig is red-brown and slightly irregular but not highly folded. More prominent longitudinally oriented rugae, or plicae, are present in the dog and cat, and in the abomasum of ruminants. Gastric secretion undiluted by ingesta in the dog or cat normally should be <pH 3.0. Abomasal content should be <pH 3.5–4.0.

Tall columnar mucous cells cover the gastric surface, and line pits or foveolae. The junction of the base of the foveola and the upper portion of the neck of the fundic gland proper is termed the isthmus. Cuboidal or low columnar pluripotential stem cells in a narrow zone in this area undergo mitosis. Three lineages are identified: (1) pit (foveolar) cells; (2) parietal cells; and (3) zymogen (chief) cells. Daughter cells of the pit cell lineage differentiate into **foveolar mucous cells**, migrating up on to the gastric surface, where they are lost, probably in about 4–6 days. The neck of the oxyntic gland below the isthmus is lined by pyramidal, peripherally located acid- and intrinsic factor-producing parietal cells. Interspersed are inconspicuous mucous neck cells, mainly in the upper neck and probably stages in the differentiation of chief, and perhaps, parietal cells, and scattered endocrine cells. In the base of the gland the pepsinogen-producing zymogen, or chief, cells are concentrated.

Mucous neck cells, like foveolar mucous cells, contain periodic acid–Schiff-positive mucus. **Parietal cells** differentiate from cells proliferating at the isthmus, and appear to be relatively long-lived, that is, of the order of weeks to months. A complex tubulovesicular/canalicular structure upon which the hydrogen ion-secretory proton pump is inserted opens at the luminal apex of the cell in the secretory state. A number of long-lived **enteroendocrine cells,** derived from proliferative cells at the isthmus, are recognized in the oxyntic gland, secreting histamine, serotonin, and somatostatin, among other endocrine/paracrine agents. Endocrine cells usually abut the basement membrane of the gland, lack exposure to the gland lumen, and have characteristic basal granules. The **chief cells** are apparently long-lived cells, derived from stem cells at the isthmus. Ultrastructurally they have extensive rough endoplasmic reticulum, a prominent Golgi zone, and numerous zymogen granules.

Normally, mitotic figures are not common in cells at the isthmus of fundic glands, and are virtually never seen at any distance from the isthmus. However, the fundic mucosa of newborn ruminants and especially piglets may be relatively poorly differentiated and proliferative. The proliferative compartment, if active, is sensitive to radiomimetic insults, such as cytotoxic agents and parvoviral infection. This is reflected by narrowing of the isthmus and upper neck and attenuation of the epithelium lining the gland.

The **pyloric mucosa** forms a slightly pitted or irregular surface in the distal portion of the stomach; it extends further cranial along the lesser than the greater curvature. The knob-like torus pyloricus at the pylorus of the pig is a normal structure. The tubular glands of the pyloric mucosa open into deep gastric pits that may extend half the thickness of the mucosa. The glands are lined by pale mucous cells, with interspersed endocrine elements, mainly G (gastrin) and D (somatostatin) cells. Scattered parietal cells may be present, especially in glands in the zone intergrading with fundic mucosa.

The stromal elements of the gastric lamina propria are relatively inconspicuous, in fundic mucosa in particular. Normally, a few lymphocytes and plasma cells, and scattered mast cells are present, mainly deep between glands. Occasional lymphocytic nodules or follicles may be present, usually near the muscularis mucosae. Lymphoid infiltrates are more common in antral mucosa. A thick band of amorphous hyalinized connective tissue, sometimes termed the *lamina densa*, is seen sporadically on the luminal aspect of the muscularis mucosae in the stomach of cats. The cause and significance are unknown.

Rapid fixation of the gastric mucosa is desirable to avoid postmortem artifacts.

Hydrolysis of protein in preparation for subsequent intestinal digestion and absorption is accomplished in the stomach by **acid** and by **pepsin**, activated by autocatalysis from pepsinogen at low pH. *Secretion of acid is the function of the oxyntic, or parietal cells*, about one billion of which are present in the stomach of a 20 kg dog. Regulation of the volume and acidity of gastric secretion is physiologically complex and highly integrated, involving neurocrine, endocrine, and paracrine mechanisms.

The parietal cell secretes hydrochloric acid in response to stimulation by histamine, acetylcholine, and gastrin. All three agonists are probably continuously present and involved in basal acid secretion. However, the effects of acetylcholine and gastrin are largely dependent on concurrent stimulation by the permissive agonist, histamine.

Histamine is a paracrine stimulant, continuously present in the environment of the oxyntic cells, and secreted by mast cells and enterochromaffin-like cells. Occupation of the H_2 histamine receptor on the oxyntic cell causes enhanced generation of cyclic adenosine monophosphate. This in turn stimulates protein kinase cascades culminating in translocation of the proton pump to the apical cell membrane, where acid is secreted.

Acetylcholine, the neurocrine agonist, is released near the oxyntic cell from processes of parasympathetic postganglionic neurons. Its release is enhanced by vagal activity during the central stimulation of the cephalic phase – the pavlovian response. Gastric distension also stimulates the parietal cell via vagovagal and short intramural reflex pathways. Acetylcholine acting on muscarinic M_3 receptors elevates intracellular Ca^{2+}, which stimulates acid secretion.

Gastrin is released into the bloodstream by G cells, many of which are in the pyloric antrum. Calcium, amino acids, and peptides in ingesta, impinging on G cells, stimulate gastrin release. Vagal stimulation during the cephalic phase, and fundic-pyloric vagovagal reflexes, in concert with local pyloric reflexes, initiated by distension, also cause G cells to release gastrin. Gastrin acts mainly by a receptor-mediated process to release histamine from the enterochromaffin-like cells. Gastrin alone is a weak stimulant of acid production, but it synergizes secretion by oxyntic cells exposed to histamine and acetylcholine. In addition, gastrin has an important trophic effect, increasing the number of parietal and endocrine cells in fundic mucosa. In turn, parietal cell mass seems to impact on chief cell differentiation.

Acid production during the gastric phase of secretion is depressed by the negative-feedback effect of acid in the antrum, through the inhibitory effect of somatostatin on the G cell below pH 3.0. Acid, fat, and hyperosmolal solutions in the proximal small intestine also inhibit acid secretion, perhaps by the mediation of neural reflexes, secretin, gastric-inhibitory polypeptide, epidermal growth factor, transforming growth factor-α, or other enterogastrones. Prostaglandin E_2 also inhibits acid production by parietal cells.

The chief cell is probably susceptible to the same general stimuli for secretion as the parietal cell.

Gastric motility is the outcome of an interaction among myogenic, hormonal, and neuronal factors, the latter two impinging directly or indirectly on smooth muscle. Mediating at least part of the neural component of this control system, by as yet uncertain mechanisms, are the interstitial cells of Cajal, pacemakers that are variously found between the layers of gastric smooth muscle, or among smooth-muscle cells.

Gastric mucosal barrier

The gastric mucosal barrier to acid backdiffusion and autodigestion resides largely in the *single layer of foveolar and surface mucous cells and its products*. Integrity of the gastric mucosal barrier implies continuity of the mucosal surface epithelium. The capacity of these cells to maintain tight junctions, to migrate rapidly to fill defects, and to secrete mucus, bicarbonate, and a hydrophobic phospholipid surface layer, is central to protecting the gastric mucosa against progressive injury by insults arising in the lumen.

Gastric mucus is freely permeable to hydrogen ions and has little innate buffering capacity, but it resists hydrolysis by intraluminal pepsin, protecting the integrity of the mucosal surface. Cardiac gland mucosa in the pig, and pyloric mucosa, secrete *bicarbonate* in considerable quantities, and normally resist acid attack. Fundic surface mucous cells also actively secrete bicarbonate into a thin unstirred layer of surface mucus. Bicarbonate and mucus secretion by mucous cells is stimulated by prostaglandin E_2. Acid is buffered by bicarbonate in the thin unstirred layer of mucus, preventing backdiffusion into the mucosa. In addition, the "alkaline tide" of bicarbonate, released into the gastric interstitial space during the course of acid secretion, further buffers the mucosa against acid backdiffusion.

Prostaglandins, particularly of the E series, ubiquitous in gastric mucosal lamina propria, may have protective effects other than by stimulation of bicarbonate and mucus secretion by mucous cells, and by inhibition of histamine-stimulated acid secretion by parietal cells. They cause proliferation, resulting in an increased mass of foveolar mucous epithelium. They may promote incorporation of surfactant molecules into the apical cell membrane of surface mucous cells, increasing its hydrophobicity and imparting greater resistance to water-soluble insults. They may also be involved in gastric mucosal cytoprotection by sulfhydryl compounds, which may neutralize free radicals and other toxic metabolites.

Prostaglandins and basal nitric oxide production cause vasodilation and increased blood flow, in addition to inhibiting acid secretion by parietal cells, and promoting bicarbonate secretion by foveolar mucous cells. The high metabolic rate of the gastric mucosa requires a high blood flow to maintain an intact, functional surface epithelium. Bicarbonate in the local circulation, resulting from the alkaline tide generated by acid secretion in glands deeper in the mucosa, is probably important in buffering the superficial lamina propria against backdiffusion of acid; adequate blood flow flushes injurious free radicals from the vicinity of surface cells. Experimentally, high blood flow is protective against many mucosal insults, whereas ischemia is ulcerogenic.

Epidermal growth factor, originating in salivary glands, and transforming growth factor-α, produced locally in the gastric mucosa, also appear protective, in that they may promote cell proliferation and migration to fill defects, and suppress acid production. Bombesin is probably protective through stimulation of gastrin-mediated nitric oxide release, promoting gastric mucosal blood flow.

Response of the gastric mucosa to injury

Restitution of acute erosive physical or chemical trauma to the mucosal surface is by rapid (minutes to hours) immigration of surviving attenuated surface and foveolar cells. Under the initial control of transforming growth factor-β and later influenced by epidermal growth factor, repair by proliferation of cells in the isthmus follows, if the erosive lesion is superficial and spares the progenitor cells. A cap of mucus, exfoliated epithelium, and fibrin over a mucosal defect may form a protective barrier conducive to effective restitution of the mucosal epithelium. An acute inflammatory reaction demarcates severely eroded or superficially necrotic mucosa, and hemorrhage may be evident on the surface and in adjacent mucosa. Mitoses become common in the upper gland.

During the early phase of repair, cells lining shallow foveolae and covering the surface are basophilic, poorly differentiated, and flattened, cuboidal, or low columnar. Sites of epithelial exfoliation and neutrophil transmigration or effusion into the lumen may be evident. Congestion, edema, mild neutrophilia, and fibroplasia are seen in the superficial lamina propria. The evolution and repair of gastric ulceration, to which erosion may be antecedent, are discussed later. The progenitor cells of the fundic mucosa have the potential to produce tall columnar mucous cells of the foveolar or surface type, to produce mucous neck cells, and by further differentiation, to evolve into parietal cells.

Atrophy of parietal cell mass without extensive mucous cell hyperplasia occurs in animals, particularly ruminants, which have signs of gastrointestinal disease, including *inappetence*. The change is not evident grossly. Microscopically, fewer parietal cells are seen in the upper neck of fundic glands, and often in the depth of the gland. This is accompanied by epithelial proliferation, indicated by moderate numbers of mitotic figures at the isthmus and in the neck of the gland. Mucous neck cells become the predominant cell in the upper gland. In extreme cases, mucous neck cells are present to the base of glands, and *achlorhydria* occurs. Similar findings occur in animals with a wide variety of syndromes involving loss of appetite. Starvation of moderate duration does not produce comparable lesions. This lesion may be the result of *reduced trophic stimulation of the fundic mucosa*, and is not to be confused with atrophic gastritis, in which loss of parietal cell mass and atrophy of mucosal thickness are accompanied by usually chronic inflammation.

Mucous metaplasia and hyperplasia of glands in the fundic stomach in all species are associated with *chronic inflammation* of the mucosa. As the lesion evolves, parietal cells seem to be lost at an accelerated rate, since they are only present in the basal portion of the glands, and they appear to be progressively displaced from above by hyperplastic mucous cells. Mitotic figures may be numerous throughout the neck of the gland, which elongates. The metaplastic epithelium in early lesions tends to resemble mucous neck cells. In established lesions, columnar mucous cells with regular nuclear polarity, similar to foveolar mucous cells, may be present. When inflammatory infiltrates are local, the mucous change is limited to a few surrounding glands. More diffuse inflammation is associated with the development of widespread epithelial mucous metaplasia. Focal or diffuse, superficial or mucosal, proprial infiltrates of plasma cells and lymphocytes are typical. Often, neutrophils, eosinophils, and Russell-body cells will be present in the lamina propria, and lymphocytes may be between epithelial cells in glands. Globule leukocytes may be present in the epithelium of glands, especially in the parasitized abomasum.

This mucous metaplasia, hyperplasia, and chronic inflammation is associated with a *variety of causes*, including chronic traumatic insults, such as those due to implanted foreign bodies, as well as in the abomasa of ruminants infected with lentiviruses. The specific agency most commonly recognized is *gastric parasitism by nematodes* such as *Ostertagia* spp., *Trichostrongylus axei*, *Hyostrongylus* spp., and *Ollulanus tricuspis*, where the distribution of the lesion is often closely related to the physical presence of nematodes and to the interstitial inflammatory reaction that they incite. Mucous metaplasia and hyperplasia are also typically present around the healing margins of chronic ulcers, perhaps in response to local inflammation.

The mucosa affected in these circumstances is grossly thickened, as on the overhanging margin of an ulcer, or in an *Ostertagia* "nodule," with a pebbled or convoluted surface if the lesion is widespread. Gastric rugae or plicae are thickened, partially as a result of mucosal hypertrophy, perhaps with submucosal edema. The surface of the stomach is usually paler than normal in affected areas; however, local congestion or hyperemia may be evident. Though the surface may be glistening, profuse mucus secretion is not usually obvious. *Achlorhydria* is the consequence of widespread change of this type. Mucous metaplasia and hyperplasia are differentiated from fundic atrophy associated with the loss of appetite on the basis of the degree of mucous cell hyperplasia and differentiation, and the presence of inflammatory cells.

The cause and functional significance of gastric mucous metaplasia are unclear. Presumably loss of parietal cells and hyperplasia of mucous neck cells is partly a response to soluble local immune-mediated stimuli or products of inflammation, since it is localized to the vicinity of glands containing larvae in gastric parasitism, but, as a general phenomenon, seems independent of parasite-specific factors. Tumor necrosis factor-α, interleukin-1, and interferon-γ are candidate cytokines involved in inflammatory mucous metaplasia of the fundic stomach. In vitro, interleukin-1β and tumor necrosis factor-α inhibit acid secretion by isolated parietal cells, and tumor necrosis factor-α induces apoptosis of parietal cells. Replacement of parietal cells by mucous neck cells, or an apparently more fully differentiated mucous cell in chronic gastritis, may be a protective response. It may eliminate the threat of local acid corrosion, and promote the transfer into the lumen of protective soluble factors such as lysozyme and IgA or its analogues.

Achlorhydria ensues in severe chronic gastritis and mucous metaplasia. The pH of gastric secretion approaches or exceeds neutrality under some circumstances, as sodium ion replaces hydrogen ion in gastric content and bicarbonate is secreted. With diminished gastric acid concentration, progressive microbial colonization of the stomach and upper intestine ensues. Parietal cell atrophy and replacement by mucous neck cells in ruminants with anorexia due to enteric disease may predispose to mycotic invasion of the mucosa, if it is physically disrupted. Mucous metaplasia and hyperplasia, as seen in chronic gastritis or conditions like ostertagiosis, do not seem to render the mucosa prone to mycosis. Loss of the hydrolytic effects of acid and pepsin, in achlorhydria, seems to have little effect on digestion of protein and uptake of nitrogen, at least in animals with ostertagiosis, and the effect on protein digestion of atrophic gastritis in humans appears to be minimal. Rather, at least in parasitic gastritis, inappetence diminishes nutrient intake on the one hand, while mucosal permeability permits protein-losing gastropathy; together, these impact on the nitrogen economy of the animal to cause reduced productive efficiency, or loss of body condition, depending on whether the animal enters negative nitrogen balance or not.

Evaluation of *gastric biopsies* is governed by the same caveats discussed below under interpretation of intestinal and colonic biopsies (p. 71). Gastritis, and the pathogenesis of gastrointestinal parasitism, are discussed later in this chapter.

Pyloric stenosis

Pyloric stenosis is a functional and sometimes anatomic problem, which in part represents probably the only *anomaly* of the stomach recognized in animals. It is relatively common in dogs, and rare in cats and horses.

Recurrent vomition and poor growth in recently weaned animals suggest the clinical diagnosis of a congenital lesion. Contrast radiographic studies will confirm *delayed gastric emptying*. There is limited critical functional information on this problem. An analogous condition in humans is associated with a lack of the interstitial cells of Cajal, but this association has not been clearly demonstrated in domestic animals, nor have morphological or significant immunohistochemical neural abnormalities been identified. In some dogs there may be hypertrophy of pyloric muscle, which appears grossly thickened. Tonic stenosis of the pyloric sphincter may occur in dogs, perhaps due to unconfirmed lesions of the myenteric plexus or due to gastrin excess. In cats, no gross alteration in the diameter of the pylorus or the thickness of its muscle is recognized. An association with esophageal dilation has been made in the cat. Congenital pyloric stenosis in a foal was associated with signs of abdominal pain and reluctance to consume solid feed. In all species, the clinical problem is usually abolished by pyloromyotomy.

Acquired functional pyloric obstruction may be a component of abomasal hypomotility, resulting in abomasal impaction, discussed below.

Acquired pyloric stenosis or obstruction due to physical causes occurs following ulceration, granulation, and stricture of the pyloric canal in any species; due to foreign bodies; as a complication of polyps and tumors in the area; and due to chronic hypertrophic pyloric gastropathy in dogs.

Chronic hypertrophic pyloric gastropathy is the term coined for a syndrome of pyloric obstruction in dogs, associated with *mucosal hypertrophy, hypertrophy of circular smooth muscle, or a combination of the two*. Mucosal hypertrophy alone is the most common lesion; muscular hypertrophy alone is the least common, though some degree of muscular hypertrophy is seen in about half the cases. Affected animals are typically of small breeds, and middle-aged or older. Males outnumber females. The pathogenesis is speculative, and it is not clear whether muscular hypertrophy is primary, as it seems to be in some cases, or whether it is secondary, in response to obstruction related to excess mucosa. Since mucosal and muscular lesions can be present independently, they may have separate causes. The mucosal hypertrophy has features in common with hypertrophic gastritis, described elsewhere. The cardinal presenting sign is *chronic intermittent vomition*, perhaps with weight loss, and with gastric distension in a few cases. Gross examination, by gastroscopy, at gastrotomy, or necropsy, in most cases reveals *enlarged mucosal folds* surrounding and obstructing the pyloric canal. This reflects hypertrophy of glands, which may involve foveolar or deeper glandular elements alone, or in combination, perhaps with cystic dilation of deeper portions of glands. There is usually a concomitant chronic inflammatory infiltrate in the mucosa and occasionally submucosa, and small erosions of the mucosal surface may occur. If there is muscular hypertrophy, this is reflected on the cut surface of the pylorus by irregular firm thickening of the circular muscle. Microscopically, smooth-muscle fibers in affected fascicles are irregularly hypertrophic. Recognition of smooth-muscle hypertrophy requires a full-thickness biopsy, which will not be obtained by endoscopy.

Gastric dilation and displacement

Gastric dilation in the horse is often *secondary* to obstruction of the small bowel, or of colic with ileus, and is also part of the syndrome "grass sickness," discussed elsewhere in this chapter. Ingestion of *Datura* sp. seeds, which contain a parasympatholytic alkaloid, can also cause ileus, leading to gastric dilation. *Primary gastric dilation* in horses is a sequel to consumption of excess fermentable carbohydrate, sudden access to lush pasture, or excessive intake of water. Dilation associated with intake of fermentable feed is likely analogous to grain overload in cattle. Ingesta may swell through absorption of saliva and gastric secretion. Evolution of gas and organic acids, including lactic acid, by bacterial fermentation of carbohydrate, occurs in the cranial portion of the stomach. An influx of water follows as the result of increased osmotic pressure in the stomach, contributing to increased distension and to systemic dehydration. Animals surviving for any time with acute gastric dilation of this type may develop laminitis.

Gastric rupture may follow primary or secondary dilation of the equine stomach; it may be idiopathic, in that no clear cause is identified. Gastric rupture is diagnosed in about 5% of horses with colic admitted to veterinary hospitals. Rupture usually occurs along the greater curvature, parallel to the omental attachment, releasing gastric content into the omental bursa or the abdominal cavity. Death ensues acutely as the result of shock and peritonitis. The margins of the laceration show evidence of antemortem hemorrhage, which differentiates the lesion from postmortem rupture of a dilated stomach. There may also be congestion of the cervical esophagus and blanching of the thoracic esophagus, producing a prominent "*bloat line*." This, and compression atelectasis of the lungs in some cases, attests to the tremendous increase in intra-abdominal and intrathoracic pressure exerted by the dilated stomach prior to rupture. **Perforation**, as distinct from rupture, of the stomach in the horse is rare, and is associated with parasitism, gastric ulcer, or neoplasia.

Gastric dilation and volvulus (Fig. 1.37) occur relatively commonly in dogs, and uncommonly in cats. In **dogs**, gastric dilation and volvulus are usually problems associated with eating, and probably aerophagia, especially in the *deep-chested breeds*, such as Great Danes, St. Bernards, Irish Setters, Wolfhounds, Borzois, and Bloodhounds. Predisposing factors are controversial but may include: increased laxity of the hepatogastric ligament; a diet of small food particles; recent kenneling; having a raised feed bowl; and infection with the nasal mite *Pneumonyssoides caninum*, which causes "reversed sneezing."

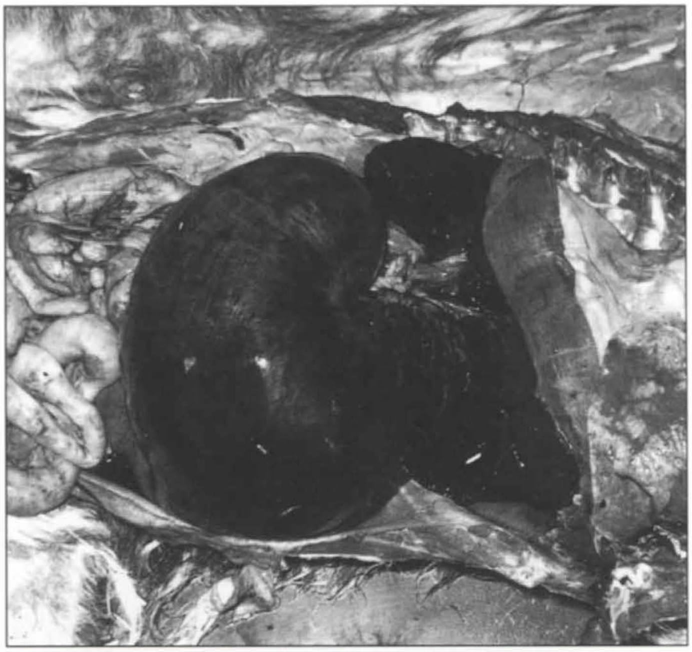

Figure 1.37 Gastric volvulus in a dog. The stomach has undergone venous infarction due to strangulation of its vascular outflow, and is extremely distended and congested.

The gas that contributes to the development of dilation is probably the result of aerophagia, and possibly the evolution of carbon dioxide by physiologic mechanisms. Inability to relieve the accumulation of food, fluid, and gas in the stomach causes the organ to dilate and alter its intra-abdominal position, so that its long axis rotates from a transverse left–right orientation to one paralleling that of the abdomen. In simple dilation, the esophagus is not physically completely occluded, the spleen remains on the left side, and the duodenum is only slightly displaced dorsally and toward the midline. Repeated episodes of gastric dilation probably compromise splenic venous return during periods when the stomach is distended, and eventually lead to episodes of splenic ischemia and segmental infarcts.

For reasons that are unclear, gastric dilation may be converted to gastric volvulus. The stomach rotates about the esophagus in a clockwise direction, as viewed from the caudal aspect. The greater curvature of the distended organ moves ventrally and caudally, and then rotates dorsally and to the right. This forces the pylorus and terminal duodenum cranially to the right and clockwise around the esophagus. Ultimately they lie to the left of midline across and ventral to the esophagus, compressed between the esophagus and the dilated stomach. Depending on the degree of volvulus, the *spleen*, which follows the gastrosplenic ligament, usually ends up lying in a right-ventral position, between the stomach and liver or diaphragm. It is bent into a "V" shape by tension on its ligaments, becomes extremely congested, and may undergo torsion, infarction, and rupture. The esophagus becomes completely occluded in volvulus, which may involve rotation of up to 270–360°. Venous infarction of the gastric mucosa ensues, as volvulus progressively constricts outflow of blood from the stomach. The mucosa, and usually the full thickness of the gastric wall, are edematous and dark red to black, and there is bloody content in the lumen of the stomach. Ischemic mucosa becomes necrotic, and the stomach may rupture. Hemoperitoneum may occur, due to avulsion of gastric blood vessels.

Obstruction of veins by volvulus, and pressure exerted by the distended stomach, result in decreased venous return via the portal vein and caudal vena cava, causing reduced perfusion of intra-abdominal organs, reduced cardiac output, and *circulatory shock*. Increased intra-abdominal pressure impinges on the diaphragm and compromises respiration. A variety of acid–base and electrolyte abnormalities ensue in dogs with gastric dilation and volvulus, contributing to the physiologically precarious state. Cardiac arrhythmias as a sequel to gastric dilation and volvulus have been associated with putative release of *myocardial depressant factor* from an ischemic pancreas, and with myocardial necrosis, resulting from ischemia. Death is inevitable in dogs with acute gastric volvulus that are not treated early. Rare cases of chronic gastric volvulus are reported, with fixation of the spleen in the right side of the abdomen by omental adhesions.

In **swine**, gastric volvulus is a cause of sudden death in *adult sows*, perhaps with a brief premonitory period of anorexia, abdominal distension, dyspnea, and salivation. It is associated with excitement in anticipation of feeding among pigs that are fed at regular, often long, intervals, and may be a sequel to unduly rapid ingestion of feed, water, and air. The twist may occur in either direction about the long axis of the stomach, though clockwise torsion predominates.

Abomasal displacement and volvulus is a common clinical problem in high-producing, intensively managed **dairy cattle**, particularly around the time of parturition, but it also occurs in animals that are predominantly pasture-fed. *The displacement is usually ventrally and to the left of the rumen*. Many affected animals have concurrent problems, including ketosis, hypocalcemia, metritis, and retained placenta. Affected abomasa have decreased sensitivity to acetylcholine, and abomasal atony has been implicated as a prerequisite to displacement. Evolution of gas in the abomasum is directly related to the amount of concentrate in the ration. Left displacement of the gas-filled abomasum is amenable to treatment, and is rarely encountered at autopsy. Handling of an affected animal postmortem may correct displacements in any case. Other than possible scarring of the lesser omentum, the abomasum may be unremarkable. *Abomasal fistulae*, draining in the right paramedian area, may ensue if, during abomasopexy to prevent recurrent displacement, nonabsorbable sutures fixing the abomasum to the abdominal wall penetrate the abomasal mucosa.

Simple right displacement, which accounts for about 15% of abomasal displacements, is probably caused by similar agencies. However, right displacement may be complicated in about 20% of cases by progression to abomasal volvulus, which is clinically serious.

Abomasal volvulus is probably the sequel to rotation of a loop formed by a distended abomasum and attached omasum and duodenum. The volvulus is counterclockwise about a transverse axis through the lesser omentum, when viewed from the right side.

Rotation, buoyed by the gas-filled body of the abomasum, may be in the sagittal plane. With a 360° volvulus, the pylorus ends in the cranial right portion of the abdomen dorsal to the twisted omasum, with the duodenum trapped medial to the omasum and lateral to the partially rotated reticulum (Fig. 1.38). Alternative modes of displacement and rotation are possible, but all may end in this relationship.

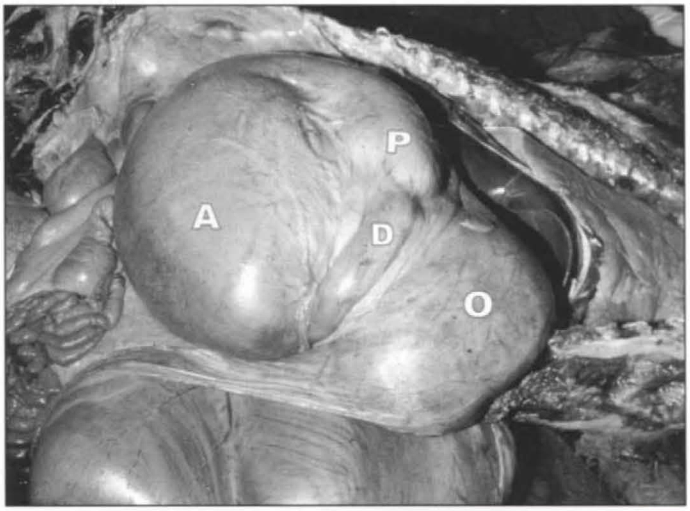

Figure 1.38 Right displacement/volvulus of abomasum. Pylorus in upper right quadrant of abdomen, with duodenum trapped between omasum laterally and reticulum (not visible) dially. A, body of abomasum; P, pylorus; D, duodenum; O, omasum.

Obstruction of duodenal outflow in volvulus results in sequestration of chloride in the abomasal content and the development of *metabolic alkalosis*. Severe volvulus causes obstruction of blood vessels at the neck of the omasum, as well as causing trauma to the vagus nerves in the region. The abomasum becomes distended with blood-stained fluid and gas. Infarction of the deeply congested mucosa may result in ultimate *abomasal rupture*, often near the omasoabomasal orifice, and peritonitis. Damage to the vagal branches may prohibit return of normal abomasal motility in animals successfully withstanding surgery, resulting in vagus indigestion. Cases of abomasal torsion are also occasionally reported in preruminant calves; these are usually fatal.

Sarcina-like bacteria have been associated with abomasal diseases in **lambs**. Pathologic findings include various combinations of abomasal bloat, hemorrhage, and ulcers.

Gastroesophageal intussusception, gastroduodenal intussusception, and **pylorogastric intussusception** are uncommon displacements, involving the stomach of dogs with signs of upper alimentary tract obstruction that require surgical correction.

Gastric foreign bodies and impaction

A variety of **foreign bodies** may be encountered in the stomach and in the abomasum. Most are incidental findings, or at worst, associated with vomition, mild acute or chronic gastritis, or occasionally with ulceration. *Trichobezoars* (hairballs) are often found in the stomach of long-haired cats, and in calves reared on diets low in roughage, where most are in the rumen, with a few in the abomasum. *Phytobezoars* and trichophytobezoars have been implicated as the cause of pyloric obstruction and death in young lambs on pasture and, in some regions, in cattle grazing fibrous plants. *Fine sand* may accumulate in the abomasum in considerable amounts, usually with no detrimental effect.

Gastric impaction by inspissated content in horses is related to factors such as consumption of fibrous roughage and persimmons, inadequate water intake, and poor mastication. It may cause anorexia, mild colic, and loss of body condition, and is to be differentiated clinically and at autopsy from gastric impaction secondary to pyrrolizidine alkaloid poisoning, from dilation secondary to intestinal obstruction, and from primary gastric dilation.

Primary abomasal impaction in cattle may result from restricted water intake and coarse, high-roughage feed, such as wheat stubble or straw. Secondary abomasal impaction may follow pyloric stenosis, physical or functional, of any cause. It is perhaps most common as a functional abomasal stasis in one of the manifestations of "*vagus indigestion.*" Loss of abomasal motility may be the product of intrathoracic inflammatory or neoplastic vagal lesions; vagal involvement in adhesions following traumatic reticuloperitonitis; vagal trauma in surgically corrected abomasal volvulus; adhesions of the abomasum and omasum that may physically impair motility; or systemic disease that causes abomasal stasis.

The abomasum is impacted with thick porridge-like or inspissated coarse fibrous digesta, despite an apparently patent pylorus. **Abomasal rupture** may ensue, particularly in primary impaction associated with coarse feed, resulting in diffuse peritonitis. Most commonly, the laceration is near the omasal–abomasal orifice, but it may be elsewhere. Omasal dilation and ruminal distension are also found in many of these cases; omasa usually contain inspissated digesta, while rumen content tends to be fluid. Metabolic derangement due to sequestration of chloride in the rumen following regurgitation from the obstructed abomasum, and hypokalemia due to decreased intake in feed in the face of continued normal renal excretion, place these animals in perilous physiologic circumstances, often before inanition becomes a significant factor.

A syndrome known clinically as **abomasal dilation and emptying defect** occurs in Suffolk and Hampshire **sheep**. The animals develop chronic inappetence and weight loss, and at necropsy they have a markedly distended abomasum containing digesta resembling rumen contents. No morphologic gross or microscopic lesions of the stomach, vagus nerve, or other organs have been found, except scattered chromatolytic and necrotic neurons in the celiacomesenteric autonomic ganglion. The cause is unknown, but it is suggested that it may be an acquired dysautonomia, possibly toxic, requiring a genetic predisposition for expression. Though rumen chloride levels are elevated, few animals become hypochloremic and alkalotic, as do cattle with abomasal impaction.

Circulatory disturbances

Edema of the gastric rugae occurs with hypoproteinemia in any species, in portal hypertension, and is found in the abomasum of cattle poisoned by arsenic, and sheep ingesting tannic acid. Edema fluid collects in the submucosa of the folds, and is particularly obvious in the normally thin abomasal plicae. Edema may contribute to the thickening of rugae seen in gastritis. Edema of the submucosa of the stomach is a common and important lesion in edema disease of swine. It is best appreciated by making several slices through the serosa and external muscle to the submucosa on the greater curvature over the body of the stomach. Edema disease is considered fully in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Hyperemia of the gastric mucosa occurs with ingestion of chemicals, which usually also cause superficial erosion and necrosis, discussed later under chemical gastritis. Focal hyperemia may be related to local irritation of the mucosa by foreign bodies, and with focal acute viral lesions of the abomasum in cattle. **Congestion** of the mucosa can occur in conditions causing portal hypertension, including cirrhosis and shock in the dog.

Uremic "gastritis," seen as severe congestion and hemorrhage of the body of the stomach, associated with signs of hematemesis and melena, is found in some dogs, and occasionally in cats and horses, with renal disease. In such animals, the mucosa is thickened and deep red-black. Lesions vary in severity from case to case, and premonitory changes without severe hemorrhage and necrosis are present in animals euthanized earlier in the course of disease. In such dogs there may be no gross gastric lesion, or variable edema and thickening of rugal mucosa, perhaps with focal ulceration, is evident.

Microscopically, the lamina propria between glands is edematous, and there are increased mast cells. Deposits of basophilic ground substance and mineral are found, especially on the basement membrane of vessels and glands, or on collagen fibrils and in degenerate smooth muscle. These changes occur particularly in the middle and deeper portions of the mucosa. Parietal cells in this area are usually mineralized as well. Such mineral deposits may be seen at autopsy in gross cross-sections of mucosa. More extensive mineral deposition also involves the muscular coats and arterioles of the submucosa and serosa. Such vessels also show evidence of endothelial damage, medial necrosis, and, in some cases, thrombosis. Severe mucosal congestion, edema, and necrosis are possibly related to ischemia secondary to the vascular lesions, though perhaps not directly associated with arterial thrombosis and obstruction, which is often not readily found. Microvascular lesions in the lamina propria, and systemic states in uremia, may be contributory. Impaired renal degradation and excretion of gastrin promote hyperchlorhydria, exacerbating mucosal damage.

The cause of the vascular lesions may be a poorly characterized circulating toxic peptide associated with uremia. Mineral deposition is probably the product of altered systemic metabolism of calcium in renal failure, perhaps coupled with the local microenvironment resulting from bicarbonate moving across the basal border of secreting parietal cells. Membrane lesions in metabolically compromised parietal cells may also act as foci of mineral deposition (see Vol. 2, Urinary system, for a discussion of uremia). Mineralization is also a feature of vitamin D intoxication.

Gastric venous infarction is a common lesion in swine, and is also encountered in ruminants and horses. It is related to endothelial damage and thrombosis in venules, usually associated with *endotoxemia or other bacterial or toxic damage*. Salmonellosis and *Escherichia coli* septicemia in all species, and in addition, in swine, postweaning coliform gastroenteritis, erysipelas, swine dysentery, and Glasser's disease are associated with the lesion. The fundic mucosa is bright red or deep red-black and may have excess mucus or perhaps fibrin on the surface. Occasionally the superficial mucosa is obviously necrotic, adopting a yellow-brown caseous appearance, and may lift off with the ingesta. In section there is thrombosis of venules in the mucosa and often at the mucosal–submucosal junction, usually with prominent fibrin plugs. Thrombosed capillaries and venules may be present at any level of the mucosa, along the base of the ischemic zone of superficial coagulative necrosis, with local hemorrhage and edema. There may be an acute inflammatory reaction delineating the necrotic area in the mucosa. Sometimes the full thickness of the gastric mucosa, focally or diffusely, may be necrotic.

Gastritis

Gastritis is a term used clinically as a presumptive diagnosis for those cases of vomiting that are thought to arise from gastric irritation rather than disease elsewhere. In pathology, the term is often used with equal imprecision, referring to a wide range of gastric injury in which histologic criteria of inflammation may not be particularly prominent. Under the broad umbrella of "gastritis" fall several different types of lesions: gastric mucosal necrosis, erosion or ulceration caused by mechanical, chemical, or ischemic insults, among which is "uremic gastritis," described earlier; true gastritis, in which the lamina propria contains the leukocytic and vascular changes characteristic of inflammation; and finally, lesions of gastric mucosal atrophy, fibrosis, and lymphofollicular hyperplasia that arguably are the residual lesions of previous active inflammatory disease.

Chemical gastritis or abomasitis, reflected in diffuse gastric congestion, hemorrhage, necrosis, and ulceration, may be induced by chemicals such as arsenic, thallium, formalin, bronopol, steroidal and nonsteroidal anti-inflammatory drugs, phosphatic fertilizers, and by the toxic principal in bitterweed (*Hymenoxon odorata*). **Blister beetle (*Epicauta* spp.) intoxication in horses**, induced by the cantharidin contained in these insects, may cause necrosis and ulceration of the distal esophagus and pars esophagea, and intense hyperemia of the glandular mucosa of the stomach, and in some cases gastric ulcers and rupture. In addition, enterocolitis, nephrosis, hemorrhages of the urinary bladder, and myocardial hemorrhage and necrosis are reported with regularity in blister beetle toxicosis. **Zinc** may cause acute mortality, in which the mucosa of the abomasum and duodenum is a distinctive lime green and necrotic, with an underlying congested, edematous submucosa. Microscopically, radiating crystals are evident in the necrotic tissue. Subacute zinc intoxication may be reflected in abomasal damage characterized by exfoliation of glandular epithelium, ablation of glands in some areas, and reparative proliferation of mucous neck cells, in addition to fibrosing pancreatitis and mild nephrosis. **Mechanical "gastritis"** is most commonly seen in dogs after ingestion of coarse foreign materials and in cats with hairballs. The lesion is discovered as an incidental finding when careful clinicians biopsy the stomach via endoscopy when making the diagnosis of gastric foreign body, or at the time of surgical removal of that foreign material. Hairballs in the abomasum of ruminants are associated with lack of roughage in young animals, but virtually never with disease.

Eosinophilic infiltrates occur in the squamous stomach of horses with an eosinophilic epitheliotropic syndrome, discussed in the section on eosinophilic enteritis in horses, below, and with dermatitis.

The majority of examples of genuine gastritis are seen in dogs and cats with more generalized gastrointestinal inflammatory disease, such as food allergy or idiopathic inflammatory bowel disease, and will be discussed further with those topics (see section on Idiopathic inflammatory bowel disease, below).

Infectious agents in small animals appear to be minor causes of gastritis, when compared with chemical, mechanical, or idiopathic insults. Following the discovery of *Helicobacter pylori* as a major cause of gastric ulceration in humans, there was a flurry of activity to document its significance as a cause of gastritis and/or gastric ulceration in other monogastric species. The picture that has emerged is a confusing one because of substantial flux in the taxonomy of the various gastric spiral organisms, and because of the existence of many different species of *Helicobacter* (only some of which have been successfully cultivated). At least 20 different *Helicobacter* species, distinguished by mRNA sequencing, have been reported from various mammalian species. It is safe to say that probably all mammals have one or more species of *Helicobacter* as part of the normal gastric flora, and thus determining a causal relationship between *Helicobacter* and gastric disease has proven very difficult.

Helicobacter pylori is a common cause of acute and chronic gastritis affecting antrum, corpus, or both, in humans and in other primates. In humans it is the leading cause of chronic peptic ulcers. This may progress in some cases to gastric mucosal atrophy, with loss of antral and/or oxyntic glands. Chronic *Helicobacter* infection in humans also significantly increases the risk for the development of gastric carcinoma and lymphoma. On the other hand, *H. pylori* appears to be a very uncommon infection in other species, and has never been proven to cause disease in nonprimates. Among nonprimates, the most convincing evidence for clinically significant gastric *Helicobacter* infection is in ferrets. Although virtually all adult ferrets have *H. mustelae* as part of the normal gastric flora, heavily colonized ferrets develop diffuse lymphocytic-plasmacytic gastritis with lymphofollicular hyperplasia and sometimes with erosions. Progression to neoplasia has not been documented.

The role of Helicobacter in the development of gastritis or gastric ulceration in other species has not been convincingly documented. Claims for the significance of *Helicobacter acinonychis* as a cause for gastritis in captive cheetahs remain unproven, in that antibiotic treatment improves the clinical disease but does not eradicate the gastric *Helicobacter* infection. Furthermore, wild cheetahs have the same *Helicobacter* colonization, but not the gastritis. In dogs and cats, it is routine to see various spiral organisms colonizing the gastric surface and within canaliculi in parietal cells in normal animals and in those with gastrointestinal disease. Depending on detection methods, the prevalence of colonization is at least 50% and may be nearly universal in adults. The prevalence of such colonization as determined by direct visualization or by culture is as high in clinically healthy animals as in those with clinical signs of gastritis. On the other hand, there are several studies claiming that dogs or cats with natural or experimental *Helicobacter* infection have a higher prevalence of mucosal mononuclear leukocytes and mucosal lymphoid follicles, and faster mucosal turnover, than is seen in animals in which *Helicobacter* infection could not be demonstrated. The problem is that the modest histologic changes have not been correlated with the development of clinical disease. The changes described resemble the kind of changes seen elsewhere in the intestinal tract with, for example, acquisition of the normal flora by germfree animals, or even as part of normal "immunologic" maturation of the gastrointestinal tract. Improvement in clinical signs following antibiotic therapy appropriate for the elimination of *Helicobacter* has not been documented convincingly.

Chlamydophila have been recognized in surface mucous cells of otherwise normal fundic mucosa in cats with no signs of disease. Experimental infection produced conjunctivitis, respiratory disease, but only mild gastritis.

Gastric mucosal hypertrophy is an occasional lesion within the stomach of *dogs*. It may be focal or diffuse. The **focal lesion** is much more prevalent, occurring as an intraluminal papillary proliferation of pyloric antral mucosa causing clinical signs of pyloric obstruction. The proliferation is mostly by mucus-containing cells of the mucosal surface and foveolae, forming papillary projections supported by a lamina propria that is either normal or that contains an increase in plasma cells and eosinophils. The significance of the eosinophilic inflammation in causing the regional mucosal hypertrophy is unknown, but many examples do not have any change in mucosal leukocytes. Surgical excision is curative. The diagnosis is usually obvious on the basis of endoscopic examination. Endoscopic biopsies may or may not permit the diagnosis, depending on the depth of mucosa captured by the biopsy forceps. The key to the diagnosis in an endoscopic biopsy is that *the entire depth of the sample is taken up by surface epithelium and foveolae*, whereas in a normal stomach a biopsy of similar size would capture at least some of the deeper gastric pyloric glands.

Diffuse gastric mucosal hypertrophy (chronic hypertrophic gastritis), similar in many respects to Ménétrier's disease in humans, is rare. Vomition and weight loss, in some cases associated with inappetence or diarrhea, are described in the history. The characteristic lesion is marked gastric rugal hypertrophy involving part or most of the fundic gland mucosa in the body of the stomach. Grossly thickened folds of mucosa over an area 4–10 cm in diameter are thrown up in a convoluted pattern that may resemble cerebral gyri.

Microscopically, these areas are composed of hypertrophic/hyperplastic mucosa that may or may not include secondary folds of muscularis mucosae and submucosa. Findings are variable in the few cases reported. There may be foveolar and glandular epithelial hyperplasia with progressive or total loss of parietal cells, which are replaced by mucous cells of various degrees of differentiation. Marked cystic dilation of mucous glands may occur, which may be evident grossly. Mononuclear cells infiltrate the lamina propria between glands and near the muscularis mucosae, and the propria may be edematous, especially superficially. If the gross appearance of the mucosa in animals with hypertrophic gastritis is not seen by endoscopy or at surgery, biopsies that do not sample the full thickness of the mucosa may be misdiagnosed as chronic superficial or diffuse gastritis.

The cause of chronic hypertrophic gastritis is unknown, but in part it may be mediated by immune events in the mucosa. The condition in humans is associated with protein-losing gastropathy. Significantly, chronic gastritis and chronic hypertrophic gastritis have been reported in the Basenji, a breed of dog in which a syndrome of protein-losing gastroenteritis and diarrhea is well recognized (see Idiopathic inflammatory bowel disease, below).

Hypertrophic antritis, producing a thickened, sometimes convoluted, mucosa in the antrum, is part of the syndrome of chronic hypertrophic pyloric gastropathy, associated with pyloric stenosis in dogs, considered earlier. Etiologic factors are unknown.

Braxy, or bradsot, is an acute abomasitis of sheep and, less commonly, calves, due to infection with *Clostridium septicum* (Fig. 1.39). It is a sporadic disease of young animals, usually occurring in cooler climates. It is reported from many temperate parts of the world. The factors initiating bacterial invasion are unknown, though local tissue damage in the abomasum is implicated. Cold weather is usually associated with the disease, but it is difficult to imagine feed being cold enough, by the time it attains the abomasum, to cause significant mucosal trauma or hypothermia and necrosis. Production of exotoxin by *C. septicum* causes the signs and death, which usually ensues quickly. A similar gastritis has been associated with *C. sordellii* infection.

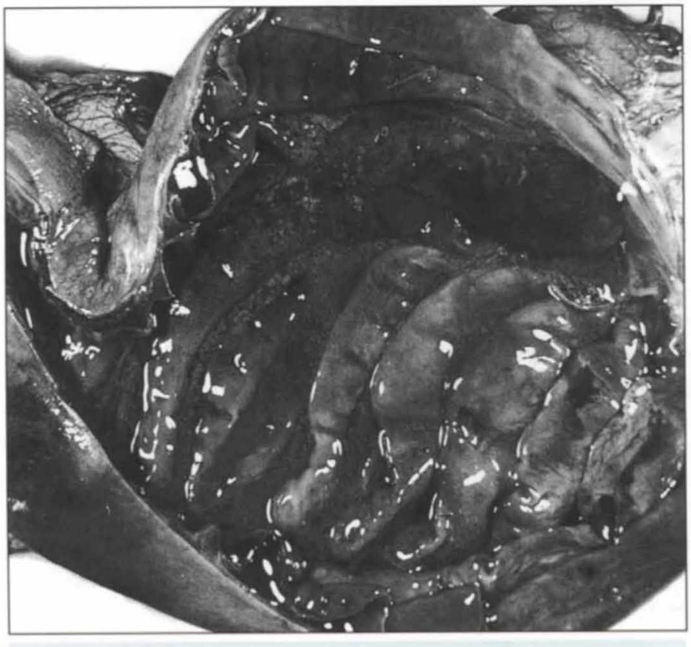

Figure 1.39 Braxy-like **clostridial abomasitis** (*Clostridium septicum*) in a calf. (Courtesy of M Bergeland.)

At autopsy there may be blood-tinged abdominal fluid and the serosa of the abomasum may be congested or fibrin-covered. Mucosal lesions may be diffuse, or involve demarcated foci of variable size and shape. Abomasal folds may be thickened, reddened, and occasionally hemorrhagic or necrotic. Most notable is the presence of extensive gelatinous edema and emphysema in the submucosa. Diffuse edema, and extensive areas of suppurative infiltrate demarcating areas of coagulative necrosis, with prominent pockets of emphysema, are evident in tissue sections. These involve mainly submucosa, and extend into adjacent mucosa and external muscle. There may be venous thrombosis and hemorrhage. Gram-positive bacilli are usually evident as individuals or colonies in affected tissue.

C. perfringens type A has been associated with a syndrome of **tympany, abomasitis, and abomasal ulceration in calves** in the western USA. Animals have abdominal tympany and pain, depression, or may die suddenly. Grossly, there is variable congestion, hemorrhage, erosion, and ulceration of the abomasal mucosa, usually in the fundic area. Circular or linear perforating ulcers may develop. In association with the expected microscopic changes in erosion or ulceration, there is exfoliation and necrosis of mucosal epithelium, edema of the submucosa, dilation and thrombosis of submucosal lymphatics, and mild acute inflammatory infiltrates in the submucosa. Gram-positive bacilli may be on the mucosal surface, or in inflamed submucosa. Proliferation of *C. perfringens* in the rumen of calves with overflow of milk from the reticular groove is believed to promote colonization of the abomasum, and production of necrotizing exotoxin. In both calves and lambs, clostridial gastritis may be preceded by the development of superficial peptic micro-ulcers, which subsequently become colonized and progress to typical clostridial lesions.

Abomasitis associated with viral infection occurs in a number of the systemic viral diseases affecting the gastrointestinal tract, including infectious bovine rhinotracheitis in calves and, rarely, older animals, herpesviral infections of small ruminants, bovine viral diarrhea, rinderpest, malignant catarrhal fever, and bluetongue. Abomasal lesions are rarely the sole manifestation of these diseases, but form part of a picture at autopsy that may suggest an etiologic diagnosis. The appearance and pathogenesis of abomasitis in these diseases vary with the conditions (see Infectious and parasitic diseases of the alimentary tract, later in this chapter).

Mycotic gastritis or abomasitis is a sporadic problem almost invariably secondary to insults that cause achlorhydria, focal atrophy, necrosis, or ulceration under conditions where mycotic colonization can occur. Compromised resistance, perhaps associated with endotoxemia, septicemia, endogenous or exogenous steroids, neoplasia, lympholytic viral disease, and altered gastrointestinal flora due to antibiotic therapy, may further promote mycosis. Fungal hyphae attaining the submucosa typically invade venules and arterioles, causing *thrombosis and hemorrhagic infarction*. The agents involved are usually zygomycetes (phycomycetes) such as *Rhizopus, Absidia*, or *Mucor*; rarely, *Aspergillus* may be implicated. The lesions are areas of necrosis, with an intensely congested or hemorrhagic periphery, ranging in diameter from 1 to 2 cm, to confluence over much of the body of the stomach (Fig. 1.40A). Affected mucosa is thickened, red or pale in the necrotic zone, and may be covered by hemorrhage. Edema and hemorrhage are evident in the submucosa. The lesion may penetrate to the serosa where it is typically seen as a roughly circular area of hemorrhage in the external muscle and subserosa. *Hyphae*, usually broad

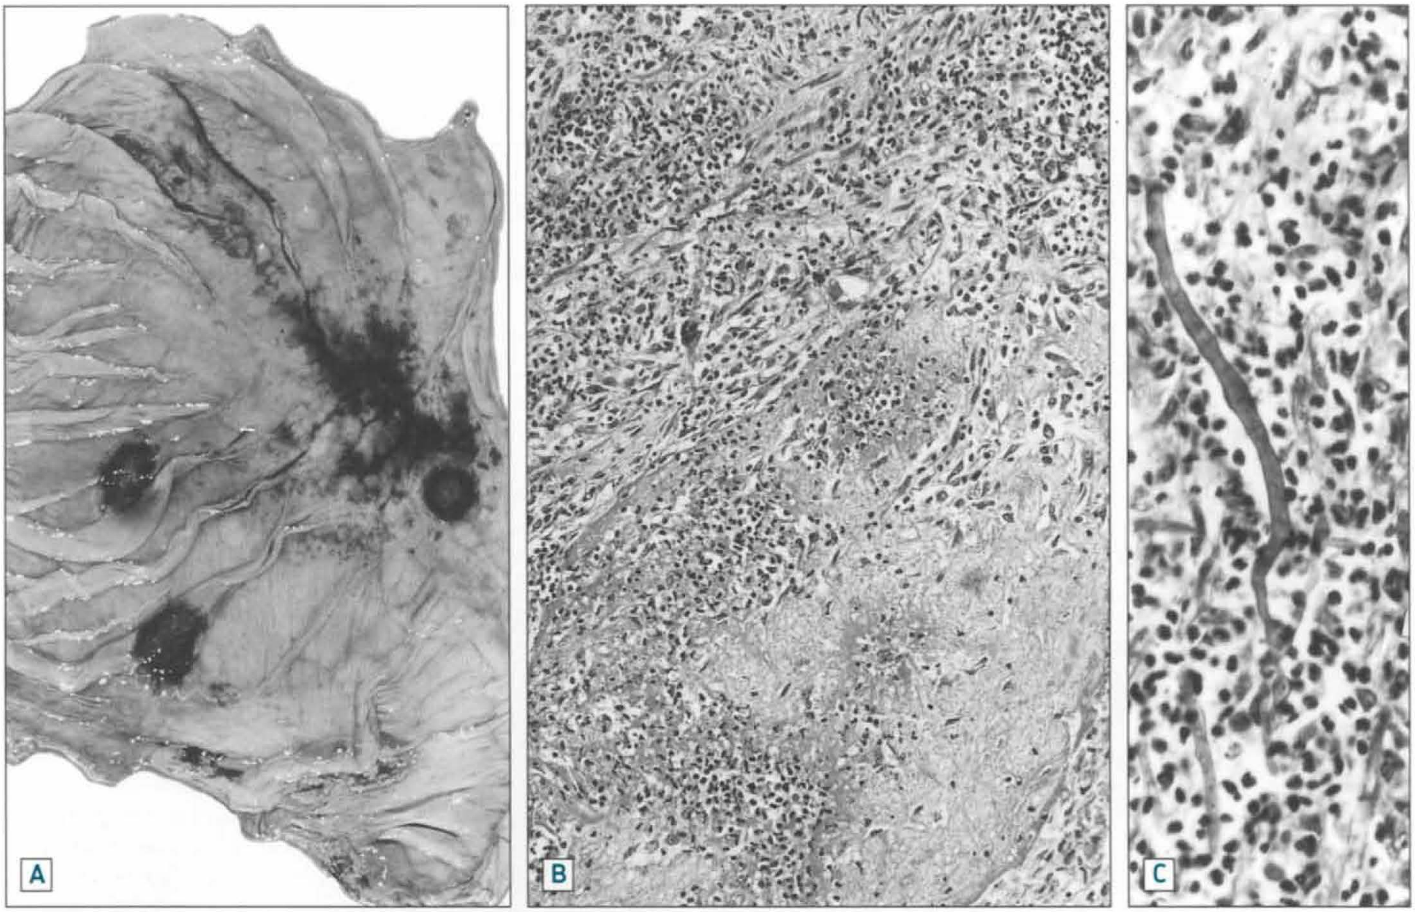

Figure 1.40 Mycotic abomasitis in a calf. **A.** Focal lesions are surrounded by deep red areas of infarction and hemorrhage due to thrombosis of mucosal and submucosal vessels. **B. Thrombosis** of a venule in submucosa of abomasum due to hyphal invasion. **C.** Nonseptate **hyphae** of zygomycete invading the submucosa.

and nonseptate zygomycotic in type, are present in sections of the necrotic mucosa, submucosa, and invading vessels, where they initiate thrombosis (Fig. 1.40B, C).

Candidiasis of the pars esophagea may occur in swine, often in association with preulcerative epithelial hyperplasia and parakeratosis. For an overview of mycosis of the digestive system, and its sequelae, see the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Parasitic gastritis is generally of little significance in small animals. Members of the genera *Physaloptera* and *Gnathostoma* are found in dogs, where the former cause focal ulceration and the latter are the cause of submucosal inflammatory cysts containing suppurative exudate and worms. In cats, *Physaloptera* spp. may attach to mucosal ulcers, whereas *Gnathostoma* spp. and *Cylicospirura felineus* are found in nodules in the gastric wall. *Ollulanus tricuspis* is found on the mucosa of the stomach in cats, where it may cause mild to, rarely, severe chronic gastritis. *Cryptosporidium* infection of the gastric mucosa occurs rarely in cats, with uncertain significance.

In horses, *Draschia megastoma* is found in inflammatory nodules in the submucosa of the cardiac zone, especially along the margo plicatus. *Habronema muscae* and *H. majus* are found on the mucosa and have been associated with mild ulceration. *Trichostrongylus axei* may cause chronic gastritis in the horse. Bots of the genus *Gasterophilus* are found attached to small erosions and ulcers in the esophageal and glandular mucosa, which very rarely become complicated or perforate.

In swine, the spirurids *Ascarops* spp., *Physocephalus* spp., and *Simondsia* spp. are associated with mild gastritis in heavy infections. *Gnathostoma* may be embedded in inflammatory cysts in the submucosa. *Ollulanus tricuspis* may be encountered. *Hyostrongylus rubidus* can cause chronic gastritis and wasting in pigs.

In cattle, sheep, and goats, members of the genera *Haemonchus* and *Mecistocirrus* are large abomasal blood-sucking trichostrongyles, capable of causing severe anemia and hypoproteinemia. *Ostertagia* spp. and related genera, including *Camelostrongylus, Teladorsagia, Marshallagia,* and *Trichostrongylus axei*, in various ruminants, cause chronic abomasitis with mucous metaplasia, achlorhydria, diarrhea, and plasma protein loss. *Cryptosporidium* sp. occasionally causes subclinical abomasitis in cattle, associated with mucosal hypertrophy, attenuation of epithelium lining the neck of fundic glands, and dilation of glands. The small basophilic organisms are present on the surface of epithelium from the base of glands to the mucosal surface. Large schizonts of undetermined coccidia in sheep and goats produce harmless pinpoint pale foci in the abomasal mucosa; the name *Eimeria (Globidium) gilruthi* has been applied. Gastric parasitism is considered more fully in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Gastroduodenal ulceration

Gastroduodenal ulcer produces signs much less often in animals than in humans. The pathogenesis of **peptic ulcer** in both humans and animals in general seems to resolve into a relative imbalance between the necrotizing effects of gastric acid and pepsin on one hand, and the ability of the mucosa to maintain its integrity on the other. Impairment of mucosal integrity in the face of normal acid secretion is probably the predominant mechanism, although there are clear instances when hypersecretion of acid is causative.

Factors implicated in hypersecretion of acid include abnormally high basal secretion, possibly associated with an expanded parietal cell mass, perhaps the result of increased trophic stimulation by gastrin. Gastrinomas cause *Zollinger–Ellison syndrome*, characterized by elevated gastric acid secretion and severe gastroduodenal ulceration. Increased histamine levels associated with mastocytosis or mastocytoma also cause acid hypersecretion and ulceration.

Ulceration due to compromise of mucosal protective mechanisms is attributed to *nonsteroidal anti-inflammatory drugs* (NSAIDs), such as aspirin, phenylbutazone, and indomethacin. Orally administered NSAIDs that are weak organic acids, such as aspirin, have a direct deleterious effect on the stomach. Active bicarbonate secretion is responsible for a pH gradient from acid in the lumen to near neutrality at the epithelial cell surface. Stimulation of this bicarbonate secretion is induced by prostaglandin E_2 and nitric oxide. Inhibition of bicarbonate secretion occurs in the presence of atropine and various NSAIDs. Phenylbutazone may also have a direct toxic effect on vascular endothelium in the mucosa, which compromises circulation and predisposes to ulceration.

In humans, gastritis associated with *Helicobacter pylori* infection, and duodenal colonization with this agent, are associated with development of duodenal ulcer. *Helicobacter*-associated gastritis extending cranially in the stomach is associated with gastric ulcer. Similar associations between *Helicobacter* infection, gastritis, and peptic ulcer have not been demonstrated convincingly in domestic animals.

Reflux of duodenal contents containing bile salts has been implicated in the induction of gastritis and gastric ulcer. Under some experimental conditions, acid backdiffusion into the gastric mucosa, and morphologic damage, have been caused by the application of bile salts. The effects are dependent on the pK_a of the bile salt, which must be soluble at acid pH, and on the concentration of hydrogen ion. Lipid solubility of bile salts, and associated damage to surface cell membranes, may mediate these effects. Alcohols, also lipid-soluble compounds, alter permeability of gastric mucosa and permit backdiffusion of acid. Lysolecithin, formed when pancreatic lipase hydrolyzes lecithin in bile, increases gastric mucosal permeability too.

Glucocorticoids and "*stress*" have been implicated in the genesis of ulcer, though the role of steroids is controversial. Experimentally, gastroduodenal hemorrhage and ulceration occur in some species of animals stressed by restraint or social factors, and they are a feature of "trap death syndrome" in small mammals. Severe gastric hemorrhage or ulceration may occur following neurosurgery, trauma to the spinal cord and burns, and it is considered by some to be stress-related. Administration of methylprednisolone sodium succinate to dogs was clearly acutely ulcerogenic. However, some experimental studies have demonstrated that glucocorticoids released during stress are more gastroprotective than ulcerogenic, although the rate of healing in preexisting ulcers was decreased in the presence of steroids.

Reduced mucosal perfusion or ischemia may be a principal factor interacting in stress-associated ulceration, and in that initiated by other modalities, discussed previously. Reduced blood flow to the mucosa in local areas, under a number of circumstances, precedes mucosal hemorrhage or erosion. Ischemia will result in hypoxemic compromise of surface mucous cells. In combination with the effects of other insults, this may initiate mucosal permeability and backdiffusion of acid. Neutralization by blood-borne bicarbonate of acid diffusing into the mucosa also may be reduced in ischemia. Mucosal ischemia may result from reduction in local prostaglandin or nitric oxide concentration, as well as local or systemic hypotension. Ischemia may be more significant in the induction of fundic, rather than antral, ulcers.

Whatever the cause, the results of a breach of the gastric glandular mucosa have the potential to follow a **common pathway to ulceration** in all species. Acute superficial lesions, such as those associated with stress or following administration of aspirin, are often seen as areas of reddening and hemorrhage, especially along the margins of rugae in the fundic mucosa. Acid treatment of hemoglobin gives blood on the surface or in the gastric lumen a red-brown or black color. In some instances, melena, presumably the result of a recent episode of gastric bleeding, may be present in the lower intestine, with minimal gross evidence of hemorrhage or ulceration in the stomach. The microscopic lesion associated with hemorrhage of this type is often subtle; bleeding seemingly results from diapedesis, with minimal mucosal damage. Usually there is superficial erosion of the mucosa, often difficult to differentiate from autolysis, with granules of brown acid hematin in debris on the surface. Inflammation is usually absent. Evidence for healing mild gastric erosion is the presence of basophilic, poorly differentiated, flattened, cuboidal or low columnar cells on the mucosal surface, with mitotic cells in the upper neck of the glands.

Lesions of any genesis proceeding to gastric ulcer do so by progressive, often rapid, *coagulative necrosis of the gastric wall.* Ulcers vary in microscopic appearance depending on their aggression, and the point in their development at which they are intercepted. Acute gastric lesions appear as erosions with superficial eosinophilic necrotic debris and loss of mucosal architecture to the depths of the foveolae, or as a depression in the mucosal surface with necrotic debris at the base. Necrosis usually extends rapidly to the muscularis mucosae, causing ulceration. Once the superficial portion of the mucosa is destroyed, natural local buffering is lost, and the proliferative compartment of the gland, which is near the surface, is obliterated, preventing a local epithelial regenerative response. Ulcers attaining the submucosa impinge on arterioles of increasing diameter, multiplying the risk of significant *gastric hemorrhage.* The ulcer may progress through the muscularis and serosa, culminating in *perforation* of the gastric wall. Severe gastric hemorrhage or perforation are relatively common sequelae of gastroduodenal ulceration in domestic animals.

Ulcers that come into equilibrium with *reparative processes* may do so at any level of the gastric wall below the mucosa, but usually at the submucosa. Subacute to chronic ulcers have a base and sides composed of granulation tissue of variable thickness and maturity, infiltrated by a mixed inflammatory cell population, and overlain by a usually thin layer of necrotic debris. Chronic ulcers wax and wane. Depending on the relative dominance of reparative processes and aggressive ulceration, the layer of granulation tissue may be thick and mature, or thinner, less mature, and with superficial evidence of recent necrosis. There is mucous metaplasia and hyperplasia in glands at the periphery of the ulcer, which, with time, overhang the edge of the lesion, whence epithelial cells may gradually migrate across, closing the defect. Restitution of mucosal integrity is promoted by local activity of cytokines and growth factors such as transforming growth factor-β, basic fibroblast growth factor, epidermal growth factor, interleukins-1β and -2, and interferon-γ, some of which may be secreted by subepithelial myofibroblasts. The mucosa of healed ulcers, even in the fundic zone, is comprised of mucous glands. Excessive scarring of healed ulcers located near the pylorus may lead to pyloric obstruction in any species.

Duodenal ulcers, which usually occur proximal to the opening of the pancreatic and bile ducts, resemble gastric ulcers in their microscopic appearance (allowing for their intestinal location), evolution, and sequelae.

Peptic ulcer in dogs is reported relatively infrequently in the literature. Signs associated with peptic ulcer include variable appetite, abdominal pain, vomition, melena, and anemia. Ulcers, a few millimeters to 3–4 cm in diameter, are found most commonly in the pyloric antrum or proximal duodenum. The gross and microscopic appearance of ulcers varies with their aggressiveness and duration, as previously described. Thrombosed arterioles and venules cut by the ulcerative process are often seen, and should be sought in the bed of gastric and duodenal lesions associated with anemia or obvious hemorrhage.

Perforation of gastric or duodenal ulcers may lead to massive hemorrhage or release of gastric contents into the abdomen. Perforating duodenal ulcer may instigate pancreatitis. Some ulcers perforate silently, the serosal lesion healing by granulation, or adhesion by, and fibroplasia in, the omentum. The irritant nature of gastric contents released in these circumstances may lead to chronic inflammation, granulation, and thickening of the serosa, even when previous perforation cannot be appreciated. A search for microscopic particles of food such as plant material or muscle fibers in the serosal inflammatory response confirms perforation in this circumstance. Chronic peptic ulcers with thickened mucosal margins, scirrhous bases, and perhaps serosal thickening associated with perforation or near perforation, must be differentiated from gastric adenocarcinoma in the dog.

Syndromes resulting from hypersecretion of acid occur in dogs. *Mastocytoma is associated with peptic ulcer,* presumably due to histamine-stimulated acid hypersecretion and microvascular effects. The tumor and mastocytosis do not involve the stomach directly, and ulcers may occur in animals with solitary skin tumors. In one series of 24 dogs with recurrent or metastatic mastocytoma, gastric and duodenal erosions or ulcers, frequently multiple, were present in 20. In many cases such lesions are clinically silent, and they should be looked for at autopsy in animals with mastocytoma. Mast cell tumors have rarely been associated with gastric ulceration in the cow, and in the cat, where gastric ulcer is very uncommon.

Zollinger–Ellison syndrome, *peptic ulcer due to gastrin-secreting pancreatic islet cell tumors or gastrinomas,* has been reported in a few dogs and fewer cats. The history usually includes inappetence, vomition, weight loss, and possibly diarrhea or melena. Reflux esophagitis and gastric or duodenal ulcer are present in most cases. Small nodular masses histologically confirmed as islet cell tumors may be found in the pancreas, and in most animals, metastases to the liver, spleen, or hepatic lymph nodes are present.

Firm diagnosis rests on demonstration of elevated serum gastrin levels by radioimmunoassay; by identification of gastrin-bearing cells in fixed or frozen tumor tissue by immunohistochemistry; or by demonstration of gastrin in extracts of frozen tumor.

The microscopic appearance of these islet cell tumors is not diagnostic for gastrinoma, nor is the ultrastructural appearance of tumor cells necessarily characteristic of the G cell. Pancreatic islet cell neoplasms may be difficult to find, and should be sought assiduously in suspect cases.

The cause in dogs of gastroduodenal ulcer possibly associated with decreased resistance to backdiffusion of acid is less clear. Hepatic disease is often present in dogs with gastric ulcer but the basis for a causal association is obscure. Some ulcers are obviously associated with administration of **glucocorticoids** in high doses as anti-inflammatory, immunosuppressive, or antineoplastic therapy. **Nonsteroidal anti-inflammatory drugs** such as aspirin, naproxen, indomethacin, ibuprofen, flunixin meglumine, and pyroxicam, sometimes given in excessive quantity, are also associated with spontaneous ulcers. Gastric hemorrhage and gastroduodenal ulceration are occasionally seen in dogs following **trauma or major surgery**. A syndrome of gastric hemorrhage, pancreatitis, and colonic ulceration and perforation is recognized in dogs following **spinal trauma**. The pathogenesis of this problem is obscure and undoubtedly complex.

Abomasal ulcers in cattle are common (Fig. 1.41); duodenal ulcer is rarely encountered in this species. Acute ulcers or erosions considered to be the result of stress are frequently seen incidentally in animals, of any age, dying of a variety of causes. They are usually present as linear areas of brown or black hemorrhage or erosion along the margins of abomasal rugae, or as punctate hemorrhages and erosions scattered over the mucosa, especially of the fundus.

Ulcers may be present anywhere in the abomasum. They are common in the pyloric region in cattle, and especially at the torus pyloricus in veal calves, but they may scallop or perforate abomasal rugae and excavate the mucosa in the fundus as well. Often more than one ulcer is present.

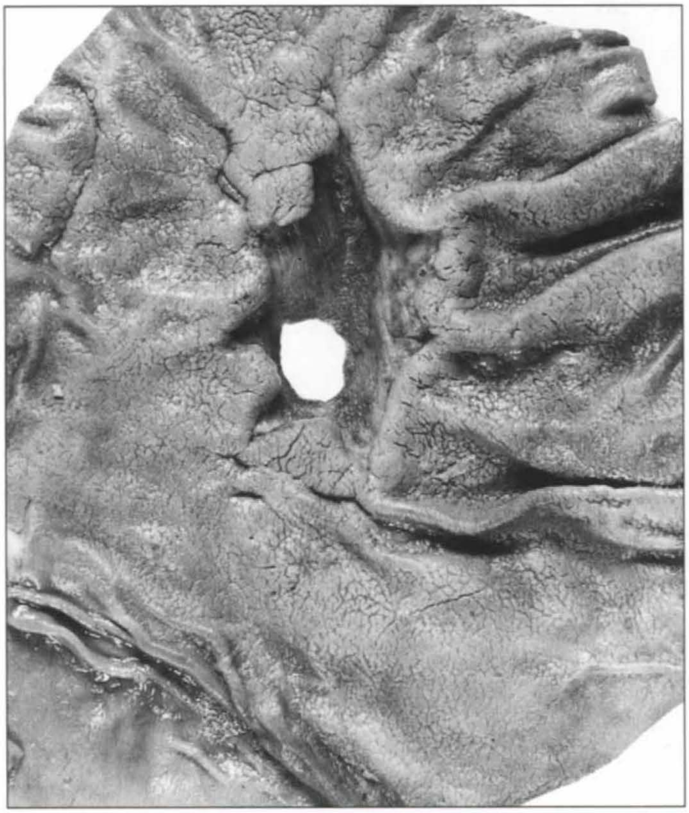

Figure 1.41 Perforated abomasal ulcer in a calf.

The causes of abomasal ulcer are usually unclear, but they are most common in young calves, dairy cows, and feedlot animals. Abomasal ulcer occurred in about 3–4% of feedlot cattle in one study, with about half the cases symptomatic, while there are reports of over 6% of European dairy cows slaughtered with evidence of active or previous abomasal ulcers. A very high proportion, often in excess of 50%, of veal calves may have abomasal ulcers at slaughter. Ulcers often appear to be subclinical, and apparently without effect on growth or performance. However, about one-third of suckling calves dying under 4 months of age in western Canada had perforating abomasal ulcers. They were often associated with hairballs, which, it was concluded, were probably not causal.

Ulcers often seem to occur under *stressful circumstances*, as in recently weaned and veal calves, postparturient cows, animals with concurrent disease such as abomasal displacement or mastitis, or after transportation. Lactic acid and histamine entering the abomasum from the forestomachs in animals poorly adapted to high-concentrate rations may contribute to mucosal damage. In veal calves, consumption of straw, shavings, or other roughage has been associated with an increased prevalence of ulcers, and there appears to be an increase in thickness and altered mucus production in the pyloric mucosa. Abomasal ulcers in range calves in western North America have been associated with *Clostridium perfringens* gastritis, consumption of roughage at pasture, and possibly copper deficiency. Perforating abomasal ulcers may develop in calves secondary to mycotic infection. Abomasal stasis may play a part in animals with physical or physiological abomasal obstruction or displacement. Ulceration of the abomasal mucosa infiltrated by lymphosarcoma will occur, and it may occur as a sequel to ingestion of toxins such as arsenic.

The presenting sign in many cases of abomasal ulceration is *melena*. Hemorrhage causing exsanguination, or perforation and septic peritonitis, is the usual cause of death due to abomasal ulcers. Bleeding abomasal ulcer should be looked for in cattle with melena or anemia, and perforating abomasal ulcer in animals presented with septic peritonitis, especially if digesta is in the abdominal cavity. Perforation may occur into the omental bursa, localizing contamination, and occasionally, points of perforation will be adherent to the abdominal wall, or occluded by superficially adherent omentum.

Gastric ulcer in swine is usually restricted to the *pars esophagea*; in a small proportion of affected pigs lesions extend into the contiguous esophagus. Rarely are significant ulcers of the cardiac, fundic or pyloric mucosa encountered in swine, sometimes in association with ulcer of the pars esophagea, occasionally with gastric parasitism or systemic disease. Venous infarcts in the body of the stomach in swine are not to be confused with gastric ulcer.

Under conditions of modern pig husbandry, the prevalence of ulcer and associated abnormalities of the pars esophagea is high. Weaned growers and feeders are commonly affected. Most lesions are subclinical; however, some prove fatal. Pigs die without premonition, or with a short history that may include anemia, weakness, inappetence, vomition, and melena. Other animals are affected chronically, with signs of anorexia, intermittent melena, and weight loss that may culminate in death or slow recovery with runting.

There is little disagreement over the morphology of ulceration of the pars esophagea, although its etiopathogenesis has been controversial. Many factors have been implicated in the etiology. Stressful husbandry practices have been considered to contribute to development of ulcer, though glucocorticoid administration results in lesions of the fundus, not pars esophagea, in pigs. High dietary copper levels, feeding of whey, starchy diets low in protein, high levels of dietary unsaturated fatty acids, and microbial production of short-chain fatty acids have been associated with the development of ulcers. Experimental infection with *Ascaris suum* has been associated with ulcer, but natural infection is not considered causally associated. While an association between the presence of *Helicobacter heilmannii* and ulceration has been proposed in pigs, this has not been strongly substantiated, and gastric ulcers in pigs involve squamous, rather than glandular, mucosa. Experimentally, factors stimulating acid secretion, especially histamine, consistently cause ulcers of the pars esophagea, suggesting that gastric acidity may play an etiologic role. Repeatedly, *finely ground rations have been found to be ulcerogenic*, and this may be the single most important predisposing factor.

Squamous epithelium has no innate buffering capacity, and it is highly susceptible to attack by gastric acid, pepsin, and refluxed bile, as occurs in reflux esophagitis. Similar events may initiate ulceration of the pars esophagea. Swine with gastric ulcers usually have abnormally fluid stomach contents. Feeding of finely divided rations and prolonged fasting are associated experimentally with increased water in stomach content. Normally there is a declining gradient of pH from esophagus to pylorus in stomach ingesta. Abnormally fluid gastric content fails to partition properly, and the pH gradient from esophagus to pylorus is not established. Relatively low pH occurs at the esophageal end of the stomach, where hydrochloric acid, pepsin, and refluxed bile, along with short-chain fatty acids produced by microbial fermentation of carbohydrate, synergistically attack the squamous mucosa. Meanwhile, the pH at the pylorus is higher than normal. Under conditions of prolonged gastric distension and relatively high antral pH, gastrin-stimulated acid secretion may be excessive, promoting that insult.

Lesions of the pars esophagea may involve only a small part, or virtually all of the gastric squamous mucosa. The lesion evolves through parakeratosis, to fissuring and erosion, with ultimate ulceration in severe cases. All stages in this progression will be encountered at necropsy in pigs. The epithelium of the pars esophagea often appears yellow and is thickened, irregular, roughened, and may flake or peel off readily. *Candida* may be present over the epithelial surface, with hyphae invading the parakeratotic epithelium, perhaps due to favorable cystine or glycogen levels. Rete pegs and proprial papillae are elongate.

Erosion of the epithelium progresses to ulceration and exposure of papillae and deeper propria, which bleed as small vessels are disrupted. Such lesions begin as fissures in the hyperplastic parakeratotic epithelium, but advance to ulcerate the entire pars esophagea. They usually spare only a microscopically visible margin of squamous epithelium adjacent to the cardiac gland mucosa. Ulcers of the pars esophagea, like peptic ulcer, have a floor of necrotic debris overlying exposed connective tissue (Fig. 1.42). Depending on the stage and aggression of the ulcer, there may be a well-developed inflammatory margin to the necrosis and a bed of granulation tissue. *Fatal gastric hemorrhage* often occurs.

Grossly, fully developed ulceration of the pars esophagea is apparent as a punched-out lesion with elevated rolled edges, obliterating the entire pars esophagea and obscuring the esophageal opening (Fig. 1.43). The floor of the ulcer may be so smooth that it is misinterpreted as normal by the inexperienced. Pigs with gastric ulcer at any stage of evolution tend to have fluid content in the stomach. Those with hemorrhagic ulcer may have red-brown gastric content, or massive hemorrhage into the stomach with large blood clots in the lumen, and smaller clots adherent to the base of the ulcer and its exposed bleeding points. Melenic content will often be present in the intestine, and the colon may contain firm black pelleted feces. The

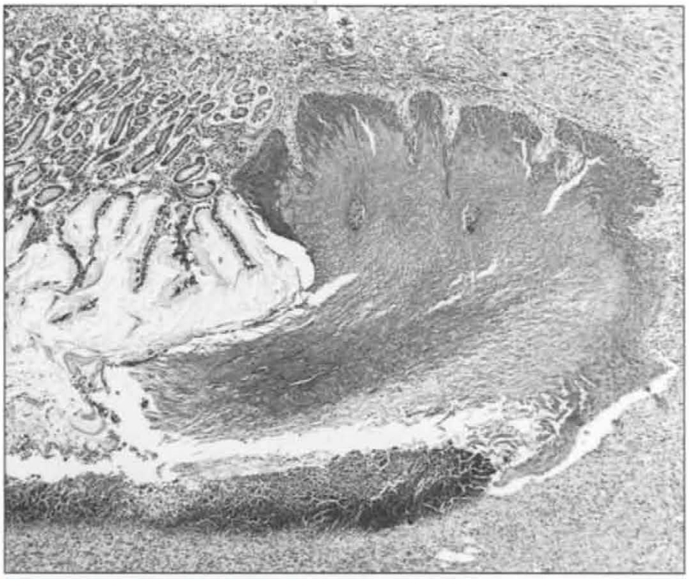

Figure 1.42 Margin of **ulcer of the pars esophagea** in a pig. Cardiac glandular mucosa and a marginal remnant of squamous mucosa overhang the margin of the ulcer, the floor of which is at the bottom.

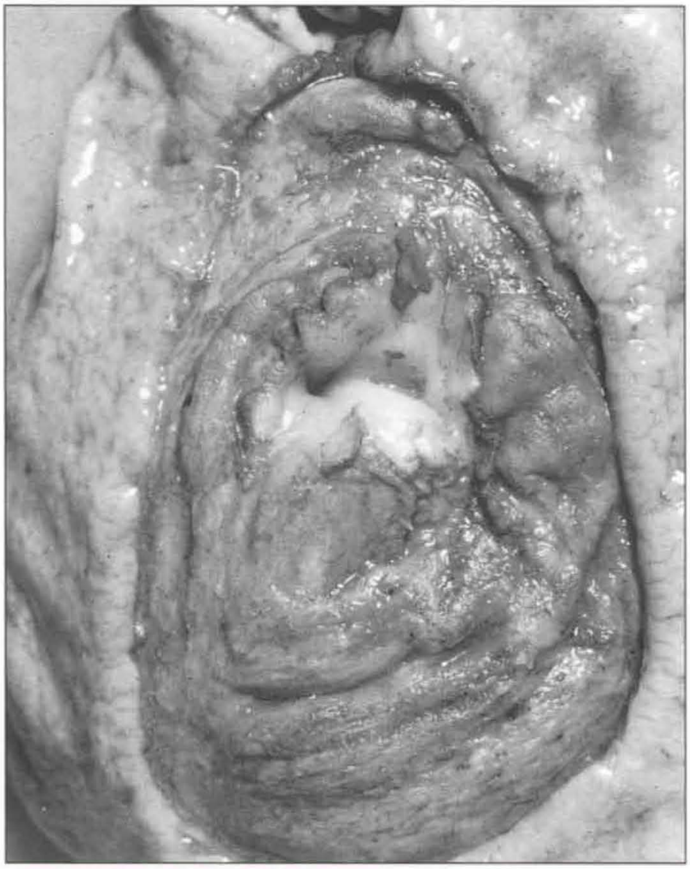

Figure 1.43 Ulceration of the pars esophagea in a pig. Squamous mucosa is ulcerated, but adjacent cardiac glandular mucosa is unscathed. Esophageal mucosa is visible opening into the upper part of the ulcer.

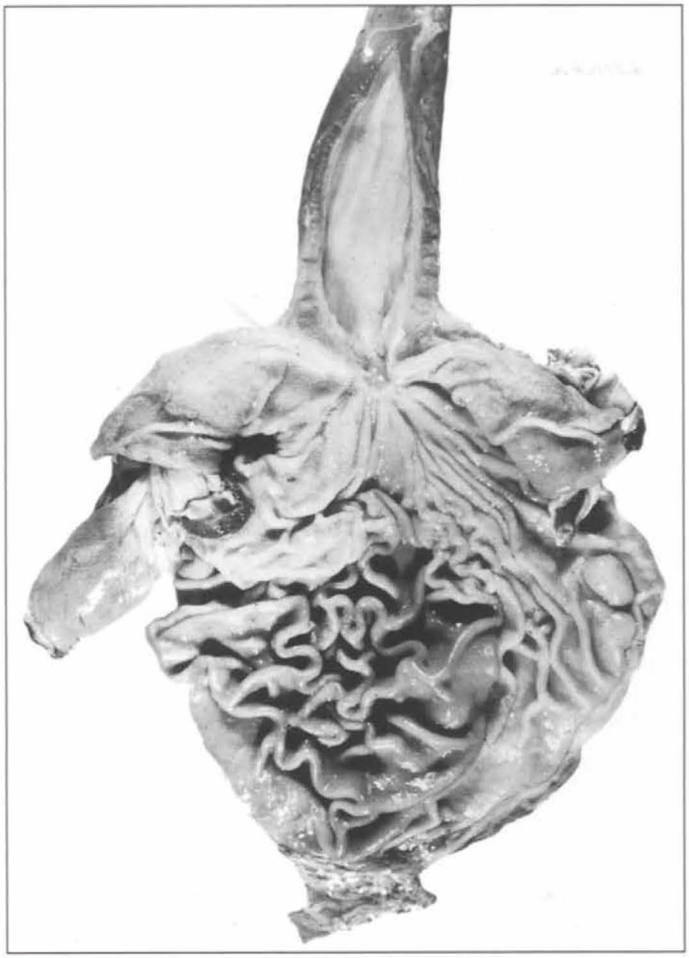

Figure 1.44 **Scarring and stricture** of distal esophagus and pars esophagea following ulceration in a pig.

carcasses of animals that exsanguinate with gastric ulcer are very pale. Blood in the intestine associated with gastric ulcer in pigs must be differentiated from mesenteric torsion and from proliferative hemorrhagic enteropathy associated with *Lawsonia*. A few pigs with parakeratosis, erosion, and ulceration of the pars esophagea have esophageal lesions suggestive of gastric reflux.

Gastric ulcers in some pigs resolve by granulation, and they may become re-epithelialized. Such lesions usually become scirrhous, puckered, and contracted as the ulcer closes from the periphery, and scarring may be visible from the serosa (Fig. 1.44). In these circumstances, stenotic occlusion of the esophageal opening into the stomach may occur, and pigs with this problem can develop muscular hypertrophy of the distal esophagus.

In **horses**, *ulcers in the stomach of foals and adults* are often found at autopsy incidental to some other disease process. Gastric ulcer as a clinical entity is less commonly recognized, though a syndrome of abdominal pain, sometimes associated with gastric reflux, has been described in foals, and gastric ulcers are associated with colic in older horses. Ulcers are common in foals under 4 months of age; about half of a group of foals without signs of gastric disease had ulcers visible by endoscopy. Ulcers have been detected endoscopically in over 65% of performance horses, in training, racing, or on endurance rides. They are often multiple, and while most frequent in the esophageal region, they can simultaneously involve all four mucosal zones of the stomach, and the duodenum, with no relationship apparent in the pattern of distribution.

Ulcers of the *esophageal zone* are common. They are usually most severe at or adjacent to the margo plicatus, involving the edge of the squamous epithelium. They are often large and irregular in shape. There may be extensive fissuring, erosion, and ulceration of the squamous mucosa on the remainder of the pars esophagea, and in the esophagus, sometimes nearly to the pharynx, in foals with reflux. Often islands of thickened white proliferative mucosa are scattered as plaques on a predominantly ulcerated mucosa (Fig. 1.45). Microscopically,

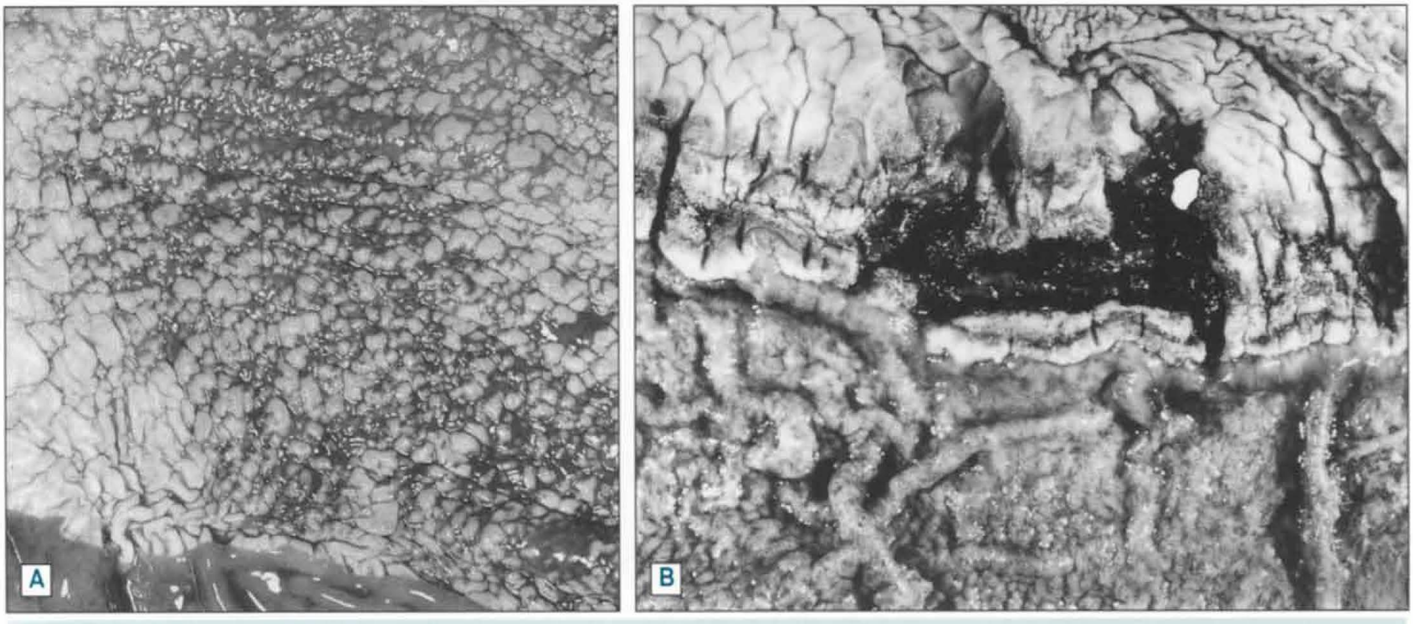

Figure 1.45 **A.** Multiple confluent areas of **ulceration** of the squamous mucosa of the stomach of a foal, with smooth nodular islands of surviving hyperplastic mucosa scattered over the ulcerated area. **B. Ulceration with perforation** of squamous gastric mucosa at the margo plicatus of a foal's stomach.

there is epithelial hypertrophy and hyperplasia in response to insult, marked in some islands of surviving mucosa, with prominent rete pegs and edematous proprial papillae. Lesions then grade through increasing degrees of epithelial erosion to ulceration, with evolution of the ulcer and ulcer bed, as described earlier in swine.

Ulcers in the secretory stomach are less common. These ulcers are also often large and multiple, though a full range from focal punctate to extensive deep lesions may be seen.

Perforation may occur at any site of ulceration, and in one series represented 1% of 600 autopsies on foals. Some foals may exsanguinate due to bleeding ulcers, and occasionally clotted blood will fill the stomach, forming a cast.

Pyloric and duodenal stenosis have been associated with healing ulcers in horses. Ulcerative lesions involving the circumference, or the antimesenteric mucosa, of the proximal duodenum have been associated with gastric ulcers in foals, and duodenal stricture may represent a more chronic phase of this process. Severe esophagitis occurs in foals with ulcer and gastric reflux.

Many cases of gastric ulcers in horses are associated with enteric disease, colonic impaction, ileus, surgery, or other circumstances that can be considered stressful or could cause gastroduodenal reflux. Ulcers are common in horses held in stalls, and alternating periods of feeding and feed deprivation have been shown to induce ulceration of the gastric squamous epithelial mucosa. The pathogenesis of ulceration in the pars esophagea in horses probably resembles that in swine. Abnormally fluid content associated with feeding patterns and feedstuffs is permissive of acid, pepsin, and bile reflux to the cranial part of the stomach, where, at pH levels <4.0, volatile fatty acids generated locally may predispose further to damage to the squamous mucosa. A diet of bromegrass hay has been implicated in causing lower gastric pH, and thus facilitating ulcer formation. Exercise increases intra-abdominal pressure, resulting in gastric compression and reflux of acidic content into the cranial stomach, possibly contributing to ulceration associated with intensive training.

It is unclear whether the *ulcerative duodenitis* seen in some cases is a product of peptic ulceration, or whether it represents a process such as "proximal enteritis," which in turn results in stricture, gastric reflux, and ulceration. *Clostridium perfringens* has been considered as a potential cause of the associated duodenitis. Administration of NSAIDs is commonly associated with gastroduodenal ulcers, and lesions of the glandular stomach, squamous stomach, and pylorus, among other lesions, have been induced in horses intoxicated with phenylbutazone.

INTESTINE

Normal form and function

The microtopography of the **small bowel** is extensively modified, to increase its surface area, by *spiral mucosal folds* in some species, and by **villi** projecting into the lumen. The villi, projections of lamina propria covered by a layer of epithelium one cell thick, expand the absorptive surface of the small bowel 7–14-fold. In most species, villi are tallest in the duodenum, and decline somewhat in height toward the ileum. The length and shape of villi in "normal" animals vary with the species, age, intestinal microflora, and immune status. In general, villi in dogs, cats, neonatal piglets, and ruminants tend to be tall and cylindrical; those in horses and in young ruminants tend to be moderately tall and cylindrical; villi in weaned ruminants and swine may be cylindrical, leaf or tongue-shaped, or rarely ridge-like, with their broad surface at right angles to the long axis of the gut. Length of villi typically declines somewhat after weaning.

Opening on to the mucosal surface around the base of each villus are several *crypts of Lieberkühn*. These are straight or somewhat coiled (depending on the species and the proliferative status) tubular gland-like structures, lined by a single layer of epithelium. The progenitor compartment of the enteric epithelium resides here, producing cells that differentiate and move up on to the surface of villi, mainly as absorptive enterocytes, ultimately to be extruded as effete cells from the tips of villi. Sloughed cells contribute to the enzyme content and complexity of the intestinal luminal content.

Stem cells are present in the crypts; depending on species and the position in the gastrointestinal tract, they are near or at the base of the crypt. They divide to produce *four main lineages of cells*. **Poorly differentiated enterocytes**, which are cuboidal or low columnar, with relatively few, short microvilli, are the predominant type of cell lining crypts. Especially in the lower half of crypts, these cells form a population that cycles rapidly, undergoing amplification division. One of the ensuing daughter cells usually differentiates and moves into the functional compartment of absorptive enterocytes on the villus. Undifferentiated crypt epithelial cells also secrete electrolytes and water.

Oligomucous cells, derived by mitosis from the basal stem cells, also form a population undergoing amplification division. They contain mucous granules, and are intermediate in structure between undifferentiated crypt epithelium and goblet cells, into which they mature. Well-differentiated **goblet cells** are present in crypts and on the surface of villi, with variable prevalence and distribution at various levels of the intestine, and in the different species. They have basal nuclei and *secrete mucus*, apparently by exocytosis, from the luminal border of the cell. **Intestinal mucus** is a gel that lubricates and probably serves to "insulate" the surface from organisms, which it may entrap or immobilize. It contains *trefoil factor*, also produced by the goblet cell, which promotes epithelial restitution or gliding after erosion; *lysozyme* and *defensins* produced by Paneth cells; and *immunoglobulin A* secreted into it by epithelial cells. Goblet-cell hyperplasia and mucus secretion are promoted by a variety of noxious stimuli, by inflammatory mediators, and by cell-mediated immune events in the gut. Production of trefoil factor may be related to the preponderance of mucous cells often present in healing mucosa.

Paneth cells, a population of enigmatic cells turning over slowly (~20 days) in the base of the crypts in small intestine, are most obvious in horses, among the domestic animals. They are not found in dogs, cats, or swine, and they are not prominent in the intestine of ruminants. Eosinophilic secretory granules are present in the apical cytoplasm of Paneth cells. They contain a number of *antimicrobial proteins and peptides* active in innate host defense, including lysozyme, phospholipase, DNAse, ribonuclease, and alpha-defensins. Adaptive increases in Paneth cell numbers and activity are initiated by T cells and proinflammatory cytokines.

The fourth type of cell found in intestinal crypts is the **enteroendocrine** cell. They too are derived from crypt stem cells, and comprise a heterogeneous population of over a dozen amine- or peptide-secreting endocrine/paracrine cells, representing about 1% of the crypt cell population. These are the cells variously recognized as *enterochromaffin, argentaffin, or argyrophil*; the specific cell type is defined by immunocytochemistry and the ultrastructure of secretory granules. Hormones with relatively clearly understood functions, such as secretin and cholecystokinin, as well as peptides or amines whose endocrine or paracrine implications are still being revealed, are secreted. With the exception of carcinoid tumors of serotonin-secreting cell origin, and rare functional neoplasms of other enteroendocrine cells in humans, the pathologic implications of this class of cells are still very poorly defined.

Enterocytes, which are responsible for the final digestion and absorption of nutrients, electrolytes, and water, are by far the predominant cell type on intestinal villi. They are normally tall columnar cells, polygonal in cross-section, with a regular basal nuclear polarity. A tight junction, which is nevertheless "leaky" to small molecules and water, joins the apical margins of adjacent cells. The barrier to transepithelial macromolecular movement is essentially maintained even at sites of extrusion of effete enterocytes at the tips of villi. Basal to the tight junction, the lateral cell membranes interdigitate loosely, and a long, narrow potential space exists between enterocytes. The basolateral cell membrane is the site of sodium–potassium-dependent adenosine triphosphatase that drives the sodium pump, and of carrier systems exporting monosaccharides from the cell. Absorptive epithelial cells lie on a basal lamina with which they interact via integrins, which may be involved in communications with the underlying mesenchyme. Immediately beneath the basal lamina lies the sheath of syncytial **myofibroblasts** that produce the basal lamina, and with which enterocytes also appear to interact. Myofibroblasts seem to be involved in intestinal organogenesis, and epithelial proliferation and differentiation, as potent sources of growth factors.

The apical surface of normal enterocytes is highly modified into **microvilli**, about 0.5–1.5 μm long and 0.1 μm wide, which are regularly arrayed in close apposition to each other at right angles to the surface of the cell. They are visible as the "brush border" by conventional microscopy. Microvilli increase the surface area of absorptive epithelium by a factor of about 15–40 times. The plasmalemma of microvilli is studded with massive numbers of enzyme molecules, including aminopeptidases and disaccharidases involved in terminal digestion of peptides and carbohydrates. These protrude as minute "knob-like" structures into the glycoprotein "glycocalyx" that coats the surface of microvilli.

In neonatal swine and ruminants, vacuolation of absorptive enterocytes is normal, and the nucleus is often also displaced into the apical cytoplasm. In piglets vacuolation is usual in the ileum, but not in the duodenum, and seems to be a function of cell age. Such

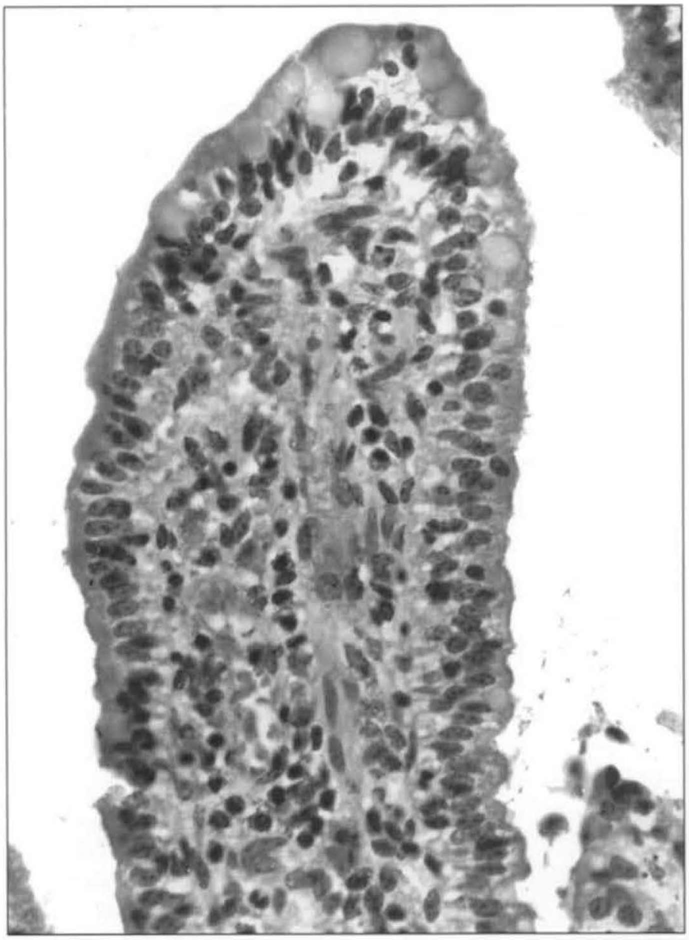

Figure 1.46 Distended vacuoles containing eosinophilic **colostral protein** in apical cytoplasm of enterocytes at the tip of the villus of a 2-day-old calf.

vacuolation should be differentiated from the presence of eosinophilic colostrum present in cytoplasmic vacuoles in the epithelial cells of neonates (Fig. 1.46).

The cytoplasm of absorptive enterocytes is stabilized at the apical border by the filaments of the terminal web. Smooth endoplasmic reticulum is most prominent in the upper half of cells, while cisternal elements of rough endoplasmic reticulum are more uniformly distributed. The Golgi zone lies above the nucleus. Free ribosomes and polyribosomes are numerous in differentiating cells of the upper crypt and lower villus, and are relatively fewer in mature absorptive enterocytes.

The complex of endoplasmic membranes and Golgi apparatus is particularly active in handling *absorbed lipid*, which diffuses from micelles at the cell surface, through the apical membrane, in the form of long-chain fatty acids or monoglyceride. These are re-esterified to triglyceride, appearing in the smooth endoplasmic reticulum, and are complexed with apoproteins produced in the rough endoplasmic reticulum, to be excreted, via the Golgi apparatus, through the basolateral cell membrane as *chylomicrons*. Chylomicrons enter the extracellular space, and leave the villus via the lacteal.

The **lamina propria**, a highly plastic mesenchymal stroma, supports the epithelium of the small intestinal mucosa. It is composed of loose fibrous tissue, through which course blood vessels, and in which smooth-muscle, inflammatory, and immune-active cells are interspersed. In addition to functioning in defense against microorganisms, macrophages phagocytose inert particulate matter reaching the lamina propria from the lumen. Bile pigment, perhaps derived from meconium, is sometimes seen in macrophages in the tips of villi in neonates. Macrophages may become iron-laden and, by loss from the mucosa, may play a role in iron homeostasis. Apoptotic bodies, ceroid, hemosiderin, and bile pigment may also be present in histiocytes in the lamina propria at tips of villi, which are particularly prominent in horses, and should not be mistaken for foci of necrosis. These may represent detritus resulting in part from apoptosis of upwardly migrating subepithelial myofibroblasts at the villus tip. Myofibroblasts are probably largely responsible for the remarkable plasticity of the villus during adaptive changes expressed as villus atrophy and reconstitution of mucosal three-dimensional morphology.

Lymphocytes, neutrophils, and eosinophils are scattered in the lamina propria of villi and between crypts. Eosinophils are especially common in the intestine of ruminants and horses, with no specific pathologic connotation, but they are highly variable in prevalence in the intestine of small animals. Intraepithelial lymphocytes are frequently found between epithelial cells on villi, and, less commonly, in crypt lining. Globule leukocytes may be found in the epithelium of crypts and low on villi, or sometimes in the lamina propria between crypts. Plasma cells are normally not numerous in villi, but are concentrated in the lamina propria between the upper portions of crypts.

The **vascular supply to the small intestinal mucosa** arises in submucosal arteries that give off arterioles at right angles, some of which send branches to a capillary plexus around crypts of Lieberkühn. The majority pass up the centers of villi, arborizing near the villus tip into a dense capillary plexus which lies immediately beneath the basal lamina of the epithelium. Capillaries in villi have fenestrations facing the basal lamina, which may be more permeable than the remainder of the endothelium. One or more venules drain blood from the capillaries in villi and between crypts, and flow into larger veins in the submucosa, which drain into mesenteric veins and the hepatic portal circulation. The *lacteal*, or central lymphatic vessel of the villus, is sufficiently permeable to permit the entry of macromolecules and chylomicrons, and is the main route of lipid transport from the villus.

The cecum and colon vary widely in anatomy and size among domestic animals, depending largely upon the significance of microbial fermentation of carbohydrate in the hindgut. *Production of volatile fatty acids* from carbohydrate by colonic flora occurs in all species. In the horse, this is a primary source of energy, and it is significant in swine and ruminants as well. Extensive movement of electrolytes and water occurs across the colonic wall. In the horse, a volume of fluid approaching that of the extracellular fluid space of the animal may be in the large bowel, which must maintain a fluid medium for microbial fermentation; daily fluid absorption from the hindgut may exceed the extracellular fluid volume. *Absorption of electrolytes and water*, an electrolyte-conserving mechanism, is probably the major function of the colon in dogs and cats, and of the distal colon of herbivores.

The mucosa of the cecum and colon in all domestic species lacks villi, though there are ridges or folds on the mucosal surface. The surface of the hindgut is lined by a single layer of columnar **absorptive epithelial cells** with basal nuclei. These cells generally have more sparse and less regular microvilli in comparison with absorptive cells of the small bowel, and numerous glycoprotein-laden vesicles are in the apical cytoplasm in most species. Typical goblet cells are also interspersed on the colonic surface in variable numbers, depending on the species and a variety of other factors.

Colonic crypts, or glands, are straight tubular structures. The architecture of colonic glands and their cell population resembles somewhat that of small intestinal crypts. *Epithelial cells*, which contain small glycoprotein-laden vesicles, differentiate progressively from stem cells in the crypt to absorptive epithelium as they approach the surface. *Oligomucous cells*, derived from basal stem cells, form a second proliferative population in the lower half of the colonic gland. Well-differentiated *goblet cells* are usually present in the upper half of glands in the large bowel, as well as on the surface. *Enteroendocrine cells* of about a half-dozen types have been recognized, scattered in the cell column lining glands in the large bowel.

The lamina propria of the colon is minimal between closely packed glands. It contains a cell population similar to that in the small bowel. Normally, relatively few inflammatory and immune-active cells are present in the superficial mucosa in small animals and young herbivores; most plasma cells and lymphocytes are between deeper portions of glands. Older herbivores may have somewhat heavier superficial proprial inflammatory infiltrates, and macrophages containing phagocytosed debris may be present below the surface epithelium between the mouths of glands, especially in the horse. In the equine colon, terminal arterioles that enter the mucosa branch at right angles from the submucosal plexus. Capillaries ramify to surround colonic glands, and form an anastomosing network at the luminal surface. Sparsely distributed venules drain the superficial capillary plexus.

The connective tissue of the **submucosa** lies between the mucosa and the **external muscle** of the gut, which is comprised of inner circular and outer longitudinal layers, made up of fascicles of smooth-muscle cells. An extensive **enteric nervous system**, with submucosal (Meissner's), and myenteric (Auerbach's) plexuses marked by ganglia, modulates external autonomic neural regulation and coordinates gastrointestinal motility and function. The neurons of the enteric system equal in number those in the spinal cord, and their ramifications sense and influence epithelial absorption and secretion, local endocrine/paracrine secretion, blood flow, immune events, and motility in the gut. Secretomotor neurons ramify axons that extend to individual crypts of Lieberkühn, where they stimulate secretion of electrolyte, water and mucus. Excitatory and inhibitory effects are mediated by acetylcholine and by amine and peptide neurotransmitters, such as substance P, adenosine triphosphate and vasoactive intestinal peptide, which in some cases are also produced by endocrine cells of the gut and pancreas. In addition, *myofibroblastic pacemaker cells of the intestine*, known as **interstitial cells of Cajal**, are distributed throughout the intestinal musculature, integrated with the extrinsic and enteric nervous systems. Abnormalities of these cells are thought to lead to disorders of motility, and to gastrointestinal stromal tumors, a specific entity described in horses and dogs. Disorders of motility associated with enteric neural lesions, such as the dysautonomias and grass sickness, are discussed in the section on intestinal obstruction, below.

Interpretation of intestinal and colonic biopsies is often subjective, unless clear-cut diagnostic criteria can be met: by recognition of an etiologic agent; a specific cell type; a characteristic pattern of inflammation or anatomic abnormality, such as lymphangiectasia; or cytologic and morphologic abnormalities indicating malignancy. There are significant variations in the microscopic morphology of the gut among individuals and between species, and with age; at different levels of the small and large intestine within species and within the same individual; and as a result of factors influencing "physiologic" inflammation in the mucosa. Limited morphometric data are available, describing in a quantitative manner the "normal" morphology of the intestinal mucosa and its epithelial and inflammatory cell populations in domestic animals. However, until more such information is available, and its application, particularly in the diagnosis of inflammatory bowel disease, is validated, pathologists would do well to expand their experience of "normal" intestinal morphology by close examination of tissues from animals in which gastrointestinal disease is not indicated clinically, and to view critically their reliability in diagnosing such entities. The various grading schemes suggested for interpretation of inflammatory lesions of the stomach and intestine leave much to be desired in terms of objectivity and potential for interobserver variation.

Biopsy interpretation is enhanced by increased size of specimen; increased numbers of specimens; the sampling of all layers of the bowel wall; minimal trauma, rapid fixation, and optimum orientation. Sacrifice of any of these attributes increases the subjectivity with which a biopsy is interpreted. Hence, in dealing with endoscopic and other small biopsies, care must be taken in handling to reduce traumatic artefact and to optimize orientation. Clinicians and pathologists dealing with endoscopic, capsule, and forceps biopsies must remember the limitations in interpretation imposed by small sample size; difficulties in orientation; the frequent failure to sample the deep mucosa; and the usual failure to sample the submucosa and muscularis. These costs are offset to some degree by the opportunity to obtain a greater number of samples than may be possible by other means, at arguably lower risk and cost, and possibly more "focused" on a lesion by direct endoscopic examination.

Immune elements and the gastrointestinal mucosal barrier

The gastrointestinal tract is presented continually with antigens in food; ingested toxins; viruses; bacteria and their products; and parasites and their excretions and secretions. The epithelial barrier of the gut is but one cell thick and has enormous surface area; the enteric mucosal surface of the average human is about 400 m^2. Therefore, it is not surprising that the epithelium and associated lymphoid and inflammatory cells in the mucosa and submucosa have evolved a complex system for excluding, blocking, sampling, tolerating, or neutralizing and eliminating antigens. At birth, intestinal immune elements are sparse and quiescent; immune activity in the gut is probably stimulated in response to colonization by normal bacterial flora beginning in the early neonatal period. In the mature animal, *lymphoid tissue has been estimated to comprise 25% of the intestinal mucosal mass*, and to exceed that of the spleen in volume.

Innate and adaptive elements of the gastrointestinal mucosal barrier include, physiologically, volume of secretion and peristalsis, which dilute and flush the contents, and gastric and bile acids and pancreatic secretions that break down ingested antigens. The indigenous microflora competitively inhibit, or actively exclude, intruding bacteria. Mucins on the luminal surface form a secretory barrier, and retain trefoil factor, antibody and soluble components of innate resistance, including those produced by Paneth cells. The epithelium provides a physical barrier; participates in innate resistance by production of proinflammatory cytokines; enables passive immunity by antibody uptake in the neonate; and by antigen uptake and presentation may contribute to active immunity. Intraepithelial lymphocytes presumably act as a first line of defense. Soluble antibody in plasma and interstitial fluid neutralizes antigens penetrating the mucosal barrier and contributes to opsonization/phagocytosis, as do endogenous components of the innate immune system, such as complement. The organized elements of the mucosal immune system, Peyer's patches, and other mucosal lymphoid follicles, are sites of induction for intestinal immune responses, generating antigen-activated B and T cells that ultimately home back to the mucosa. Within the lamina propria reside populations of such B and T cells, macrophages, and dendritic cells. Regional lymph nodes receive and trap free and phagocytosed antigens, and antigen-presenting cells activate more B and T cells, promoting mucosal and systemic immunity. Escape of viable infectious agents past the mesenteric lymph nodes permits systemic disease.

The **epithelial cell** of the neonate is capable of uptake and transport of macromolecules from the intestinal lumen to the basolateral cell surface. In all species of domestic animals, **colostral transfer of immunoglobulins** by this route provides the neonate with passive humoral immunity during the early postnatal period. The period of active uptake of macromolecules is short, usually only 24–48 hours in ungulates, and "closure" precludes further bulk transport of macromolecules.

Although bulk transport does not occur, nutritionally inconsequential amounts of macromolecules continue to be transferred by enterocytes in mature animals. For uptake to occur, molecules must escape intraluminal hydrolysis, and pinocytosis must exceed the rate of lysosomal degradation to permit molecules to be exported from the cell. Fully differentiated small intestinal absorptive epithelial cells express on their basolateral membranes major histocompatibility complex class II molecules, as do antigen-presenting macrophages and dendritic cells. Enterocytes are probably capable of directly presenting antigen to T cells. As well, via *pattern recognition molecules* – surface Toll-like receptors and cytosolic nucleotide-binding oligomerization domain (Nod) molecules – they detect highly conserved molecular structures (pathogen-associated molecular patterns) produced by luminal bacteria, and some viral components, activating cellular production of proinflammatory or immunomodulatory cytokines.

Intestinal intraepithelial T lymphocytes form a large population strategically located between intestinal epithelial cells, adjacent to the basement membrane. They may comprise up to 10–20% of the cells within the epithelial layer. In domestic animals they are comprised mainly of cytotoxic T cells, with a small minority of CD4+ and $\gamma\delta$ T cells. They presumably function as a front line of defense, reacting, as part of the innate response, to bacterial and plant products such as amylamines, and to damaged enterocytes. They also presumably participate as components of the adaptive response, responding to antigens entering from the lumen and in tumor surveillance. Some may kill compromised epithelial cells. Most, but not all, intraepithelial lymphocytes appear to originate in Peyer's patches.

Globule leukocytes are visible in hematoxylin and eosin-stained tissue sections as *mononuclear cells with large eosinophilic cytoplasmic granules*, in the epithelium of the crypt and lower villus, and sometimes in the lamina propria. Their origin has been uncertain. Formerly postulated to be derived from mast cells, the weight of evidence suggests that they are *granular lymphocytes*.

Specific epithelial cells called **"M" cells**, associated with Peyer's patches and intestinal lymphoid follicles, actively "sample" particulate matter and macromolecules impinging on the mucosal surface. M cells are interspersed among other cells of the follicle-associated epithelium resembling absorptive enterocytes, on the surface of the "dome" in the mucosa overlying lymphoid aggregates in the submucosa. They often adopt an inverted "cup" shape, with one or more lymphocytes and occasional macrophages, in the basal concavity, in contact with the membrane of the M cell. Material taken up by M cells is transmitted to the associated lymphocytes or macrophages. Despite, or perhaps because of, its role in adaptive immunity, the M cell is exploited as a likely portal of entry to the mucosa by certain pathogenic bacteria, including *Salmonella, Yersinia*, and *Listeria* in some species, and for some viruses. Neutrophils are seen transmigrating the epithelium of the dome, and are found in the lumen over the dome, in enteric bacterial infections of calves in particular.

The **aggregated lymphoid follicles**, or **Peyer's patches**, are scattered in the mucosa of the small intestine, and lymphoglandular complexes or solitary proprial lymphoid nodules may be grossly visible, studding the colonic mucosa. Peyer's patches are present throughout the length of the small intestine in all species, though they tend to be larger distally. They are grossly visible, usually as oval or elongate structures up to several centimeters wide, thickening the antimesenteric wall of the intestine. They may project slightly above the mucosal surface, or appear as cupped depressions, which must not be mistaken for ulcers, especially in dogs. In neonates of some species, including swine, they may be poorly developed and not visible grossly. Elongate **continuous Peyer's patches** are found in the distal ileum, involving the terminal 15–20% of the small intestine, in calves, lambs, and piglets. This structure is different morphologically and functionally from other gut-associated lymphoid tissue, and may be a primary site of B-cell generation. Continuous Peyer's patches involute as the animal matures.

Peyer's patches are comprised of *follicular aggregates of B lymphocytes in the submucosa*, underlying a discontinuous muscularis mucosae. Between the upper borders of adjacent lymphoid follicles are *aggregates of T lymphocytes*. Overlying the lymphoid follicles is a mixed population of T and B lymphocytes extending into the lamina propria in rounded mucosal projections, the *domes*, which lie between villi. Short crypts provide epithelium to domes and adjacent villi. Cell populations of Peyer's patches in newborns and gnotobiotes of most species tend to be sparser than those in older or bacterially colonized animals, though those in neonatal calves appear relatively well developed.

B and T immunoblasts gain access to Peyer's patches via permeable *postcapillary venules*, mediated by specific receptors in the postcapillary venules. The major cell populations in Peyer's patches appear to be B lymphocytes committed mainly to IgA production, while among the T cells is a large proportion of T helper cell precursors. Antigen is processed and presented to lymphocytes in Peyer's patches largely by **dendritic cells**. The cytokine context within which dendritic cells function may determine whether, in response to presentation of a soluble antigen, they induce a persistent clone of activated lymphocytes, or it is deleted, causing tolerance. Alternatively, under some conditions dendritic cells may induce clones of regulatory suppressor T cells, mediating tolerance. Mesenteric lymph nodes play a crucial role in the induction of mucosal immunity and tolerance. Antigen presentation by dendritic cells trafficking to the nodes from the gut, or trapping antigen, perhaps associated with apoptotic enterocytes, draining via lymphatics, is more important than in Peyer's patches. Dendritic cells in the liver may also play a role in inducing tolerance. **Macrophages** are less common in Peyer's patches than in lamina propria, and their role in the interaction among M cells and T and B lymphocytes is unclear. They probably play an effector role in cell-mediated reactions to bacteria entering via Peyer's patches, and certainly in response to agents such as *Mycobacterium avium paratuberculosis* and *Histoplasma capsulatum*, found in the lamina propria.

In the **lamina propria**, **dendritic cells** scattered beneath the epithelium throughout the gut can sample the intestinal luminal content directly by extending dendrites between enterocytes, without compromising the integrity of the mucosal barrier. They may also sample the environment by taking up antigen presented by enterocytes, or by phagocytosing apoptotic enterocytes. **Macrophages** and **dendritic cells** may present antigen to sensitize proprial lymphocytes, and promote cytokine production. Macrophages also sequester iron, inhibiting bacterial metabolism. Macrophages in colonic lamina propria are highly phagocytic, but have a low ability to activate T cells and promote T-cell-mediated immune responses. Proprial T cells are mixed CD4+ and CD8+, most numerous between upper crypts and in the propria of villi, and are likely antigen-activated cells. Cytokine production by these cells is probably determined by the cytokine milieu, but evolution of interferon-γ, tumor necrosis factor-α, and interleukins-1, -4, -5, -8 and -13, activating macrophages and promoting inflammation, are likely.

IgA lymphoblasts leave the Peyer's patch for the mesenteric lymph node and, via the thoracic duct, the general circulation, whence they home on the intestinal mucosa and other mucosal surfaces, including the respiratory tract, mammary gland, and salivary glands. In the lamina propria of the intestine they differentiate into IgA-secretory plasma cells, found mainly in close apposition to columnar epithelium of the upper crypt. Dimeric IgA binds via the J chain to glycoprotein "secretory component" present on the basolateral border of columnar crypt epithelial cells. With secretory component, it is transported in vesicles through the cytoplasm to be released from the apical border of the cell into the lumen of the crypt. It then spreads over the intestinal surface, partly bound to mucus.

IgA-secreting cells are the predominant class of plasma cell in the lamina propria in most species. However, **IgM-secreting plasma cells** are prevalent in young calves, swine, and dogs. IgM is also taken up by secretory component in some species and transported to the intestinal lumen. This may be significant in the young piglet and calf. Although IgA and IgM are secreted, IgG1 is the major antibody class in intestinal secretion in cattle; it appears to be selectively secreted by the gut and in the bile in that species.

The function of IgA in the gut lumen probably lies mainly in blocking attachment by bacteria and viruses to epithelial cells, neutralizing intraluminal toxins, and in limiting absorption of antigens originating in food and produced by microorganisms in the gut. It thereby reduces the likelihood of reaginic and other forms of immune response in the propria. Secretion into the bile, by hepatocytes, of IgA complexed with antigen may, in the species in which it occurs, be a significant means of clearing the circulation of antigen absorbed from the gut. IgA deficiency is reported in Beagle, German Shepherd, and Shar-Pei dogs, where it is associated with increased susceptibility to parvoviral infection, and chronic small intestinal and respiratory disease.

Plasma cells containing IgG are relatively uncommon in the intestinal lamina propria in species other than ruminants. However, locally produced and systemically circulating IgG may assume significance when vascular permeability and inflammation occur, due to its ability to fix complement, facilitate antibody-dependent cell-mediated cytotoxicity, and to opsonize.

Plasmacytes producing IgE are present in the lamina propria, in small numbers in most species. This class of immunoglobulin has been particularly implicated in immune responses to some intestinal parasites. Its significance may be in IgE-dependent cytotoxicity by eosinophils and perhaps by mast cells, as well as in mediating immediate (type I) hypersensitivity reactions in the mucosa.

Intestinal mucosal mast cells differ histochemically and physiologically from mast cells in most other tissues. They are not as demonstrable using standard stains after formalin fixation as are connective tissue mast cells from other tissues; they stain well in tissue fixed in basic lead acetate or Carnoy's fluid. They contain only tryptase, but no chymase, in contrast to connective tissue mast cells, and their granules are few, and variably, rather than uniformly, electron-dense under the electron microscope. Proliferation of intestinal mast cells is T-cell-dependent, and is prominent in some parasitisms. Histamine, serotonin, and other mediators released by mast cells have many and complex effects on vascular tone and permeability; on motility, chemotaxis, and effector function of leukocytes; on immune-active cells; and possibly on mucus release. Mast cells interact with the enteric nervous system, sensing antigen with their IgE immune probe, and communicating with the sensory arm of the enteric nervous system by degranulation, releasing stimulatory soluble mediators. They undoubtedly play a central role in regulation of physiologic, immune, and inflammatory processes in the gut. The enteric nervous system also modulates cytokine release by T cells, through interactions involving a variety of neuropeptides for which T cells have receptors. Peptide release by neuroendocrine cells may also impact on T-cell activity, as well as on intestinal function.

Intestinal **eosinophils** probably do not differ functionally from eosinophils in other sites, being cytotoxic effector cells and modulators of local inflammation.

Immunoinflammatory events in the large bowel are less well understood than those in the small intestine. Presumably, similar principles prevail. **Lymphoglandular complexes**, consisting of submucosal follicular lymphoid aggregates penetrated by glands extending from the mucosa, occur in the cecum and proximal colon of the dog; in the porcine colon; at the cecocolic junction, beginning of the spiral colon, and in the terminal rectum, in ruminants. Epithelium lining the glands is in close contact with lymphocytes. **Solitary mucosal lymphoid nodules**, normally without penetrating glands, and generally restricted to the lamina propria and superficial submucosa, are also scattered throughout the cecum and colon in all species.

Gastrointestinal microbiota

After birth, no part of the gastrointestinal tract is sterile. Hundreds of species of commensal bacteria, many of them unidentified, inhabit the stomach and intestine, forming an ecosystem of enormous complexity, in which yeasts, fungi, and protists participate in many circumstances. This ecosystem ferments exogenous and endogenous substrates, often those not within the competence of host epithelium to absorb, producing energy in the form of short-chain fatty acids, synthesizing vitamins, and converting amino compounds to ammonia. Four niches are recognized: *(1) the lumen; (2) unstirred surface mucus; (3) mucus deep in crypts; and (4) the surface of enterocytes.*

Generally, bacterial populations are least in the stomach and upper small intestine of ruminants and carnivores, being limited by the acid gastric environment and by peristalsis. The anaerobes and facultative anaerobes increase to about 10^7 per gram of content in the lower small intestine, and total bacterial populations in excess of 10^{10} or 10^{11} per gram of content are present in the cecum and colon. Prominent among colonic bacteria are coliforms, *Lactobacillus,* and strict anaerobes, including *Bacteroides*, *Fusobacterium*, *Clostridium*, *Eubacterium*, *Bifidobacterium*, and *Peptostreptococcus*. Spirochetes are found in swine and dogs. Anaerobic bacteria outnumber facultative anaerobes by a thousand-fold in the large bowel.

The complex ecology of the gut flora imparts upon it considerable stability, and if disturbed it tends to return toward the original state. It is relatively resistant to the intrusion of new inhabitants and this is one of the major factors protecting against the establishment of pathogenic bacteria. It is no coincidence that bacterial diarrhea occurs most commonly in the neonate with a poorly established flora, or after changes in husbandry or antibiotic therapy which may disturb the enteric bacterial population.

The normal flora acts as a barrier to colonization by pathogens through several means. The secretion of proteins such as colicins has little significance in modulating enteric bacterial populations; more important is the production of acetic and butyric acids by the anaerobes. Under the pH and redox conditions in the large bowel, short-chain fatty acids are highly detrimental to members of the Enterobacteriaceae. The high population of lactobacilli in the gut of milk-fed animals probably reduces the establishment of Enterobacteriaceae by this means. Facultative anaerobes are important in maintaining the redox environment for strict anaerobes, by scavenging oxygen. Competition for energy, and the effect of metabolites other than short-chain fatty acids produced by the native flora, militate against establishment by exogenous bacteria. *Host factors* influencing gut flora include composition of the diet; peristalsis, which continually flushes the small intestine of a large proportion of its bacterial population; lysozyme; lactoferrin; gastric acidity if unbuffered or undiluted; and, in the abomasum of suckling calves, perhaps a lactoperoxidase–thiocyanide–hydrogen peroxide system.

The use of probiotics, deliberate oral administration of specific microbial cultures, has been shown to improve body weight gain and decrease diarrhea in newborn calves and pigs, as well as to protect adult animals from colonization with certain pathogens, including *Escherichia coli* O157:H7 and some *Salmonella* spp.

The enteric microbial flora promotes the development of a population of immune and inflammatory cells in the lamina propria, by antigenic stimulation. Mucosal epithelial kinetics are also sped up in conventional animals, in comparison with those which are germfree. IgA secretion into the lumen may influence populations close to the mucosa, and immune activity as a whole must limit establishment on and ingress by microorganisms and their products into the mucosa, as well as establishing tolerance for normal members of the ecosystem. Lactogenic immunity similarly has an inhibitory effect on enteric organisms to which specific antibody is present in ingested milk.

Electrolyte and water transport in the intestine

Water movement in the bowel is passive, following osmotically the transport of electrolyte and nutrient solutes. The small intestinal mucosa is highly permeable to the passive movement of small ions and water and is therefore considered "leaky," despite the presence of "tight" junctions at the apical margins of absorptive enterocytes. This ensures that the content of the small bowel is approximately isosmolal with the interstitial fluid space. The permeability of junctional complexes appears to be sensitive to Starling forces, influenced by intravascular hydrostatic and oncotic pressure, so that fluid and solute actively absorbed may leak back into the lumen, thus modulating net absorption by the mucosa.

Sodium absorption takes place by a number of active transcellular mechanisms, which vary in importance at different levels of the gut, and with the physiologic circumstance. Fundamentally, Na^+ absorption depends on electrochemical forces established by the adenosine triphosphate-dependent Na^+ pump on the basolateral cell membrane of the absorptive enterocyte. This pump moves Na^+ up a concentration gradient from the cell into the lateral intercellular space.

The concentration of solute, especially Na^+, in the lateral intercellular space, causes water to follow from the intestinal lumen. Since cell membranes and junctional complexes are highly permeable to water, movement is rapid via both transcellular and paracellular routes, and differences in osmotic pressure between lumen and lateral intercellular space are small. Absorbed solute and water in isotonic proportions move into the interstitium of the villus, where, within a few micrometers, they encounter a subepithelial capillary or lacteal. The tight junctions also appear to become permeable during Na^+-nutrient cotransport across the apical cell membrane, resulting in solvent drag of large nutrient molecules into the lateral intercellular space.

The colon of carnivores, the spiral colon of ruminants and swine, and the small colon of the horse are charged with the task of reducing the volume of electrolyte and water lost to the animal in the feces. In contrast to the small intestine, *the colonic epithelium is relatively restrictive to the free movement of sodium and chloride*, though not to potassium. Therefore it is capable of maintaining differences in osmotic pressure, ionic composition, and electrical potential between luminal and proprial surfaces, which make it more efficient than the small bowel in absorbing some electrolytes and water. Ultimately, fecal water may be hypotonic with respect to plasma. Absorption of volatile fatty acids also accounts for considerable water absorption from the colon. Potassium increases in concentration in colonic content as Na^+ concentration declines; this is due to an active secretory process, and a passive response to transepithelial electrochemical gradients.

The mucosa of the small and large intestine, under some conditions, also *secretes chloride, potassium, bicarbonate, and water*. This process, which can be a function of both surface and crypt cells, is important in some pathologic states; but it is also physiologic, and segmental, maintaining the fluidity and buffering capacity of the intestinal content.

Solute movement across the intestinal epithelium is regulated by a number of *hormones and neurotransmitters*, which act through intracellular second messengers. Activation of adenylate cyclase and guanylate cyclase, and increased intracellular Ca^{2+}, all depress nutrient-independent absorption of Na^+ by enterocytes, and open Cl^- channels in crypt cells, promoting secretion. Some products of intrinsic and extrinsic neurons, such as vasoactive intestinal polypeptide and acetylcholine, may be secretory, while others, such as somatostatin and norepinephrine, are absorptive or antisecretory. Local paracrine effects are mediated by the products of enteroendocrine cells, such as somatostatin, and neurotensin (secretory). Serotonin is secretory, possibly directly, and also through stimulation of local prostaglandin production. In addition, guanylin, a peptide secreted from epithelial cells, acts to increase local fluid secretion. Mesenchymal elements in the lamina propria, including myofibroblasts, lymphocytes, mast cells, macrophages, and other inflammatory and connective tissue cells, also produce locally active substances with a direct or indirect effect on epithelial function. Circulating hormones also influence mucosal function. Aldosterone and glucocorticoids enhance Na^+ absorption by the colon, and the latter may inhibit local production of eicosanoids.

Hence, immunoinflammatory events are integrated with the systemic and local neural and hormonal regulation of intestinal absorption and secretion. Dysfunctions of absorption and secretion will be considered in the section on the pathogenesis of diarrhea, below.

Epithelial renewal in health and disease

Small intestine

The intestinal surface is lined by a population of cells ultimately derived from *stem cells* that are present at or near the base of crypts or glands, but with its proximate source in amplifier populations of undifferentiated columnar or oligomucous cells in the lower half of the crypts. These cells lose their ability to undergo mitosis, and differentiate into *goblet cells* and the functional population of *enterocytes* as they move from the crypt to the villus. In most species, they are *shed from the tips of villi* in about 2–8 days; apoptosis is a minor contributor to physiological enterocyte loss. Generally, cells move off the villus more quickly in the ileum than in the duodenum, perhaps related to the decline in height of villi with distance down the gut in most species.

Normally, the mass and topography of the mucosa are quite stable. This steady state is the product of a dynamic equilibrium between the rate of movement of cells out of crypts and on to villi, and the rate at which they are lost from the tips of villi. Equilibrium is based on interaction of the microflora with the epithelium, and presence of cell cycle regulators, especially transforming growth factor-β and other mediators, including glucagon-like peptide 2, and urokinase, which may facilitate cell shedding.

In the young animal the intestine grows by generation of new crypts, and with them, new villi. As the bowel attains mature size, the number of villi stabilizes, and apparently remains relatively constant. The number of crypts also stabilizes, but some adaptive variation in the ratio of crypts to villi may occur. Adaptive responses to a variety of factors alter the size and rate of turnover of the proliferative and functional epithelial cell populations and with them the microtopography of the gut. The appearance of the small intestinal mucosa is a compromise, achieved by the equilibrium between the rate of cell production and rate of loss. At one extreme lies the intestine of the germfree animal, with a short crypt containing a small proliferative compartment, and tall villi supporting a large functional compartment with a low rate of cell loss. At the other end of the spectrum is the animal suffering from severe intestinal helminthosis, with long crypts reflecting an increased proliferative compartment, yet a flat mucosal surface with relatively few functional enterocytes and an apparently high rate of cell loss.

Although quantitative description of epithelial kinetics is possible experimentally, in the diagnostic situation it is necessary to make a subjective or semiquantitative assessment of the status of the proliferative and functional compartments in tissue sections. The size of the proliferative compartment is reflected in the length and diameter of the crypts, and in the location of the uppermost mitotic cell. The prevalence of mitotic figures can be assessed subjectively, but beyond calculating a mitotic index, no inferences can be drawn about the proportion of the crypt cell population that is replicating, or the duration of the cell cycle.

The *degree of differentiation*, and hence functional status, of enterocytes on villi can be inferred from their appearance. Cytoplasmic basophilia; loss of regular basal nuclear polarity; low columnar, cuboidal, or squamous shape; and an ill-defined brush border all point to a poorly differentiated population of surface enterocytes, which is possibly turning over more rapidly than normal.

Fasting reduces the mucosal epithelial mass; the atrophy is related to prolongation of the postmitotic phase of the cell cycle in the proliferative compartment. Villi do not regress severely, however, since cells on the surface persist for twice as long, moving off the villus more slowly. The effect is immediately reversed by refeeding. Weaning also has similar profound effects on the structure of the intestine, resulting in marked reduction in height of villi in most species.

Restitution of epithelial integrity following minor loss of mucosal surface cells is by *lateral migration of adjacent intact epithelium*, and occurs within minutes. If epithelium on villi is obliterated, for instance by transient ischemia or by viral cytolysis, the villus core contracts, probably due to myofibroblast activity mediated by the enteric nervous system, and stromal elements rapidly undergo apoptosis. Surviving epithelial cells become attenuated, and extend across the denuded intercrypt surface. Restitution is positively influenced by local growth factors and especially by trefoil factors present in mucus.

Regeneration of the mucosa follows, as the three-dimensional architecture is restored within a few days, during which the proliferative compartment undergoes hyperplasia, generating new epithelium, and the stroma is rebuilt. Extensive mucosal ulcers will form a bed of granulation tissue, and with time (weeks to months) may become covered by a neomucosa, with crypts and villi, which evolves following the centripetal immigration of flattened epithelium from the periphery of the lesion. A similar process repairs the mucosal gap in healing intestinal anastomoses.

Villus atrophy

Atrophy of villi is a common pathologic change in the intestine of domestic animals. It results in malabsorption of nutrients, and is sometimes associated with increased plasma protein loss into the gut. Mucosa with short villi can be categorized morphologically into two broad types, recognition of which has implications with respect to pathogenesis and prognosis. The first category includes intestine with apparently normal or hypertrophic crypts, associated with atrophy of villi to various degrees. The second category is comprised of gut with some evidence of damage to the proliferative compartment, and variable villus atrophy. The recognition, evolution, and interpretation of each will be considered in turn.

Villus atrophy with an intact or hypertrophic proliferative compartment takes two forms in domestic animals. A **primary increase in rate of loss of epithelium** from the surface of villi is one mechanism initiating such a lesion. This is the major pathogenetic action of a number of important viral diseases, including coronaviral and rotaviral infection; of coccidial infections which damage surface enterocytes predominantly; of some enteroinvasive bacteria; of transient ischemia, in which the effect is limited to the functional compartment; and, in some circumstances, of necrotizing toxins released by clostridia in the lumen of the bowel. The effect of these agents is to cause significantly increased loss of surface epithelium over a relatively short period of time, while sparing the proliferative compartment in crypts. Villi contract as the size of the functional compartment is diminished, and they may become very stubby. If the animal survives the metabolic sequelae to the malabsorption that results from the damage to surface cells, *compensatory expansion of the proliferative compartment in crypts* permits complete recovery. Epithelium emerging from crypts regenerates villi, resulting in a normal mucosal topography within a few days, and full function returns.

The microscopic appearance of the mucosa depends partly on the number of functional cells lost, which determines the initial degree of villus atrophy, and partly on the amount of regeneration that has occurred by the time the gut is examined. During the early phase of cell loss, damaged epithelium may be seen exfoliating into the lumen of the gut, and villi are shorter or blunter than normal, or sometimes more or less of normal length, but somewhat pointed. Subsequently, the atrophic villi are covered by poorly differentiated, low columnar, cuboidal or squamous cells. There may be fusion of the lateral surfaces or tips of villi in some areas. In severe atrophy there may be mild erosion if inadequate epithelium is available to cover even the much-reduced mucosal surface area. In the acute phase, crypts appear of normal size, but within 12–24 hours, proliferative activity is noticeably increased. Crypts enlarge in diameter and length to accommodate more mitotic cells, which are basophilic, crowded, and obviously dividing, sometimes very close to the surface of the mucosa. The lamina propria appears moderately hypercellular, perhaps due to condensation, possibly due to a mild mononuclear cell infiltrate. As regeneration occurs, progressively longer villi with increasingly well-differentiated epithelium are evident, and hypertrophy of the proliferative compartment gradually subsides.

Atrophy of villi and hypertrophy of crypts is also associated with **chronic or persistent processes** such as nematode parasitism; chronic coccidial infection of surface epithelium; giardiasis in some species; response to dietary components in some species, including soybean protein in calves, kidney bean protein in pigs, and wheat in dogs; idiopathic or specific granulomatous enteritis, such as Johne's disease and histoplasmosis; and chronic inflammatory bowel disease characterized by heavy lymphocytic/plasmacytic infiltrates in the mucosa. Epithelial kinetics have not been investigated in most of these situations in domestic animals. However, they all have in common chronic antigenic exposure, parasitism, or a persistent infectious process in the lumen, epithelium, or lamina propria, usually associated with a significant lymphocytic and plasmacytic infiltrate in the mucosa. Where the etiology can be eliminated, the lesion usually remits, implying that it requires active interaction between host and parasite for its induction and maintenance. The situation is entirely analogous to that of celiac disease in humans, which clearly is an immune-mediated response to specific dietary antigens, through activation of mucosal T cells secreting γ-interferon, among other cytokines. Strong evidence implicates Th2 lymphocyte-driven nitric oxide production in the pathogenesis of villus atrophy in experimental helminth infections in mice. The source and effect of the nitric oxide are uncertain, as is its possible interaction with cytokines such as interleukin-12, interferon-γ, and tumor necrosis factor-β, also implicated in villus atrophy of this type in experimental models. T-cell activity seems to be associated with villus atrophy of this type in parasitisms such as giardiasis as well.

Immune reactions in the gut are associated with increased epithelial cell proliferation. Hypertrophy of the proliferative compartment in these conditions *precedes* the development of villus atrophy, and *is not a response to it.* Evidence points to local stimulation of the proliferative compartment, and perhaps the associated myofibroblast sheath, by cytokines or nitric oxide released by activated T lymphocytes in the mucosa. Epithelial cells leaving the crypts usually do not differentiate fully. They exfoliate prematurely, low on the villus or near the crypt opening, and as the pre-existing enterocytes are shed, villi undergo atrophy over a period of several days. Epithelium that reaches the surface subsequently fails to differentiate fully, though it may become mucous metaplastic, and is rapidly lost into the lumen, matching the rate of cell production.

Hypertrophy of crypts is the early and outstanding change in this lesion, and is consistently present. In its milder forms, the lesion may be better characterized by elongate crypts than by obvious atrophy of villi. The proliferative compartment is expanded and active, and mitotic figures are numerous; goblet-cell hyperplasia may also occur. Elongation of crypts may be so great that even with severe atrophy of villi the total mucosal thickness will not be much reduced from normal. Close observation may reveal poorly differentiated enterocytes exfoliating prematurely from intercrypt ridges on the mucosal surface, or from buttress-like folds around the base of stubby villi. The lamina propria has a prominent population of lymphocytes, plasmacytes, and associated inflammatory cells, and intraepithelial lymphocytes are common. The etiologic agent, in the form of parasites, intracellular bacteria, or yeasts, may be evident. Removal of the causal stimulus, where that is possible, usually results in a return to "normal" within days or weeks.

However it is induced, atrophy of villi with hypertrophy of crypts is associated with local malabsorption of nutrients and water; elongate crypts and perhaps poorly differentiated surface epithelium may secrete electrolytes and water; and if there is proprial inflammation and microerosion of the mucosa, effusion of tissue fluid may ensue. Increased turnover of epithelium may contribute to enteric loss of endogenous protein.

Villus atrophy associated with damage to the proliferative compartment is also commonly seen in domestic animals. It is the sequel to insults that cause necrosis of cells in crypts, or impair their mitotic capacity. The agents that produce these lesions usually have a propensity for damaging dividing cells in any tissue. Since ionizing radiation was recognized early as a cause of such lesions, they are often termed "*radiomimetic.*" Other causative agents include cytotoxic chemicals and mitotic poisons, such as cancer chemotherapeutic agents, T-2 mycotoxin, and pyrrolizidine alkaloids in large doses; viruses that infect proliferating cells, particularly the parvoviruses, and *Bovine viral diarrhea virus* and *Rinderpest virus*. Ischemia of sufficient duration to cause necrosis of some or all cells lining the crypts also causes a lesion of this type.

The microscopic appearance of affected mucosa depends on the severity and extent of the insult, and the interval since it occurred. The primary event is damage to the proliferative compartment, and, except in ischemia, lesions will be evident in crypts well before significant atrophy of villi occurs. Apoptotic epithelial cells and neutrophils may be present in the lumen of damaged crypts, which tend to dilate. If crypt cell necrosis is severe, remaining cells become extremely flattened in the course of attempting to maintain the integrity of the crypt lining. Following radiation, cytotoxic damage, and parvoviral infection, bizarre irregular epithelial cells with large nuclei and nucleoli may be present in crypts and will migrate on to the surface.

Pre-existing surface epithelium continues to move off the tips of villi at an apparently normal rate, even though few or no new cells emerge from crypts. Villi eventually become atrophic or collapse as the surface cell population shrinks. If most proliferative and stem cells have been damaged, crypts stripped of epithelium will also collapse, or "drop out," perhaps leaving a few scattered cystic remnants, lined by attenuated epithelium, in the deeper lamina propria. The overlying surface will be covered by squamous epithelial cells derived from surviving crypts, or will be eroded; the mucosa may eventually ulcerate, to be lined by granulation tissue. Crypts that have not been so severely damaged will undergo hypertrophy within a week or so of the original insult, as compensatory hyperplasia of lining cells occurs.

In viral diseases, the severity and appearance of the lesion often vary considerably at different sites in the gut, and even within an individual tissue section. Lesions due to ischemia tend to be uniform in severity but may be localized; acute or subacute lesions are often hemorrhagic, if there has been reflow.

Extensive lesions due to crypt cell necrosis lead to erosion or ulceration, with severe malabsorption, and effusion of tissue fluid and hemorrhage. The mucosa is often invaded by the enteric flora, sometimes including fungi. Local ulceration may lead to persistent plasma loss, and, if circumferential, to stricture and stenosis. Small ulcers in areas where a few crypts have dropped out will heal as epithelium from adjacent crypts moves over the surface, but crypts may not regenerate for some time, and local villus atrophy will persist.

Large intestine

Epithelial turnover in the cecum and colon is fundamentally similar to that in the small intestine, though villi are not present on the surface. Cells lose the ability to divide after leaving the proliferative compartment in the lower part of the gland. In the upper portion of the gland they differentiate into goblet cells or columnar absorptive cells that emerge and move out over the surface. They are lost into the lumen, probably within about 4–8 days of being produced, though no studies of colonic epithelial turnover have been made in domestic animals. Fasting reduces, and refeeding restores, proliferative activity in colonic glands in experimental animals, and physical distension and certain types of dietary fiber in the colon also appear to be trophic for the mucosa. The colon of gnotobiotic animals has a small number of proliferative cells, limited to the lower portion of the glands. With conventionalization of the gut flora, the proliferative compartment expands.

Restitution of the epithelial integrity of the surface of the large bowel, following insult to, and exfoliation of, surface cells, resembles that in the small bowel. Within a few minutes of injury, surviving surface epithelium, and cells emerging from crypts, become attenuated and migrate at a rate of several micrometers per minute to extend over mucosal defects. Ulcers, surgical incisions, or anastomotic sites in the colon heal by immigration of a single layer of epithelium from the periphery of the defect, with gradual differentiation of crypts, and eventual restitution of normal mucosal architecture. In the horse, depending on the type of anastomosis, epithelium may take over 2 weeks to bridge the granulation tissue in the gap in the mucosa, and restitution of mucosal architecture may require about 2 months.

Lesions in the large bowel presumed to be associated with *increased epithelial turnover* include alterations in both surface and glandular epithelium. The number of goblet cells on the surface and in the upper portion of glands is often diminished, and epithelium in these areas appears poorly differentiated, is more basophilic than normal, and may be low columnar, cuboidal, or squamous. In severe diseases, microerosion of the surface is present. The proliferative compartment in the gland may hypertrophy, causing glands to elongate and dilate. Crowded mitotic cells are present over a greater proportion of the length of the gland, sometimes virtually to the surface of the mucosa, though in some situations goblet-cell hyperplasia may occur. Such changes may be associated with acute, chronic, or chronic-active inflammation of the lamina propria. It is uncertain whether such changes are caused by primary damage to surface epithelium, or by cell-mediated immune effects on the proliferative compartment, analogous to those that occur in the small intestine in celiac disease of humans.

The *proliferative compartment* in the cecal and colonic glands is damaged by the same insults that attack cells in the crypts of the small bowel. However, cytotoxins and parvoviruses tend not to produce severe lesions so commonly in large bowel as they do in small intestine, perhaps because a lower proportion of the proliferative compartment is in mitosis at the time of maximum availability of drug or virus. Additions to the list of agents damaging the proliferative compartment in large intestine include coronavirus in calves, cattle, and dogs, and several species of coccidia in ruminants, which develop in the cells lining glands in the large bowel.

The *evolution and sequelae of lesions* resulting from damage to proliferative epithelium in the large intestine are similar to those in small bowel. Dilation of crypts containing necrotic debris, and lined by attenuated epithelium, indicates such damage. Severe lesions will lead to loss of glands, erosion, and ulceration of the mucosa, perhaps with hemorrhage. Stricture and stenosis may ensue. Following milder damage that spares some stem cells in each gland, the mucosa has the potential to recover fully after a period of reparative hyperplasia.

Pathophysiology of enteric disease

Protein-energy malnutrition, due to intake of too little feed, or of feed deficient in quantity or quality of nutrients, results in *depletion of fat and muscle mass*, emaciation, and ultimately, death by starvation. In addition, immune function is impaired, predisposing to infection.

Inappetence or, in extreme cases, **anorexia**, are commonly associated with gastrointestinal diseases. Appetite is modulated by a complex and incompletely understood meshwork of neurologic, neuroendocrine, and systemic cytokine inputs impacting centrally on satiety. The potential for physical impairment of gastrointestinal function to affect appetite seems relatively obvious. Less apparent, but highly significant, are the effects on appetite of chronic inflammatory diseases affecting the alimentary system, or distant sites. Possible direct or indirect mediators of this effect are tumor necrosis factor-α and interleukin-1 released from macrophages and other cells. In addition to simply reducing food intake, they may play a role in the complex metabolic puzzle that is the **cachexia**, characterized by active erosion of adipose tissue and muscle mass, associated with chronic inflammatory disease and neoplasia.

Protein-energy malnutrition must be differentiated from the effects of endogenous conditions resulting in malassimilation or protein-losing enteropathy, from cachexia induced by chronic inflammatory and neoplastic disease, and from other problems that may result in recumbency.

In neonates, several factors predispose to death by starvation within the first few weeks of life. These include increased energy demands due to cold and exposure; fetal malnutrition with poor fat depots at birth; and postpartum hyponutrition, which in calves is often associated with poor-quality or insufficient milk replacer. Piglets are born with negligible fat reserves and die quickly of hypoglycemia if not fed adequately. Neonatal ruminants usually have fat depots sufficient to compensate for longer periods of inanition (2–4 days for lambs; 6–10 days for calves), if cold stress is not severe.

In animals that have died of inanition, muscle mass is reduced, due to mobilization of amino acids for gluconeogenesis. Fat in the bone marrow, coronary groove, on the pericardial sac, and around the kidneys is completely depleted, and has the gelatinous clear pink appearance of **serous atrophy**. The liver may appear small, with sharp margins, presumably due to reduced trophic stimuli. A diagnosis of starvation is supported by a history of conditions compatible with reduced quantity or quality of feed, and by steps to rule out problems causing malassimilation and protein-losing gastroenteropathy.

Malassimilation

Digestion and assimilation of nutrients have an *intraluminal phase*, mediated by the biliary and pancreatic secretions, and an *epithelial phase*, carried out by enzyme systems on the surface and in the cytoplasm of absorptive enterocytes. The final step is delivery of the nutrient by the enterocyte to the interstitial fluid, and its uptake into the blood or lymph.

Exocrine pancreatic insufficiency *is the major cause of intraluminal maldigestion*, and it is usually due to juvenile pancreatic atrophy in dogs, or to pancreatic fibrosis and atrophy following repeated episodes of pancreatic necrosis (see Vol. 2, Pancreas). It is occasionally seen in cats. This condition may be complicated by bacterial overgrowth of the small intestine. Bile salt deficiency is rarely seen as a cause of intraluminal maldigestion in domestic animals.

The **epithelial phase of digestion** *is impaired by loss of functional epithelial surface area*. This occurs in short-bowel syndrome following intestinal resection, in which greater than 75–85% of the small bowel has been lost, and, more commonly, in *villus atrophy*. Neonates and ruminants have low levels of maltase; ruminants lack sucrase. In most species, lactase levels decline with age, and malabsorption in dogs fed milk has been attributed to low levels of lactase. The poorly differentiated surface epithelium present on atrophic villi may lack the full complement of enzymes on the brush border and in the cytoplasm necessary for nutrient digestion and assimilation. Lectins present in uncooked beans attach to and damage microvilli on enterocytes, which may explain the malabsorption and diarrhea associated with their use in feeds; lectins also promote bacterial adhesion and overgrowth in the small intestine. A heritable syndrome of *gluten-sensitive enteropathy* has been reported in Irish Setter dogs. This entity is characterized by villus atrophy, increased intraepithelial lymphocytes, and abnormal levels of mucosal microvillar hydrolases. *Cobalamin malabsorption* has been described as a hereditary defect in Beagles, Giant Schnauzers and Border Collies, resulting in anemia and failure to thrive. Delivery of nutrients, especially lipid, to the circulation, may be impaired in lymphangiectasia. The pathogenesis of malabsorption of the major classes of nutrients will be considered briefly.

Assimilation of fat is susceptible to interference at all three phases of digestion and absorption. Lipolysis is impaired if insufficient lipase is available. Most commonly this is a result of pancreatic atrophy or fibrosis. It may also be due to failure by atrophic intestinal mucosa to release the cholecystokinin/pancreozymin necessary for pancreatic secretion. The availability of bile salts for micelle formation is reduced in intrahepatic cholestasis, biliary obstruction, and by depletion of the bile salt pool due to reduced ileal absorption following resection or atrophy. As a result, fatty acid and monoglyceride are not incorporated on to micelles and emulsified; they are therefore not as accessible to absorptive enterocytes. Reduced surface area for lipid uptake will contribute to malabsorption of fat. Poorly differentiated enterocytes on atrophic gut may be less able than normal epithelium to re-esterify long-chain fatty acids to triglyceride and to produce chylomicrons for export from the cell. In lymphangiectasia, granulomatous enteritis, and intestinal lymphosarcoma, lymphatic drainage may be obstructed, and with it the flow of chylomicrons to the systemic circulation.

Malabsorption of lipids may cause *steatorrhea* (excess fat in the feces). It is seen in monogastric animals, especially dogs. Severe fat malabsorption may result in deficiencies of fat-soluble vitamins. Malabsorption of calcium, magnesium, and zinc occurs due to their sequestration in soaps formed by combination with malabsorbed luminal fatty acids. Increased absorption of oxalate, and consequent nephrolithiasis, may be a sequel to reduced concentrations of calcium in the lumen due to soap formation. Malabsorbed lipid may cause *colonic diarrhea*, by mechanisms that will be discussed subsequently.

Maldigestion of polysaccharides occurs if levels of pancreatic amylase are reduced; this is most commonly encountered in dogs with severe loss of functional exocrine pancreatic tissue. Calves and older ruminants normally lack significant amounts of pancreatic amylase and digest starch poorly in the small intestine. Mucosal oligosaccharidase deficiency occurs in villus atrophy, with reduced mucosal surface area. Poor differentiation of enterocytes results in irregular, short, and sparse microvilli, and a reduced complement of oligosaccharidases. The result is impaired membrane digestion of disaccharide and malabsorption of carbohydrate, much of which is subsequently fermented by colonic flora. The osmotic effect of malabsorbed disaccharide augments intraluminal fluid accumulation in the small intestine, and this may be compounded by hydrolysis in the colon. Carbohydrate malabsorption is an important component of disease in neonatal diarrhea due to rotavirus and coronavirus, and in other conditions in which there is extensive villus atrophy in the small intestine.

Protein digestion in the lumen is reduced if pancreatic protease activity is decreased to ~10% of normal, as may occur with exocrine pancreatic insufficiency. Loss of gastric proteolytic activity is of little nutritional significance. In conditions with villus atrophy, reduced mucosal surface area and poor differentiation of enterocytes result in malabsorption of small peptides and particularly of amino acids by mechanisms similar to those involved in carbohydrate malabsorption.

Diarrhea

Diarrhea is the presence of water in feces in relative excess in proportion to fecal dry matter. Diarrhea usually reflects increased absolute fecal loss of water, but may not, if absolute fecal dry-matter excretion is markedly reduced. Loss of solute and water in diarrhea may lead to *severe electrolyte depletion, acid–base imbalance, and dehydration*, which are life-threatening if not corrected.

Large volumes of fluid derived from ingesta, and from gastric, pancreatic, biliary, and enteric secretion, enter the small bowel; in addition, considerable passive movement of water occurs into the upper small bowel from the circulation in response to osmotic effects. Overall, the bulk of the fluid entering the small intestine is absorbed by the enterocytes, so that the volume leaving the ileum and entering the colon is but a small fraction of the total fluid flux through the small bowel. The large size of this flux implies that relatively small perturbations in unidirectional movement of electrolyte and water may have significant effects on the net movement of fluid.

The colon, in addition to its fermentative function, has the ultimate responsibility for conserving electrolyte and water by absorption from the digesta, thereby minimizing fecal loss. It has a finite capacity for absorption, and if this is exceeded by the rate at which content enters from the small bowel, diarrhea occurs. This is important in "small-bowel" diarrheas, where the lesion is in the small intestine. Since the colon has reserve absorptive capacity, the excess volume entering from the ileum must be considerable for diarrhea to occur. The large capacity and fermentative function of the equine colon may mitigate to some extent the expression of "small-bowel" diarrhea in mature animals of that species.

"Large-bowel" diarrhea, on the other hand, reflects an intrinsically reduced capacity of the colon to handle even normal volumes of fluid and electrolyte presented to it by the small intestine.

Small-bowel diarrhea is classed as "secretory," "malabsorptive," or "effusive," but the mechanisms are not mutually exclusive.

Secretory diarrhea is due to an excess of secretion over absorption of fluid, resulting from derangement of normal secretory and absorptive mechanisms. It is best exemplified by the effects of *diarrheagenic bacterial enterotoxins. Vibrio cholerae* and *Escherichia coli* are the most important sources of such toxins, though only the latter occurs in domestic animals; some *Salmonella* serotypes, *Yersinia enterocolitica*, *Shigella*, and *Campylobacter jejuni* also produce enterotoxin. Cholera, heat-labile *E. coli*, and *C. jejuni* enterotoxin act through the mediation of cyclic adenosine monophosphate (cAMP). Toxin-stimulated cAMP shuts down sodium chloride cotransport at the luminal cell membrane of enterocytes, reducing passive water absorption. Meanwhile, cAMP-stimulated chloride secretion is promoted, and water follows. The resultant increase in secretion and decrease in absorption increase the solute and water load passing from the small bowel to the colon. Heat-stable *E. coli* and *Y. enterocolitica* enterotoxins stimulate cyclic guanosine monophosphate-mediated secretion by the mucosa.

In addition to bacterial enterotoxins, *other factors* may potentially cause secretory diarrhea. Prostaglandins, other eicosanoids, histamine, kinins, and various cytokines directly or indirectly stimulate secretion, often by local stimulation of enteric nervous reflexes, and they may contribute to diarrhea in inflammatory bowel disease. Vasoactive intestinal polypeptide secreted by pancreatic islet cell tumors causes severe diarrhea in humans with such tumors, and is probably the final mediator in secretion stimulated by the enteric nervous system. Thyroid C-cell tumors secrete calcitonin; carcinoids secrete serotonin, bradykinin, and substance P; while mast cell tumors secrete histamine, which is also diarrheagenic. Peptide YY has been identified as a powerful inhibitor of intestinal secretion; its presence is mediated by prostaglandin profiles.

Malabsorptive diarrhea is exemplified by the osmotic retention of water in the gut lumen by poorly absorbed magnesium sulfate, used therapeutically as a laxative. *Malabsorption commonly results from villus atrophy, no matter what the cause.* Electrolyte and nutrient solute, malabsorbed as the result of reduced villus and microvillus surface area, are retained in the lumen of the bowel, along with osmotically associated water. The additional solute and water are passed on to the colon. A secretory component probably contributes to diarrhea due to villus atrophy, at least in transmissible gastroenteritis in pigs. Here, since the villus limb of the postulated crypt–villus fluid circuit is diminished or missing, fluid secreted by the crypts may not be absorbed. Poorly differentiated cells emerging on to the intestinal surface from crypts may also retain some secretory capacity. Malabsorptive diarrhea also occurs in *short-bowel syndrome*, due to reduced absorptive surface.

Increased permeability of the mucosa may contribute to diarrhea by permitting increased retrograde movement of solute and fluid from the *lateral intercellular space* to the lumen, or by facilitating transudation of tissue fluid. **Filtration secretion** is characterized by increased fluid movement through the epithelial membrane via the *paracellular route*; the force for secretion is provided by the transepithelial hydrostatic pressure gradient. Elevated capillary hydrostatic pressure, or decreased plasma oncotic pressure in the villus, alters Starling forces, resulting in edema. This overrides the hydrostatic pressure in the interepithelial space, and permits leakage of interstitial fluid and large protein molecules into the lumen through enlarged pores at the tight junctions. Portal hypertension, right-sided heart failure, hypoalbuminemia, and expansion of plasma volume establish such conditions. Effusion may occur in lymphangiectasia, and in inflamed lamina propria, with increased vascular permeability, proprial edema, and enteric plasma protein loss. Increased exfoliation of epithelium and transient microerosions may provide further potential sites for effusion of interstitial fluid.

Severe necrosis of the epithelium and vascular damage in the mucosa cause obvious malabsorption, and effusion of tissue fluid and blood, evident as fibrin and hemorrhage, in the lumen.

Large-bowel diarrhea *is due to a reduction in the innate capability of the colon to absorb the solute and fluid presented by the more proximal bowel.* A reduction in net absorption by the colon that is relatively small in absolute terms may be sufficient to cause fluid feces. Colonic diarrhea is characterized by *frequent passage of small amounts of fluid feces*, perhaps with mucus and blood.

The colonic mucosa is not as "leaky" as the small intestinal mucosa due to the nature of the tight junctions between epithelial cells. As a result, it is relatively resistant to alterations in permeability due to increased hydrostatic pressure in the propria, in comparison with the small intestine.

Bile acids mediate diarrhea associated with ileal disease. When normal enterohepatic circulation of bile acids is interrupted by ileal damage or resection, *excess bile acids* enter the colon where they stimulate chloride ion secretion through a cAMP-dependent mechanism, resulting in diarrhea. *Fatty acids* enter the colon in increased quantities in steatorrhea resulting from bile salt depletion. Both dihydroxy bile acids and long-chain fatty acids, especially hydroxy fatty acids produced by bacterial action, alter mucosal permeability and cause mild damage to the surface epithelium. The result is net fluid secretion by the colon, and diarrhea. This is also the mode of action of a number of laxatives, including senna and castor oil, which contains the hydroxy fatty acid ricinoleic acid.

Although colonic secretion stimulated by bacterial enterotoxin is not clearly implicated in diarrhea, alterations in the flora in the large bowel may be detrimental to normal function. Absorption of volatile fatty acids produced by bacterial fermentation is responsible for considerable concurrent absorption of water in the large intestine. Reduced production or absorption of volatile fatty acids, secondary to *imbalance of the bacterial flora* in the cecum and colon, may explain some problems of wasting and diarrhea in horses in which no morphologic abnormality of the mucosa can be found.

Osmotic overload of the large bowel results from the delivery by the small bowel of a large volume of fermentable substrate. This may result from excessive intake, but is usually due to malabsorption in the small intestine. Of the malabsorbed nutrients, carbohydrate is the only one of significance in initiating *colonic osmotic overload*. Bacterial fermentation of carbohydrate results in the production of excess volatile fatty acid. This is readily handled by the colon under normal circumstances, by rapid absorption and by bicarbonate buffering. However, a heavy carbohydrate load may overwhelm the colonic buffering capacity, and cause reduced pH. This results in an *altered gut flora* dominated by organisms producing lactic acid, which is absorbed at a slower rate than the volatile fatty acids. Further acidification causes mucosal permeability, permitting an influx of water and solute into the lumen from the tissue, as a result of the increased osmotic pressure generated by lactic acid in the lumen. Diarrhea follows.

Increased intestinal motility probably does not have a primary role in the pathogenesis of diarrhea. Often the small intestine of animals with diarrhea is flaccid and fluid-filled, rather than hypermotile. Increased colonic motor activity is often segmental and antiperistaltic, and probably unrelated to increased transit. Hypermotility, if it does occur, may be in response to, rather than a cause of, increased volumes of fluid in the gut.

Small intestinal bacterial overgrowth (SIBO) may be a consequence of ileus or hypomotility, partial small-bowel obstruction, and radiation injury. Achlorhydria or hypochlorhydria and pancreatic exocrine insufficiency in the dog may also predispose to this problem. Not associated with any histologic changes other then the presence of bacterial colonies in mucus on the mucosal surface in some cases, SIBO is thought to result in increased intestinal permeability that translates clinically to diarrhea.

Protein metabolism in enteric disease

Disorders of protein metabolism attributable to enteric disease are responsible for significant economic loss in the form of reduced weight gain, wool growth, and milk production. Severe derangement, resulting in negative nitrogen balance in any species, may lead to cachexia, hypoproteinemia, and death.

Decreased protein intake is the most obvious threat to the nitrogen economy, and it is probably the most important in many chronic gastrointestinal diseases. Subclinical inefficiency in production, reduced growth, and emaciation may be the product of various degrees of inappetence, or difficulty in prehension, mastication, and swallowing, or recurrent regurgitation. Low feed quality compounds the effect of reduced feed intake.

A sharp decline in appetite, or *anorexia*, is a common sign of indigestion, obstruction, or systemic disease. In ruminants, loss of appetite to various degrees is an especially important component of the pathogenicity of gastrointestinal parasites, including those infecting the abomasum (*Ostertagia*), small intestine (*Trichostrongylus*), and large bowel (*Oesophagostomum*). Interactions among cholecystokinin, parasympathetic efferent and afferent reflexes, and systemic or gastric leptins, appear to mediate satiety. How they are disrupted in disease states is unclear.

Malabsorption of peptides and amino acids may occur locally in the small intestine as a result of significant *villus atrophy*. However, unless the lesion is widespread, or low in the small bowel, net absorption of nitrogen over the length of the small intestine may not be reduced, due to the compensatory capacity of more distal normal mucosa. Overall, the contribution of malabsorption to disordered nitrogen metabolism appears to be *minor* in most situations.

Protein-losing gastroenteropathy, increased catabolism and loss of endogenous nitrogen via the gastrointestinal tract, is important in many diseases. Excess endogenous protein entering the intestine is derived from two main sources, namely *increased turnover of cells lining the gut*, and *effusion of plasma protein into the lumen of the bowel*; the latter is probably the more important.

Plasma protein loss into the gut presupposes abnormal permeability of the mucosa to large molecules. This may be the product of the blood-sucking activity of nematodes such as *Haemonchus, Ancylostoma,* and *Bunostomum*, or hemorrhage from sites of trauma in the mucosa caused by the feeding activity of worms such as *Oesophagostomum columbianum, Chabertia*, and *Strongylus*. Erosive lesions result in considerable loss of red blood cells and plasma protein. Such lesions may be due to infarction, severe cryptal necrosis, or acute inflammatory damage to the mucosa associated with bacteria, viruses, and coccidia, causing fibrinohemorrhagic enteritis. Microscopic "leaks" in the mucosa also permit plasma loss into the gut. These may result from increased exfoliation of enterocytes into the lumen in villus atrophy, as transient gaps in the mucosa at the site where the cell sloughs. In villus atrophy with a high rate of enterocyte turnover, temporary micro-erosions may develop when flattened cells fail to maintain the integrity of the surface epithelium. The permeability of tight junctions between epithelial cells may be sufficiently altered to permit transit of plasma protein molecules, associated with **filtration secretion** when the hydrostatic pressure in the proprial interstitium is elevated in congestive heart failure and portal hypertension; by decreased plasma oncotic pressure; by increased vascular permeability in acute or chronic inflammation; and in lymphatic obstruction or lymphangiectasia. Tumor necrosis factor-α, prevalent during chronic inflammation, may cause increased paracellular epithelial permeability to large molecules entering the mucosa, and such conditions may permit plasma protein molecules to move in the luminal direction.

Plasma protein loss into the gut is nonselective. Albumin, immunoglobulins, clotting factors, and a variety of transport or carrier proteins, including transferrin, ceruloplasmin, and transcortin, are lost. The physiologic consequences of protein-losing enteropathy may reflect increased catabolism of any of these molecules, but are most obviously related to increased turnover of the albumin pool. Plasma albumin loss into the gut, when expressed as a proportion of the total body pool, will vary in absolute terms, depending on the size of the pool. This concept of **fractional catabolic rate** is essential to understanding the kinetics of plasma protein turnover.

In protein-losing enteropathy, albumin turnover may pass through three phases. During the first phase, the *fractional catabolic rate increases* and, with it, the absolute amount of protein lost into the bowel; as the size of the circulating pool of albumin shrinks, so does the absolute rate of loss of protein, even though the fractional rate remains the same. During the second phase, the size of the circulating pool stabilizes as the rate of albumin synthesis by the liver increases to match in absolute terms the rate of loss. The plasma albumin pool is then in a state of *hyperkinetic equilibrium*; the pool is smaller, with a higher than normal fractional catabolic rate compensated by an increased rate of hepatic synthesis. Provided that the amount of albumin lost does not exceed the synthetic capacity of the liver, this equilibrium may persist for a considerable period. In the third phase, *hypoalbuminemia* *develops as the fractional catabolic rate exceeds in absolute terms the synthetic capacity of the liver.* Alternatively, hypoalbuminemia occurs in the third phase if the rate of synthesis declines, due to deficiency in amino acids derived from the diet and by catabolism of other body protein. The hypoalbuminemia in enteric plasma loss is often associated with *hyperglobulinemia*, since compensatory synthesis of immunoglobulin is remarkable. Several times more immunoglobulin than albumin may be lost into the gut as a result.

The progress and clinical manifestations of protein-losing enteropathy vary with the rate of onset of plasma loss and the fractional catabolic rate. A sudden onset of severe plasma protein loss may cause death during the first phase, before there is time for compensatory synthesis. If the fractional catabolic rate is gradually and only slightly increased, so that compensation occurs with the albumin pool in equilibrium at only a marginally reduced state (perhaps near or within the normal range), subclinical protein loss occurs. Though the fractional catabolic rate is only slightly elevated, the relatively large size of the albumin pool may mean that the absolute loss of protein exceeds that in a hypoalbuminemic animal with a higher fractional catabolic rate, but a smaller albumin pool.

Plasma protein leaking from the stomach or upper small intestine, and protein derived from exfoliated cells in villus atrophy, may be digested and absorbed in the small intestine. This is dependent on luminal proteolysis by pancreatic enzymes, and compensatory membrane digestion and absorption making up for any malabsorption by proximal atrophic mucosa. But the efficiency of protein digestion, even if it is not reduced, is not total. Therefore, a proportion of the increased endogenous protein entering the lumen will be added to the protein escaping digestion in the small bowel, and will enter the large intestine. Here, most of this protein may be converted to ammonia by the colonic flora and absorbed, so that in animals losing protein high in the gut, there may be little or no increase in fecal nitrogen excretion. On the other hand, much of the protein lost into the colon from lesions at that level is passed in the feces, often as protein, and is lost. Ammonia nitrogen absorbed from the colon is converted in the liver mainly to urea. Animals with increased endogenous protein loss into the stomach or small intestine tend to have slightly raised levels of plasma urea, and an elevated rate of urinary urea excretion.

Elevated hepatic synthesis of albumin due to increased turnover of the plasma albumin pool, and increased enteric protein synthesis in support of elevated epithelial turnover in conditions with chronic villus atrophy, is at the expense of anabolic processes elsewhere. Dietary amino acid is diverted to preferential synthesis of plasma and enteric protein. If protein intake is poor due to inappetence or a low-quality ration, or if the rate of protein loss is high, the animal moves into **negative nitrogen balance**. Catabolism of peripheral protein then assumes an increasingly important role in maintaining the pool of amino acids available for plasma and intestinal protein synthesis. This explains in part the reduced growth rate, decreased muscle mass, and reduced bone matrix in sheep with subclinical or mild parasitism, and the cachexia and osteopenia of severe parasitism. These principles probably hold for all syndromes causing enteric loss of endogenous protein in any species.

Loss of enteric protein, and especially plasma, should be suspected in cachectic or hypoproteinemic animals. Diarrhea is often, but not invariably, present. *The two major routes of occult abnormal loss of plasma protein are the kidney in glomerular disease, particularly amyloidosis, and the gastrointestinal tract.* Weeping skin lesions are another source. Anemia and hypoproteinemia may be due to hemorrhage externally or into the gastrointestinal tract. Advanced liver disease may cause hypoalbuminemia, in which case other signs of hepatic failure will likely be concurrent (see Vol. 2, Liver and biliary system). Inability or reluctance to eat, inadequate nutrition or starvation also cause emaciation, usually without profound hypoalbuminemia. The cachexia of malignancy must also be differentiated.

Provided it is adequately hydrated, the hypoalbuminemic animal shows evidence of subcutaneous, mesenteric, or gastric submucosal edema, perhaps with hydrothorax or ascites. Wasting of muscle mass may be marked if the protein loss has been severe and chronic. Unlike starvation, protein-losing gastroenteropathy may be associated with the presence of internal fat depots, since assimilation of energy is not necessarily severely impaired, especially in ruminants.

Anemia

The development of anemia and the kinetics of the erythron following blood loss into the gastrointestinal tract are similar to those of albumin in plasma loss. *Blood loss of any origin, including that due to hematophagous parasites, may cause anemia.* Erythroid hyperplasia in the marrow or in extramedullary sites may not compensate for the continued bleeding. Resolution of the hemorrhage results in eventual restoration of normal red cell numbers and an ultimate decline in erythrocyte production. Chronic blood loss may culminate in depletion of iron stores and development of a nonresponsive hypochromic microcytic anemia.

Congenital anomalies of the intestine

Segmental anomalies of the intestine are commonly encountered. In early embryonal life the intestine consists of a simple tube, the lumen of which is lined by epithelial cells of endodermal origin. An outer layer of connective tissue from the splanchnic ectoderm surrounds and supports the tube. As the intestines grow with the developing fetus, they form coiled loops that herniate into the umbilicus. In later stages of fetal development, the intestines withdraw, in a cranial to caudal direction, from the umbilicus into the abdomen. The most plausible cause of segmental defects in intestinal continuity is *ischemia of a segment of gut during early fetal life*, resulting in necrosis of the affected area. In addition, an association has been postulated between pressure on the amniotic vesicle during palpation of the embryo for pregnancy diagnosis prior to 42 days of gestation, and the development of atresia coli in calves. The mechanism of this effect is uncertain.

The segmental anomalies of the intestine may vary in degree. **Stenosis** *implies incomplete occlusion of the lumen; complete occlusion is referred to as* **atresia**. Atresia is further subdivided into *membrane atresia*, when the obstruction is formed by a simple membrane or diaphragm; *cord atresia*, in which the blind ends of the gut are joined by a cord of connective tissue; and *blind-end atresia*, in which a segment of gut and possibly the corresponding mesentery are missing, leaving two blind ends. All types of segmental anomaly can be produced experimentally by ischemia to a portion of the fetal intestine.

Atresia coli *is the most common segmental anomaly of the intestine in domestic animals*. It is seen particularly in the spiral colon of Holstein calves, and in the large and small colon of foals; it occurs rarely in cats. Atresia coli may be an autosomal recessive trait in Holsteins. A predisposition for male calves has been described, but this is not consistent among studies. Atresia of the small intestine is less common. **Atresia ilei** is most prevalent in calves, and rare in foals, lambs, piglets, and pups.

These obstructions prevent the normal movement of gut content and meconium in the fetus and neonate. Therefore, they lead to dilation of the proximal segment, with progressive abdominal distension, which may become so extensive prepartum as to cause dystocia. The bowel beyond the discontinuity is small in diameter, and devoid of content other than mucus and exfoliated cells. Animals fail to pass feces after birth.

Atresia ani (*imperforate anus*), *overall, is the most common congenital defect of the lower gastrointestinal tract*. It may affect all species, but is most often encountered in calves, and in pigs, in which it is considered to be hereditary. The defect may consist only of failure of perforation of the membrane separating the endodermal hindgut from the ectodermal anal membrane, or both anus and rectum may be atretic. Atresia ani may be an isolated abnormality, or it may be associated with other malformations, especially of the distal spinal column (spinal dysraphism, sacral or coccygeal vertebral agenesis), of the genitourinary tract (rectovaginal fistula, renal agenesis, horseshoe kidney, polycystic kidneys, cryptorchidism, duplication of scrotum), and occasionally, with intestinal atresia or agenesis of the colon. *Caudal spinal syndromes* occur in humans and animals commonly associated with atresia; this association is presumably because of a reduction in the available pool of neuronal cells in the spinal region during intestinal development. Atresia ani may occur with congenital vitamin A deficiency.

Short colon, probably the result of abnormal rotation of the midgut and failure to lengthen during fetal life, has been reported in several cats and dogs. Signs were mild, and possibly unrelated to the colonic lesion. The cecum was on the left side, and ascending, transverse, and descending colon were not demarcated on contrast radiographs. In several cases, anorectal or urogenital abnormalities were concurrent. **Anomaly of the colonic mesenteric attachments**, presumably congenital, has been associated with the development of colic in a horse, due to distortion and convolution of the large colon.

Hypoplasia of the small intestinal mucosa, with short villi and sparse crypts, has been reported in foals with failure of passive transfer of immunoglobulin. This may represent a defect in fetal organogenesis.

Congenital colonic agangliosis, somewhat analogous to Hirschsprung's disease in humans, occurs in *white foals* that are the offspring of "frame overo" spotted parents. It has not been convincingly demonstrated in other species of domestic animals. Clinically, the foals, which are predominantly white with perhaps a few pigmented dots on the muzzle, abdomen, and hindquarters, develop colic, and die generally within 48 hours of birth. There is stenosis mainly of the small colon, but the entire colon and rectum may be involved. The intestine proximal to the stenotic segment is distended with gas and meconium. The descending colon is contracted but patent. Microscopically, *ganglia of the myenteric plexus are absent in the walls of the terminal ileum, cecum, and colon*, though occasional nerve fibers are evident. Except for the few pigmented spots, melanocytes are absent in the skin. The condition, which appears to be an autosomal recessive trait, is similar to aganglionic colon in Piebald and Spotted Mutant mouse strains. Cutaneous melanoblasts and the myenteric plexus are both derived from the neural crest, which may explain the association between unpigmented skin and lack of the myenteric ganglia. A similar condition of megacolon due to segmental colonic aganglionosis has been reported in pigs. Megacolon associated with few myenteric ganglion cells in Clydesdale foals is not clearly congenital, and is discussed with intestinal obstruction, as is megacolon in other species.

Persistent Meckel's diverticulum is an uncommon anomaly of the lower small bowel, mainly in swine and horses (Fig. 1.47). It is derived from the omphalomesenteric (vitelline) duct, which is the stalk of the yolk sac. Although usually an incidental finding, it may be associated with impaction or intussusception. Also, an increased incidence of tumors has been noted at this site. **Persistent vitelline duct cysts**, distinct from Meckel's diverticulum, have been described on the ileal serosa and in a mesodiverticular band, as an incidental finding in a dog.

Intestinal diverticula, not always clearly remnants of the vitelline duct, occur rarely in dogs, cats, and horses. They may be incidental, or are associated with obstruction, diverticuloumbilical fistula, or with diverticulitis, perforation, and peritonitis. Intestinal adenocarcinoma, smooth-muscle tumors, and heterotopic gastric fundic and pyloric mucosa may occur in the wall.

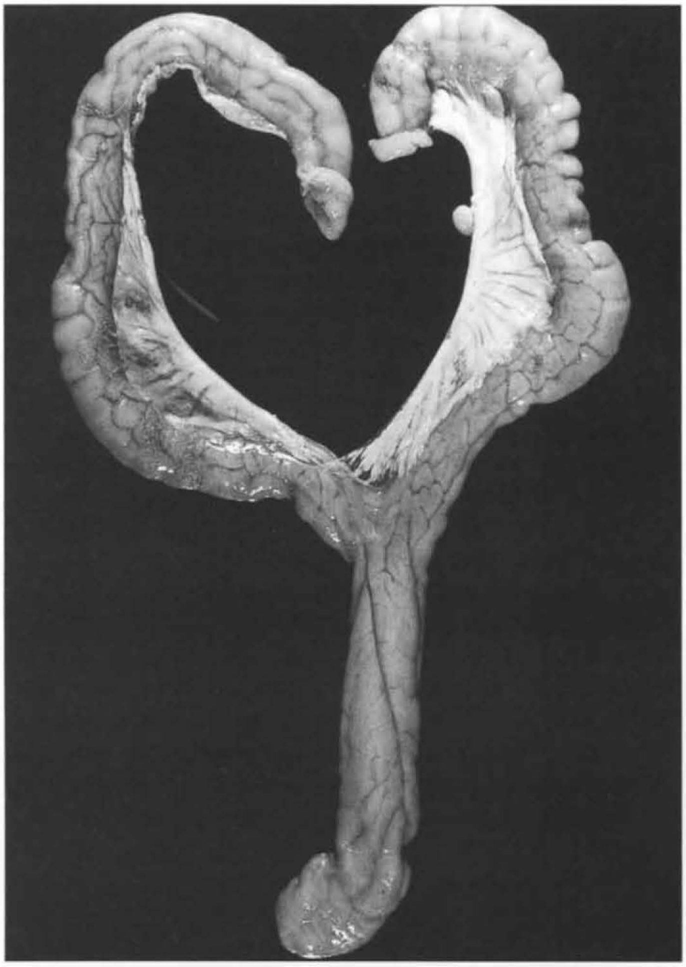

Figure 1.47 Persistent **Meckel's diverticulum** in the mid-jejunum of a pig.

Intestinal obstruction

Clinically, acute obstruction typically involves the upper or middle small intestine; chronic blockage usually involves the ileum and large bowel. Intestinal obstruction may be the sequel to a physical blockage of the lumen resulting from **stenosis** (narrowing, stricture) due to an intrinsic lesion involving the intestinal wall, **obturation** (occlusion) by an intraluminal mass, or **extrinsic compression**.

Failure of the intestinal circular smooth muscle to contract blocks the peristaltic wave, causing **functional obstruction**, or **pseudo-obstruction**, a clinical syndrome in which there is no physical occlusion of the lumen of an impacted intestine. **Adynamic ileus**, or intestinal obstruction resulting from inhibition of bowel motility, is a common sequel to peritonitis and pain.

Circulatory embarrassment of a segment of bowel, through embolism or venous infarction, will also cause functional obstruction without a physical blockage. Many of the displacements of gut that produce obstruction, such as volvulus, incarceration, strangulation of a hernia, or intussusception, may cause *ischemia*. The term "**strangulation obstruction**" is applied to an event that simultaneously causes ischemia and physically blocks the intestine. Mucosal hypoxia may also be a sequel to venous occlusion resulting from distension of gut proximal to a site of obstruction; it may result from local pressure caused by an adjacent mass; or it may be a sequel to circulatory failure. Ischemia in any circumstance is a serious complication, the pathogenesis of which is dealt with later.

Proximal to the point of obstruction there is *accumulation of fluid*, derived from ingesta, gastric, biliary, pancreatic, and intrinsic intestinal secretion, and *gas*, swallowed or originating with bacterial activity in the gut. Intestinal distension results in sequestration of water and electrolytes in the intestinal lumen, edema of the mucosa, further secretion into the gut, perhaps associated with contractile stimuli, and, in extreme cases, transudation from the peritoneal surface. Upper small-bowel obstruction progresses rapidly to cause *vomiting* in those species that can vomit, with dehydration, hypochloremia, hypokalemia, and metabolic alkalosis due to loss of acid in vomitus, or sequestration of fluid in the forestomachs.

Obstruction of the lower small intestine may result in distension with dehydration. But there is usually less acute electrolyte and acid–base imbalance, since vomition is less severe and absorption of fluid proximal to the obstruction may prevent serious distension and its associated secretion, for some time. Metabolic acidosis eventually ensues following dehydration and catabolism of fat and muscle due to cessation of food consumption and assimilation.

If ischemia and its complications, including rupture, do not ensue, the animal with acute obstruction succumbs to the *systemic effects of hypovolemia, electrolyte, and acid–base disturbance*. Lower intestinal or colonic obstruction may result in eventual metabolic acidosis and loss of body condition following a chronic course. In the horse particularly, obstruction or impaction of the cecum or colon may result in *local ischemia and rupture*.

In obstruction the outstanding gross alteration in the bowel is distension proximal to the point of blockage, due to ileus and the accumulation of fluid contents and gas. The volume of accumulated content may be remarkable in distal intestinal obstruction, such as rectal stricture in the pig, which causes overt abdominal distension. The location, degree, and duration of the obstruction determine the segment and length of bowel involved and the degree of distension. As distension increases, interference with venous return may develop and the mucosa and submucosa become congested. Devitalization of severely dilated gut, or pressure necrosis of the mucosa at the site of lodgment of intraluminal foreign bodies may occur, leading to gangrene or perforation and peritonitis. Distal to the point of obstruction, the bowel is collapsed and empty.

Stenosis and obturation

Intrinsic obstruction due to congenital segmental atresia and imperforations is considered under congenital anomalies of the intestine, above. **Acquired stenosis** due to pathological processes arising within the wall of the intestine may be partial or complete. The primary lesions include intramural abscesses, intramural hematomas, neoplasms (Fig. 1.48), and scarring following ulceration. Many of these develop slowly with a course as described above for simple chronic obstruction.

Foreign bodies of all kinds are commonly found. Small rounded foreign bodies and even some sharp-edged objects may pass through the intestines uneventfully, but for these and many large foreign bodies the course is unpredictable. Some may reside in the intestine for long periods and produce no disturbance until they act as a nucleus for the development of an enterolith. Sharp-pointed foreign bodies may become impacted in the intestine and cause pressure necrosis with ulceration and possibly perforation. Blunt foreign bodies that become impacted cause acute or chronic obstruction depending on their size and location; often they cause local pressure necrosis, and perforation may occur in some cases. **Linear foreign bodies**, such as strips of cloth or string, which are not infrequently ingested by dogs and cats, may pass through the intestine. However, if they become immobilized they produce a typical lesion. One portion of a string becomes fixed, commonly around the base of the tongue, or by impaction at the pylorus. A free end is then stretched taut distally by peristaltic movements, which pleat the gut on the string (Fig. 1.49). It progressively cuts into the lesser curvature of intestinal loops, causing first a puckering of the mesentery and finally perforation and peritonitis.

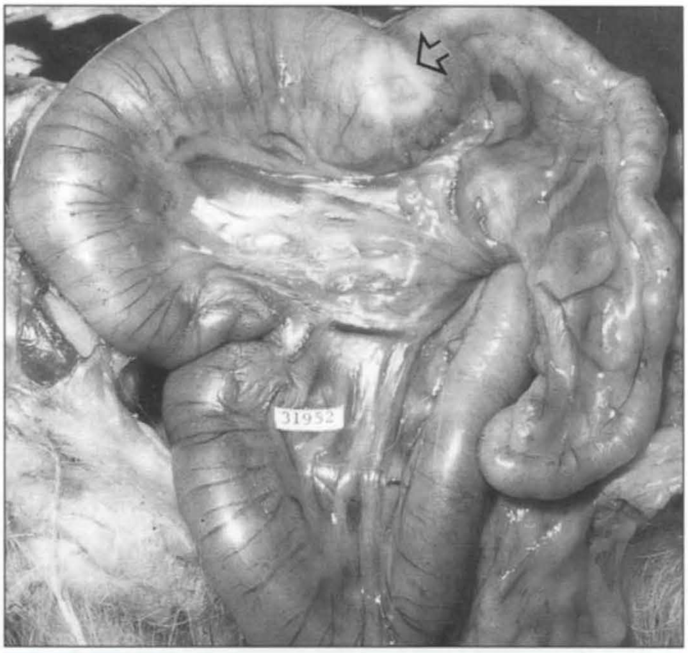

Figure 1.48 Scirrhous adenocarcinoma (arrow) infiltrating wall of small intestine, causing obstruction in a dog. Dilation is present proximal to the obstruction, with contraction of the empty intestine distally.

Enteroliths (mineral concretions) were common in the colon of horses in the past, and they seem to be re-emerging as a problem in some areas, such as California and Florida. Arabians, Morgans, American Saddlebreds, and donkeys are overrepresented with respect to this problem. The mean age for equine enterolithiasis is about 11 years. The stones are comprised of *magnesium ammonium phosphate* deposited in concentric lamellae, at the center of which there is a *nucleus* – a foreign body such as a nail, wire, stone, or particle of feed. They vary greatly in size, some weighing as much as 10 kg, and there may be one or more large ones or many small ones. They are usually smooth and often spherical, but contact with other liths, and abrasion, may smoothly flatten some surfaces. Irregular mineralized masses may also occur, usually based on a fibrous nidus, such as twine, rope, or netting. The source of the magnesium phosphate is probably grain, bran, alfalfa, or alkaline water. The mineral salts deposit around a nidus under poorly understood circumstances, but colonic pH above 6.6 seems to contribute to their formation.

Fiber balls (**phytobezoars** or phytotrichobezoars), which consist largely of plant fibers impregnated with some phosphate salt, may especially be found in the colon of horses. They are not as heavy as enteroliths, are moist, and have a velvety surface. They are usually round and smooth, but some are convoluted like the surface of the cerebrum (Fig. 1.50). Hairballs (**trichobezoars**) sometimes occur in dogs and cats and in ruminants; in ruminants they occur in the forestomachs and abomasum. They may obstruct the pylorus, but rarely cause problems in the intestine.

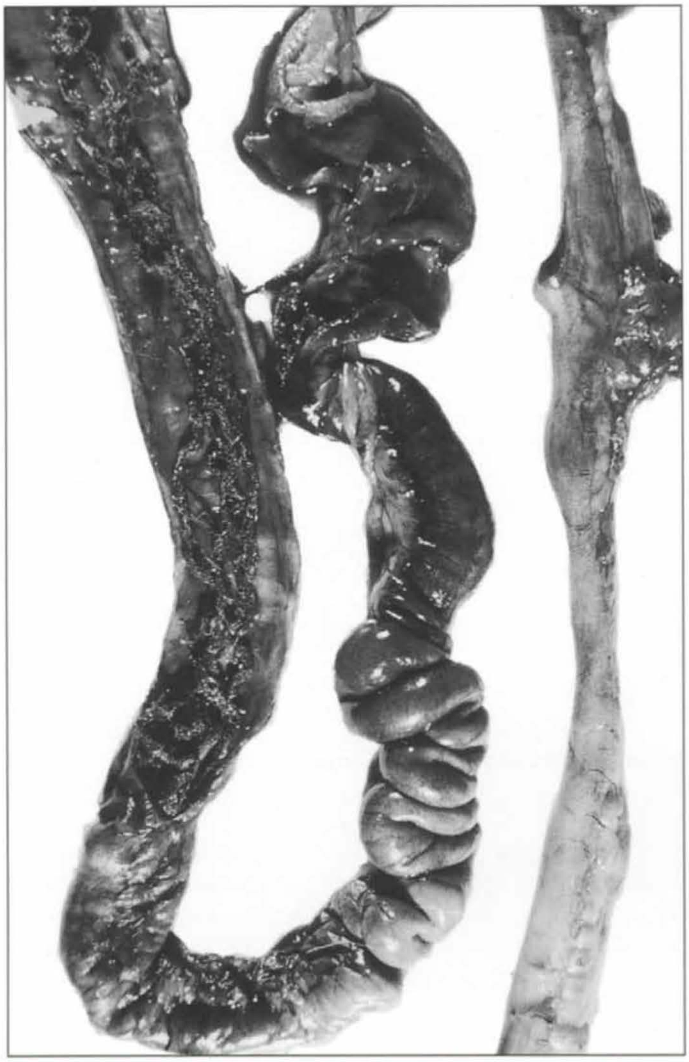

Figure 1.49 Pleating of the small intestine along a **linear foreign body** in a cat. The lower segment of bowel is normal (right).

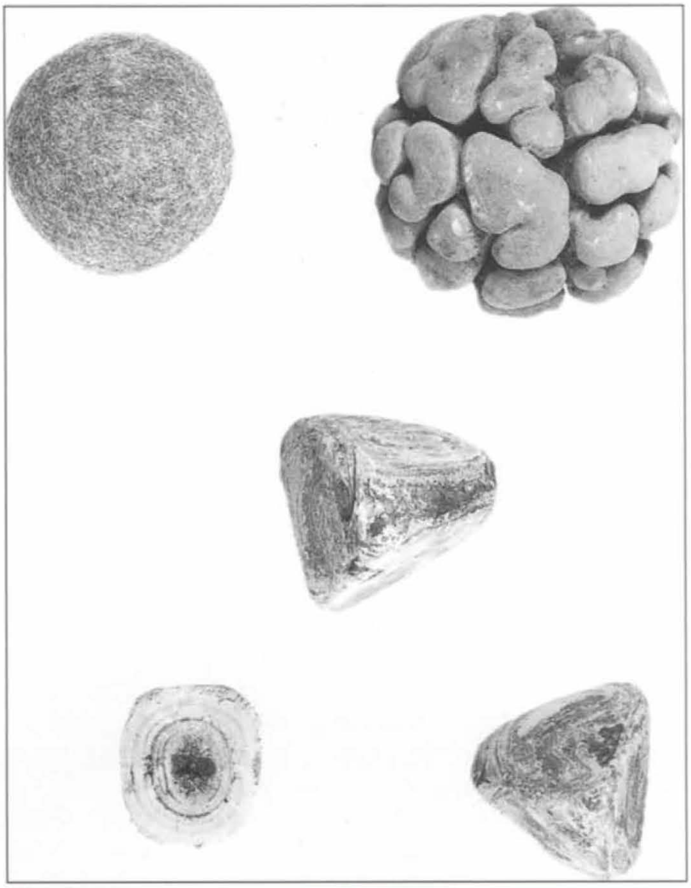

Figure 1.50 **Trichobezoar** (top left). **Phytobezoar** (top right). **Enteroliths** (below).

Enteroliths and bezoars in horses are usually not significant, and small ones may pass in the feces. Apparently they are moved about enough by peristalsis to avoid pressure necrosis. They may obstruct the gut when they are impacted, usually where the colon narrows, in the pelvic flexure and transverse or small colon.

Small intestinal obstruction may be caused by parasites that can form rope-like tangled masses in the lumen. This may occur in pigs and foals infested with large numbers of *ascarids*. It also occurs rarely in sheep heavily infested with tapeworms. Impaction of the ileum is the most common cause of small intestinal, nonstrangulating obstruction in horses. Feeding of a high-fiber diet, such as coastal Bermuda grass hay, predisposes to this condition. Gravel has been reported as a cause of duodenal obstruction in cattle.

Impaction of the colon, by feces in dogs and cats, and by digesta, fibrous foreign material, sand, or feces in horses, is not uncommon and causes simple intestinal obstruction, complicated in the horse by intestinal tympany from fermentative gases if the obstruction is complete. In dogs, obstipation of the colon may be the result of voluntarily suppressed painful defecation, as in prostatic enlargement and inflammation of the anal sacs. Occasionally, it is due to impaction with foreign bodies, especially hair or fine bones in the colon or rectum, or due to stenosis caused by tumors or strictures. It may also complicate trauma to the pelvic area, and paralyzing lesions of the spinal cord; it may occur in Manx cats due to sacral spinal cord anomalies. **Megacolon** may ensue, if the obstruction persists. In small animals, megacolon is frequently idiopathic. Examination of the syndrome in cats reveals no histologic abnormalities and it is suggested that the underlying problem is disturbance in the activation of smooth-muscle myofilaments.

Impaction of the cecum or colon in horses may be precipitated by water deprivation, a change of diet from something soft and lush to hay or chaff, or poor dentition. In animals with dental problems, impaction of the cecum may be recurrent, and cecal smooth muscle may become hypertrophic. Abnormal motility due to altered colonic or cecal pacemaker activity may explain impaction in the absence of other predisposing causes. Deficiency of neurons in the myenteric plexus at the base of the cecum may cause chronic uncoordinated hypercontractility and result in hypertrophy of the circular muscle layer of the cecum. In the colon, fibrous digesta usually impacts at the pelvic flexure, transverse or small colon. Ingestion of indigestible *synthetic fibers* has been associated with colonic impaction. *Sand* may sediment in the colon of horses that have grazed on poorly covered sandy soils. Sand may cause chronic colitis with diarrhea and weight loss, or it may accumulate at any level of the large or small colon, causing one or more points of impaction obstruction, often associated with concurrent displacement or torsion. Ingestion of large numbers of *acorns and leaves* may also cause impaction of the intestinal tract in ruminants. Rupture of the viscus may occur if impactions are not treated, and the bowel wall becomes ischemic and devitalized.

Cecal rupture in horses occurs as a complication of impaction, and of parturition in mares. It has also been reported secondary to ulceration as a result of phenylbutazone therapy. Idiopathic cecal rupture, associated with "overload" of normal digesta, rather than impaction, is also reported, sometimes as a complication of general anesthesia. Also termed cecal "dysfunction," **cecal overload** is differentiated from impaction by the more fluid consistency of the contents. The cecum is distended, and the mucosa may be hyperemic and somewhat thickened at surgery. Disordered motility with increased intracecal pressure has been invoked speculatively to explain subsequent cecal rupture. The lacerations of the cecum in this circumstance are reported on the medial aspect at some distance from the base, but this is not consistent.

Extrinsic obstruction

Compression of intestine causing obstruction is rather common and is caused by tumors, abscesses, peritonitis, and fibrous adhesions. **Neoplasms** involve the intestine by extension from adjacent viscera, particularly pancreas. Therefore, many tumors involve the craniodorsal part of the abdominal cavity and impinge on the duodenum. Inflammatory peritoneal **adhesions** are common, and fibrous bands may stretch from the wall of the bowel to some fixed point, or between two or more points along the bowel or mesentery; the obstruction develops gradually as scarring ties the bowel down or puts kinks in the mesentery. Large firm masses of **abdominal fat necrosis** cause compression stenosis of small intestine, coiled colon, and particularly descending colon and rectum of cattle. **Pedicles of some tumors**, especially *mesenteric lipomas in older horses*, occasionally become wound about loops of intestine and cause obstruction and strangulation. Similarly, the **suspensory ligaments of the ovary** may entrap the equine colon if the ovary is enlarged by neoplasia or other phenomena. Incarceration in hernias, discussed with other displacements of the bowel, is also a common cause of compression obstruction of the gut.

Functional obstruction

Adynamic (paralytic) ileus is in itself not of specific interest to the pathologist but is a rather common condition. It frequently follows abdominal surgery in transient episodes, especially when the intestines are handled roughly, or traumatized. It also occurs in peritoneal irritation of any cause, especially in peritonitis. It is the result of neurogenic reflexes that interfere with control of the inhibitory neurons of the myenteric plexus. Continual tonic discharge by these neurons inhibits contraction of circular smooth muscle and prevents peristalsis.

The intestines are distended with a mixture of gas and fluid, and the wall is flaccid. The defect may be segmental, involving less than a meter of the intestinal length, but there may be many such segments involved, especially in diffuse peritonitis. Gastric rupture may occur in the horse as a complication of obstructive or postoperative ileus of the small intestine.

Pseudo-obstruction, a clinical syndrome in which there is *no physical occlusion of the lumen* of an impacted intestine, may result from segmental or diffuse neuromuscular dysfunction in the gut. It overlaps in part with paralytic ileus, and with elements of impaction and megacolon related to intestinal dysmotility, discussed below. Pseudo-obstruction associated with neuronal hypocellularity or ganglioneuritis involving autonomic ganglia in the gastrointestinal tract, systemic dysautonomia, and intrinsic disease of intestinal smooth muscle are recognized among domestic animals, in addition to congenital aganglionosis of spotted foals, discussed earlier. Occasionally a segment of contracted bowel is noted, causing obstruction; more commonly, in neurogenic disease, affected bowel is dilated, flaccid, and incapable of maintaining tone.

Megacolon in Clydesdale foals, in association with *hypoganglionosis of the myenteric plexus*, has been reported from the USA and Australia in animals 4–9 months of age. The dorsal colons were markedly dilated and the intestinal wall thin. Small colon was patent but devoid of content. Ganglion cells of the myenteric plexus in the transverse and small colons were reduced or absent. There was variation in ganglion cell density in the dorsal colon; in two cases they were present, while in the third, they were markedly reduced in number. Inflammation was not noted. The time of clinical onset of these cases suggests that they may not have been congenital. The common breed suggests a possible genetic basis for the syndrome. If the lesion is acquired, the factors causing myenteric ganglion cell loss are unknown.

Grass sickness in horses, the prototypic **dysautonomia** in domestic animals, occurs chiefly in parts of the UK and western Europe, usually in animals at pasture. Although horses of any age may be afflicted, the disease is more common in those 3–6 years of age. Affected animals are dull but show occasional bouts of colicky restlessness. In the acute disease, there is progressively severe tympany, swallowing is avoided, and saliva drools freely. Any attempt to swallow is apparently painful and stimulates reverse peristalsis in the esophagus. Fine muscular tremors develop over the shoulders and there is sweating. The course in acute cases is from 12 to 72 hours. Some survive the acute phase to live much longer, but may die in due course of the disease. With careful nursing, recovery may be complete but take months to years.

Acute lesions at necropsy are confined to the alimentary tract. The esophageal wall is sometimes edematous, and the mucosa may show longitudinal bands of congestion and ulceration, which may extend into the stomach. The stomach is distended with alkaline mucinous fluid, often of khaki color and pea soup consistency, although sometimes more watery with fibrous material. Sometimes the stomach is ruptured. There may also be excess fluid in the small intestine. The large intestine is impacted with dry contents and the fecal pellets in the small colon are small and dry. These masses may have a surface blackened by a small amount of exuded blood. In chronic cases, the volume of alimentary content is reduced to scant amounts in the stomach. There may be hypertrophy of intestinal musculature, often most prominent in the jejunum.

Degenerative lesions, marked by often subtle chromatolysis, nuclear eccentricity, and neuronal necrosis, and the formation of perineuronal eosinophilic axonal spheroids, have been described in many autonomic ganglia, and a central neuropathy has also been described, as has a reduction in the number of interstitial cells of Cajal. Significant inflammation is not evident. Severity of lesions has been shown to correlate with decreased functional cholinergic responses. *Clostridium botulinum* is thought to play a role in equine dysautonomia, which may hence be a toxicoinfectious form of botulism.

Feline dysautonomia, or Key–Gaskell syndrome, is an autonomic dysfunction of unknown etiology, most common in the UK and continental Europe, with sporadic cases reported elsewhere. A similar syndrome has also been reported in a few dogs. All age groups are affected. Signs include depression, anorexia, reduced lacrimation and salivation, bradycardia, pupillary dilation with delayed pupillary light reflex, megaesophagus, constipation, and, rarely, ileal impaction. Diarrhea is reported in some dogs with dysautonomia. The gastrointestinal signs suggest *disordered motility*, and animals often succumb to the effects of regurgitation, inanition, or aspiration pneumonia, among other problems. Cases tend to occur in clusters, suggesting an environmental toxin or infectious agent, and exposure to botulinum toxin has been suggested, although no conclusive etiologic associations have been made.

Involvement of functions controlled by both sympathetic and parasympathetic divisions of the autonomic nervous system, and of some functions under voluntary control, is reflected in the distribution of neuronal lesions in ganglia of the autonomic system, and in cranial nerve nuclei III, V, VII, and XII, ventral horns of the spinal gray matter, and in dorsal root ganglia. Chromatolysis-like lesions of affected neurons seen by light microscopy have a *distinctive ultrastructural appearance in dysautonomia*. Autophagocytic vacuoles, large cisternae, and complex stacks of smooth endoplasmic membranes are in the cytoplasm of affected cells. Neuronal lesions and subsequent drop-out may be transient, and in the later stages of the disease diagnosis may need to be based on comparative cell counts in ganglia of affected and unaffected cats, unless neuronal loss has been obviously severe.

Intrinsic disease of intestinal smooth muscle may produce a syndrome of **intestinal sclerosis**, somewhat resembling that in progressive systemic sclerosis or *scleroderma* of humans. However, in dogs the lesions are restricted to the intestinal tract, where they usually appear to involve the small and large bowel diffusely. There is typically mild to obvious dilation of the bowel. In section, there is a mononuclear inflammatory infiltrate among smooth-muscle fibers in the circular and longitudinal layers of the bowel wall. Associated with this is interstitial fibrosis, and atrophy of smooth-muscle cells. Fibrosis of the small intestine has also been reported in horses, concentrated in the submucosa and accompanied by arteriolosclerosis. A geographic cluster suggests an environmental basis.

Displacements of the intestines

Eventration

Eventration is displacement of a portion of the gut, usually the small intestine, outside the abdominal cavity. This is commonly *congenital*, as in schistosomus reflexus, patent umbilicus, and congenital diaphragmatic hernia. Acquired eventrations result from *trauma*, and therefore are varied. The displaced intestine herniates into the abdominal muscle or subcutis, or it may be completely exteriorized. Vaginal eventration may occasionally occur in females following trauma.

Cecal and colonic dilation, tympany and torsion

In ruminants, cecal dilation and torsion is an uncommon condition. It mainly occurs in animals fed *high-concentrate rations*, but it has been associated with late gestation, and ileus from other causes. It usually occurs within 2 months postpartum in cattle. It is rare in other ruminants. About 30% of the carbohydrates in the ration are digested in the cecum of ruminants. Sudden change from a roughage to a grain-based ration results in an increase in the concentration of volatile fatty acids, with only a slight decrease in pH of the cecal contents. An increase in the concentration of dissociated volatile fatty acids, especially butyric acid, causes atony of the cecum, and dilation follows. Once the cecum is dilated and distended with watery digesta, various degrees of clockwise or counterclockwise rotation can occur, which may incorporate adjacent terminal ileum or proximal colon.

In horses, cecal and colonic tympany has a similar pathogenesis. Readily fermentable carbohydrate, following a sudden change in feed, results in an increase in volatile fatty acid production, which exceeds the buffering and absorptive capacity of the organ. As the pH drops, and fermentation shifts to production of the less well-absorbed butyric and lactic acids, water is drawn into the lumen by the osmotic effect. The large bowel dilates with fluid digesta and gas, and motility is reduced by the effects of the volatile fatty acids. Severe abdominal distension, compression of intra-abdominal organs, reduced cardiac return due to postcaval compression, and reduced respiratory capacity due to compression of the diaphragm may follow, with attendant severe pain. Death due to hypovolemia and acidosis may occur before the large bowel ruptures. In recovered horses, laminitis may occur, due to absorption of endotoxin through the cecal mucosa, which becomes eroded and permeable as a result of local acidosis.

Displacements of the equine colon

The large colon of the horse is comprised of a loop of capacious bowel joined along its length by the short mesocolon, and folded upon itself at the sternal, pelvic, and diaphragmatic flexures. The loop is only fixed at its base, by the cecum, the transverse colon, and mesenteric root. Its volume and lack of attachment make the large colon prone to displacement or torsion.

Right dorsal displacement of the colon involves displacement of the left colons to the right of the cecum. Consequently, when the carcass is opened, the left colons are visible first, with the pelvic flexure located near the sternum. It presumably results from displacement and wedging of the large colon due to tympany. The left colon may become displaced clockwise (in the standing animal viewed from above) to the right of the cecum as the pelvic flexure migrates cranial to the cecal root, caudad and to the left across the pelvic inlet, and craniad on the left side, coming to rest at the sternum. This is termed *right dorsal displacement with flexion*. Alternatively, the left colon may move in the opposite direction, caudal and to the right of the base of the cecum, with the pelvic flexure again lying at the sternum. This is termed *right dorsal displacement with medial flexion*. Some degree of torsion may also occur, and obstruction, with mild to severe colic, ensues. Surgery is required to correct the displacement.

Left dorsal displacement of the colon, variously known as entrapment of the colon by the nephrosplenic, renosplenic, or phrenicosplenic ligament, or by the suspensory ligament of the spleen, is also encountered as a cause of obstruction and colic in horses (Fig. 1.51). The left dorsal and ventral colon move laterally and dorsally between the spleen and the left body wall, and become trapped, with the spleen to the left and below, the suspensory ligament of the spleen below, the left kidney on the medial aspect, and the abdominal wall dorsally. The sternal and diaphragmatic flexures may be in their normal position, ventral to the stomach, or they may have moved cranially and become displaced dorsal to the stomach. The colon caudal to the entrapment may become curved cranially, with the pelvic flexure rotated through 180°, due to tension on the taeniae. The stomach and spleen may be displaced caudally and ventromedially, if the flexures have become displaced dorsally into the space cranial to the stomach, in apposition with the left lobe of the liver. If the colon has moved dorsal to it, the stomach often becomes grossly distended, as a result of compression of the esophagus and the duodenal outflow by the incarcerated colon. Compression of the colon at the point of entrapment can cause local bruising or edema and partial ischemia of the displaced organ, and results in obstruction, which may be incomplete. If the gut remains patent, clinical signs are intermittent. The cecum and small intestine may be distended as a result of the colonic obstruction. The cause of left dorsal displacement is unknown, but may be related to an anatomic predisposition resulting from a large cleft between the spleen and the left kidney.

Colonic torsion and volvulus *is one of the most common and grave colic conditions in horses.* The loop of large colon, with or without the cecum, may rotate around itself at some point along its length, or around the root of the mesentery. The condition is life-threatening because of severe vascular embarrassment, and is discussed further under Intestinal ischemia and infarction, below.

Internal hernia

This is a displacement of intestine through normal or pathological foramina within the abdominal cavity without the formation of a hernial sac. It is *uncommon*.

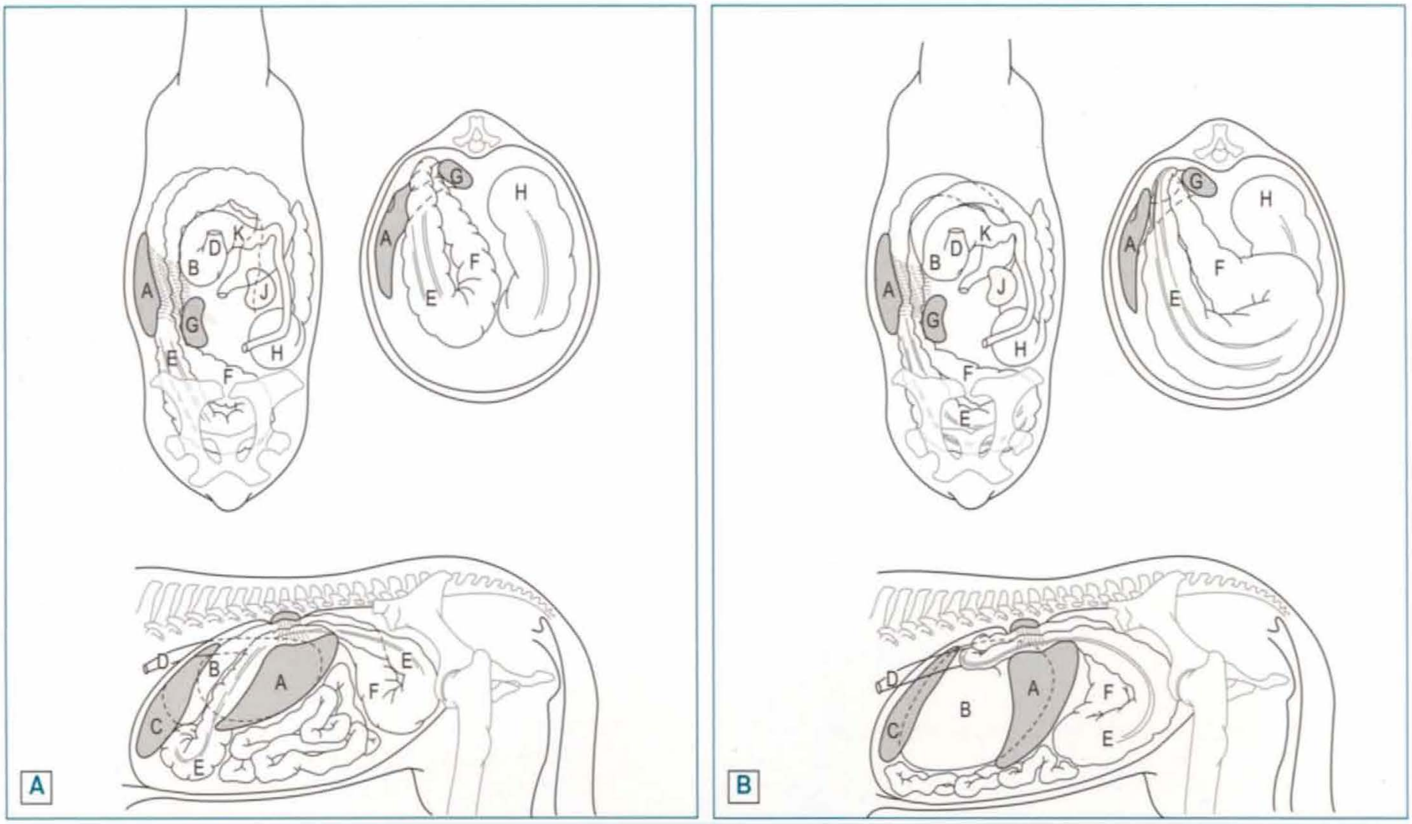

Figure 1.51 A. Left dorsal displacement (nephrosplenic entrapment) of the equine colon. Entrapment with the sternal and diaphragmatic flexures of the colon below the stomach. **B. Entrapment** with the sternal and diaphragmatic flexures displaced dorsal to the stomach. (Reprinted with permission from Livesey MA, et al., Can Vet J 1988;29:135–141.)

Herniation through a natural foramen occurs mainly in horses. In **incarceration in the epiploic foramen**, a portion of small intestine, usually distal jejunum and ileum, may pass down into the omental bursa and become incarcerated, if the normally short and slit-like epiploic foramen of Winslow is dilated for any reason. In these circumstances, the wall of the omental bursa often ruptures.

Omental hernia occurs when a loop of intestine passes through a tear in the greater or lesser omentum. **Mesenteric hernia** is due to passage of intestine through a tear in the mesentery. These are probably traumatic defects and usually involve the mesentery of the small intestine, but occasionally, that of the colon.

Pelvic hernia occurs in young ruminants, and rarely in other species, following castration. During the operation, excessive traction on the spermatic cord may tear the peritoneal fold of the ductus deferens which fixes the duct to the pelvic wall. A hiatus is formed between the ductus deferens and the lateral abdominal or pelvic walls and, through it, loops of intestine may become incarcerated.

Gut may also become incarcerated by passing through lacerations in the lateral ligament of the bladder, or through entrapment by the remnant of a persistent urachus, by the gastrosplenic ligament, and by mesodiverticular or vitelloumbilical bands in the horse.

External hernia

External hernia typically consists of a *hernial sac* formed as a pouch of parietal peritoneum; a *covering* of skin and soft tissues; depending on the location of the hernia, a *hernial ring*; and the *hernial contents*. The hernial ring is an opening in the abdominal wall, and this may be acquired, or it may be natural as, for example, the vaginal ring at the inguinal canal. The hernia usually contains a portion of omentum, a freely mobile portion of the intestine and occasionally, other viscera.

Ventral hernia of the abdominal wall occurs uncommonly in horses, rarely in cattle, and exceptionally in other species, except perhaps following blunt trauma or biting injuries in small animals. These hernias, through the abdominal musculature into the subcutaneous tissue, may be spontaneous in heavily pregnant females, especially older animals, or be a consequence of blunt trauma, bite wounds, horn injuries, surgical scars, or inflammations, which cause weakening or perforation of the muscle. In pregnant mares, they often occur in the lower flank lateral to the mammae, where there is only a single layer of muscle, the transverse abdominal. They may become very large in herbivores because of the weight of the alimentary viscera and pregnant uterus. The lesion must be differentiated from rupture of the prepubic tendon, and from postmortem rupture of abdominal muscle in bloated animals.

Umbilical hernia is *common* and is often present as a congenital and perhaps inherited defect. It is most frequent in pigs, foals, calves, and pups and depends on persistent patency of the umbilical ring. It is the *most common congenital defect in cattle* and has a hereditary component in the Holstein breed. It is also significantly predisposed by umbilical infection. The hernial sac is formed by peritoneum and skin; the contents depend on the size of the ring and of the sac.

Incarceration of enclosed intestine is uncommon. Formation of an *enterocutaneous fistula*, a rare complication of umbilical hernia, is seen most frequently in the horse.

Inguinal hernia may evolve to **scrotal hernia** when the herniated viscera pass down the inguinal canal. The internal, or deep, inguinal ring remains patent in intact male animals, but its diameter and the tendency to herniation in the neonate may be inherited. Inguinal hernias are classified as direct or indirect.

In **direct inguinal hernia**, which is less common, abdominal contents pass through the internal inguinal ring and come to rest in a subcutaneous position, through a tear in either the peritoneum or the fascia around the deep inguinal ring. This is most commonly seen in foals and is thought to result from increased intra-abdominal pressure during passage through the birth canal. These direct inguinal hernias often cause necrosis of overlying skin, can become fixed by adhesions, and strangulate. They are life-threatening.

Indirect inguinal hernias, by contrast, *consist of abdominal contents contained within the tunica vaginalis*. These are by far the *most common form*, occurring as a congenital problem in the young of many species, and as an acquired problem in older animals. While size of the inguinal rings may be a factor in neonates, there is usually no apparent cause in acquired cases. The herniated viscus passes through the inguinal and vaginal rings within the vaginal sheath, coming to lie in the scrotum inside the cavity of the tunica vaginalis. If the hernia is scrotal, there may be degeneration of the testicles. Routine castration of such animals can lead to eventration through the scrotal incision, and closed castration may cause infarction of the herniated loop of gut.

Congenital inguinal hernia is rare in dogs; West Highland Whites, Pekingese, and Basenjis may be predisposed, and it is more common in males than females. However, overall, inguinal hernia is much more common in female dogs. The bitch differs from females of other species in having a patent inguinal ring and canal, through which the omentum and the uterus may pass. The herniated uterus may become incarcerated when pregnant, or if pyometra develops. In horses, indirect inguinal hernias may rupture through the inguinal canal, coming to rest in a subcutaneous location. These ruptured indirect hernias have a similar prognosis as the direct inguinal hernias described above.

Femoral hernias develop as an outpouching of peritoneum through the femoral triangle along the course of the femoral artery. They contain omentum and small intestine.

Perineal hernias *occur principally in old male dogs in association with prostatic enlargement and obstipation*. They are precipitated by abdominal straining and are probably predisposed to by weakening of perineal fascia and muscles from some unknown cause, possibly hormonal. They are very unusual in females. Retroperitoneal pelvic fat bulges through a defect between the coccygeus medialis muscle and the cranial border of the anal sphincter. Usually this is the only tissue to prolapse, and the lesion consists, essentially, of a loss of support on one side of the anal ring. Concomitant with the loss of pelvic support the rectum deviates, and the prostate and the bladder may move into the pelvis. Further displacement may occur occasionally and then the latter organs are forced through the ruptured perineal fascia, causing acute urethral obstruction. Perineal hernias are most commonly unilateral, but bilateral hernias may occur.

Diaphragmatic hernias are *common*. The defect in the diaphragm may be congenital, but most often it is acquired, generally as the result of increased abdominal pressure. Though abdominal viscera pass into the thoracic cavity, strangulation of displaced gut is rare. Acquired diaphragmatic hernias are considered more fully in the section Abnormal contents in the peritoneal cavity.

The sequelae of hernias depend largely on their location and content, but some generalities apply to all. As long as the hernial contents remain freely movable and reducible, there may be no untoward sequelae. Fixation of the hernial contents (*incarceration*) is a serious development. Incarceration may result from stenosis or tension of the hernial ring, adhesion between the contents and the sac, or distension of the herniated viscus. This distension may be due mainly to mural congestion and edema in any incarcerated viscus, accumulated gas or ingesta in the intestine, urine in a herniated bladder, and fetuses or pus in a herniated uterus. Incarcerated intestine may become obstructed, or undergo ischemic necrosis and perforate, causing peritonitis. Small intestine fixed by incarceration may be predisposed to volvulus.

Intestinal ischemia and infarction

Inadequate or interrupted circulation of blood to the gut is a common problem, particularly in the horse. Obstruction of the efferent veins, blockage of afferent arteries, and reduced flow through an open circulation cause hypoxic damage to the intestine. Whatever the initiating cause, the effect of hypoxia at the level of the mucosa is similar.

In the **small intestine**, within 5–10 minutes of the onset of ischemia, changes are observed at the tips of villi in tissue sections examined under the light microscope, and lesions are well advanced by 30 minutes. Separation of the epithelium from the basement membrane, beginning at the tip of the villus, and progressing with time toward the base, causes the formation of the so-called Gruenhagen's space. Epithelial cells appear relatively normal, but may separate from the villus in sheets. The core of the villus contracts toward the base. Within 1–3 hours, the villus is completely denuded of epithelium, and the mesenchymal core is disintegrating or collapsed and stumpy, with hemorrhage from capillaries.

That this lesion is largely a function of hypoxia is indicated by the mitigating effects of intraluminal oxygen perfusion. The putative countercurrent exchange of oxygen between the afferent arteriole and efferent venules in the villus, and an associated progressive decline in oxygen tension distally in the villus, may render the tip prone to early damage in hypoxia. Villus smooth-muscle contraction, exacerbating the epithelial exfoliation on the distal villus, may be mediated by sympathetic stimulation in ischemia.

Dissociation and necrosis of cells in the crypts of Lieberkühn begin about 2–4 hours after the initiation of ischemia, and within 4–5 hours the epithelium appears completely necrotic or has sloughed, leaving a mesenchymal ghost of the mucosa. The muscularis mucosae may undergo necrosis, but the muscularis externa remains viable for 6–7 hours. During acute ischemia, there is initial hyperexcitability of muscle in affected areas, followed by progressive loss of contractility, which will fail to recover if ischemia persists beyond 4–6 hours. Mesothelial cells on the serosa undergo necrosis within 30–60 minutes of ischemia, and exfoliate; there is a local acute inflammatory response, which may predispose to the development of adhesions. *The speed with which lesions develop in hypoxia emphasizes the significance of rapid fixation of intestinal mucosa if artifact is to be avoided.*

The **colon** of the dog and horse seems less sensitive to short-term ischemia than the small intestine. Mild morphologic damage, characterized by mild edema, and separation and exfoliation of surface epithelium between crypts, is found after 1 hour. However, by 3–4 hours, crypt epithelium is becoming necrotic, dissociating, and exfoliating, and from that point events progress as in the small intestine.

Reperfusion injury, superimposed on the effects of ischemia alone, may enhance the severity of the lesion, if hypoxia is only partial, or ischemia is transient, and reflow of blood raises the tissue oxygen tension. Reperfusion injury implies that the effects of the hypoxic episode have not progressed to complete necrosis of the mucosa, and that further damage is possible. Hence, there is a relatively short duration of hypoxia, and a concomitant mild-to-intermediate degree of mucosal damage, permissive of this phenomenon. In cases of enteric ischemic disease encountered in veterinary medicine, this threshold may frequently have been crossed by the time that the animal is presented for therapy. In addition, there is evidence that in swine, and in the horse, where intestinal ischemic events are most common, reperfusion injury is less likely to occur than in other species.

Reperfusion injury is the result of an interplay among free-radical-mediated damage to the microvasculature and probably stromal elements and epithelium; neutrophil margination and diapedesis into tissue; complement activation; and release of proinflammatory proteins and cytokines, some of which may have systemic effects.

Free radicals in reperfusion injury are largely generated through xanthine oxidase mechanisms in the intestinal mucosa, and through NADPH oxidase mechanisms in leukocytes, mainly neutrophils, already resident in or recruited to the damaged tissue. Hypoxia stimulates the conversion of xanthine dehydrogenase to xanthine oxidase in epithelial cells. In the presence of xanthine oxidase, hypoxanthine accumulating from adenosine triphosphate degradation in hypoxia is converted to xanthine, and molecular oxygen is reduced, generating hydrogen peroxide, superoxide radical and hydroxyl radical intermediates, which inhibit the accumulation of protective nitric oxide. The hydroxyl radical is likely most significant in damaging proteins and initiating a cascade of lipid peroxidation, resulting in metabolic and structural lesions and culminating in cell death.

The acute inflammatory response that accompanies reperfusion results in production of free radicals by the respiratory burst from neutrophils, release of proteolytic enzymes, and physical impairment of the microcirculation. Reduction in tissue nitric oxide permits dismutation of oxygen free radicals to H_2O_2, which promotes activation of phospholipase, leading to the accumulation of proinflammatory mediators, and production of cytokines (tumor necrosis factor-α and -β, interleukins) and adhesion molecules by endothelium. Complement activation is mediated by adhesion molecules, promoting inflammatory events and release of cytokines such as tumor necrosis factor-α and interleukin-1, as well as other cytokines, which increase during reperfusion.

Sequelae of ischemia vary with duration, and hence severity, of insult. Short-term ischemia (maximally, ~3–4 hours), with preservation of at least the base of the crypts of Lieberkühn, will permit repair, as *cells proliferating in the crypts re-epithelialize the mucosal surface within 1–3 days*. Normal architecture is re-established after up to 1–2 weeks, though necrotic muscularis mucosae is not replaced. Effusion of tissue fluid and acute inflammatory cells prevails until epithelium extends to cover the eroded surface fully. Partial damage to the proliferative compartment initially results in dilation of crypts, lined by flattened epithelium resembling that seen after radiation injury (Fig. 1.52). If the amplifier population of progenitor cells can be regenerated, hyperplastic basophilic cells will populate crypts until the mucosal architecture is reconstituted.

Ischemic necrosis of the full thickness of the mucosa will be bounded by an acute inflammatory reaction in the submucosa, which,

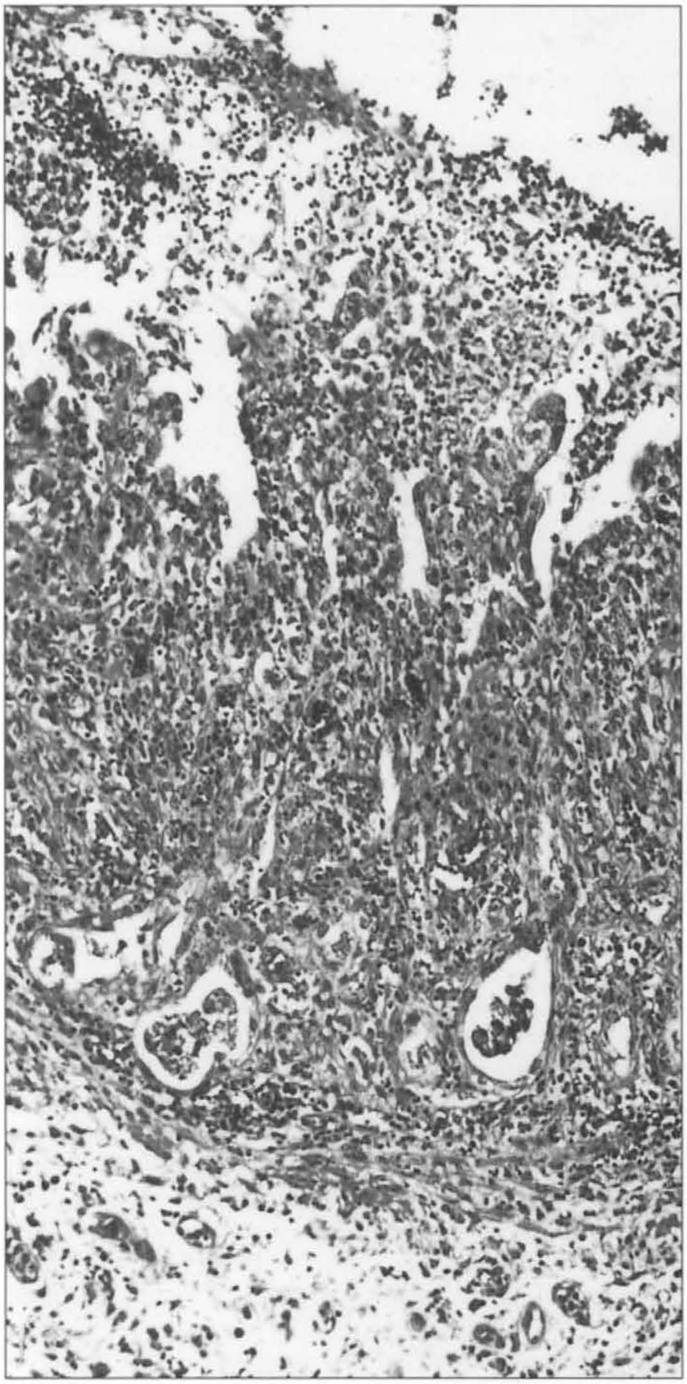

Figure 1.52 Small intestine, **sequel to transient ischemia** 2 days previously. Ulcerated mucosa and dilated crypts are lined by attenuated epithelium and contain necrotic debris. Inflammatory cells and fibrin exude from the mucosa, which is devoid of villi.

under favorable conditions, evolves into a granulating ulcerated surface. Focal ulcerative lesions may ultimately heal by epithelial migration, over the bed of granulation tissue, from surviving crypts within the lesion and around the periphery.

Extensive *mucosal ulcers* that form following severe ischemia have little chance of resolution, due to their large surface area. Chronic ischemic ulcers in the small bowel tend to develop a depressed, fairly clean granulating surface, occasionally with some fibrinous exudate. Ischemic ulcers in the large bowel, especially of horses, develop a dirty yellow-gray fibrinonecrotic surface, perhaps due to the effects of anaerobic bacteria. If the animal does not succumb to the effects of malabsorption and protein loss from the defect, or to transmural bacterial invasion, scarring and stricture may occur. The sequelae of ischemia with reflow are mainly seen in strangulated segments of gut that have been reduced without, or with inadequate, resection, and in some cases of presumed thromboembolic infarction of the equine colon.

Persistent ischemia results in necrosis involving all mural elements. The full thickness of the gut wall ultimately becomes gangrenous, green-brown or black, flaccid and friable.

The *consequences of ischemic lesions* are partly a function of the species, and of the level of bowel affected. Strangulation, volvulus, and similar lesions cause physical obstruction at the site, and ileus proximal to it. Reduced arterial perfusion or thromboembolism causes functional obstruction and ileus. Loss of mucosal integrity results in cessation of electrolyte and water absorption, and ultimately in effusion of tissue fluid and blood into the lumen. Proliferation of anaerobes occurs in the lumen of the stagnant ischemic area, with accumulation of gas, and extreme distension of the closed loop in strangulation obstruction. Toxin production by anaerobes, particularly clostridia, plays a large part in gangrene and ultimate rupture of ischemic gut, as well as having systemic effects. Absorption of endotoxin from the lumen may occur through devitalized mucosa via the portal flow, lymphatic return, or peritoneum. Toxins have a severe detrimental effect on cardiovascular function, contributing to circulatory failure. If death from some other cause does not supervene, transmural invasion by enteric bacteria or perforation of the devitalized wall results in septic peritonitis that is ultimately fatal.

Venous infarction

Obstruction of efferent veins is by far the most common cause of intestinal ischemia. This is a sequel to *incarceration* of herniated loops of bowel; *strangulation* by pedunculated masses, such as lipomas in older horses; *torsion* (twist about the long axis of the viscus); *volvulus* (twist across the long axis of the gut); and *intussusception.* In these circumstances compression of thin-walled veins tends to occur before the influx of arterial blood is obstructed.

In venous infarction, the affected tissue field, often including involved mesentery, becomes intensely edematous, congested, and hemorrhagic, so that the hypoxic bowel wall is thickened and eventually assumes a deep red-black appearance (Fig. 1.53). It has been estimated that 40 liters of fluid may accumulate in the wall of a horse colon that has undergone volvulus. Bloody fluid content and gas distend the lumen of the infarcted segment. As gangrene of the intestinal wall proceeds, the tissue becomes green-black, and septic peritonitis eventually ensues, with or without perforation of the bowel. Advanced venous infarction involves the full thickness of the intestinal wall, and the initiating intestinal accident is commonly evident, except in cases subjected to surgery. Even if a displacement, volvulus, or strangulation has been reduced, the limits of the infarcted segment are usually relatively sharply demarcated, and the affected bowel remains edematous and hemorrhagic. Microscopically, severe transmural edema, congestion, distension of veins, sometimes venous thrombosis, and hemorrhage are present, initially most severe in the mucosa and submucosa. With time, the full thickness

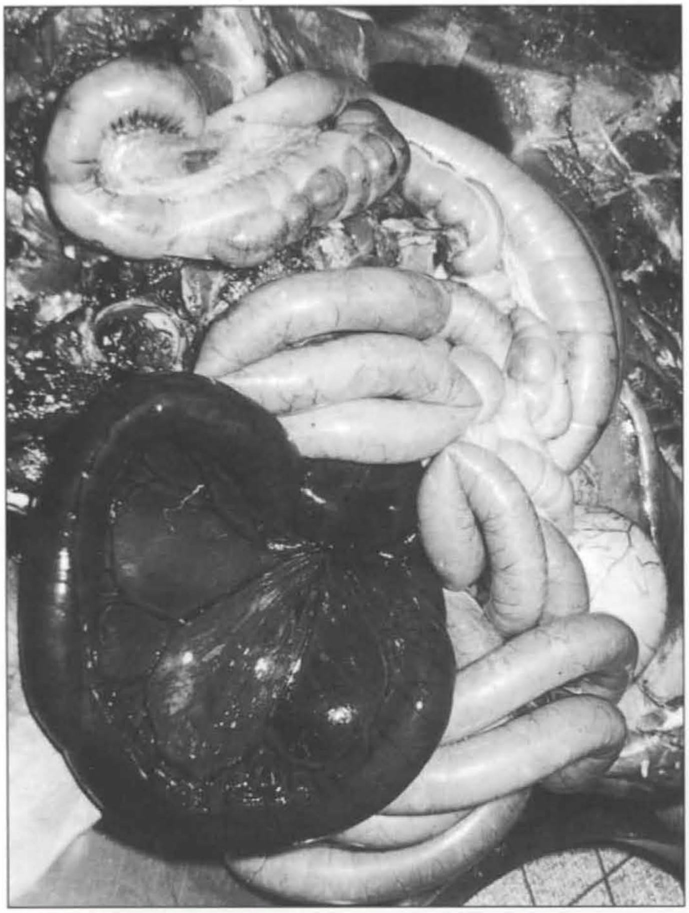

Figure 1.53 Venous infarction of a segment of equine ileum that has undergone volvulus.

of the mucosa becomes necrotic, and the deeper layers of the muscular wall are also devitalized, with invading enteric flora present throughout. Lesions which have advanced to significant necrosis or effacement of the crypt epithelium are associated with failure of the animal to survive, due to either euthanasia on the grounds of the degree of damage, or systemic complications despite correction of the strangulation, or resection.

Displacements of intestine that may progress to incarceration or volvulus with strangulation and infarction have been discussed in the previous section. They are a common cause of colic and mortality in horses.

Torsion of the long axis of the mesentery occurs commonly in suckling ruminants and in swine, uncommonly in horses, and rarely in cats and dogs. The abdomen is distended and, upon opening the cavity, tensely dilated deep red-to-black loops of bowel are usually immediately apparent.

In *swine*, the mesentery of the small intestine and sometimes the large bowel is often involved in a torsion that is usually counterclockwise, when viewed from the ventrocaudal aspect. In torsion involving the small and large intestines, the apex of the cecum may be pointing cranial in the cranial left quadrant of the abdomen, reflecting the rotation of about 180°. In swine, mesenteric torsion may be due to gas production from a highly fermentable substrate in the colon, and its subsequent displacement, with progression to mesenteric torsion. Mesenteric torsion is a common cause of sporadic sudden death in swine but may occur as a recurrent problem in a herd. Many cases of so-called "intestinal hemorrhage syndrome" in that species are probably misdiagnosed mesenteric torsion.

Death due to mesenteric torsion is common in suckling or artificially reared *calves and lambs*. In these species, vigorous ingestion of large amounts of feed over a short period may predispose to gas formation in the gut, or perhaps hypermotility, which induces torsion. Usually only the mucosa of the proximal duodenum and terminal ileum, cecum, and colon is spared from infarction, though occasionally volvulus is restricted to shorter segments of intestine. Similar lesions are occasionally encountered in other species.

In *dogs*, mesenteric torsion has been associated with ingestion of large quantities of food, and with exocrine pancreatic insufficiency in German Shepherds. It is occasionally accompanied by gastric volvulus.

Volvulus of various lengths of the small intestine may occur in any species, but is perhaps most prevalent in the horse, where it is a common cause of strangulation obstruction of the bowel.

Volvulus of the large colon of the horse is predisposed by its lack of mesenteric anchorage, and potential mobility. It may be due to dorsomedial (ventral colon rotating dorsally and medially relative to the dorsal colon) or dorsolateral rotation of the colonic loop along its long axis. Rotation of the left colon commonly progresses to volvulus at the sternal and diaphragmatic flexures. The right colon may rotate in its middle, cranial to the level of the cecocolic fold. Part of the cecum may be incorporated in the volvulus, the right colon and cecum rotating in the region of attachment of the cecocolic fold. Or almost the entire large colon and cecum may be involved in a rotation at the cecal base and transverse colon. The equine cecum alone rarely undergoes torsion, and if so, it may be related to hypoplasia of the cecocolic fold.

The most common direction of rotation of the right colon is *dorsomedial*. The direction and sites of rotation suggest that lesions may begin with tympany and dorsomedial torsion in the left colon, with progression of the twist, from left to right colon. The sternal and diaphragmatic flexures presumably provide some resistance to rotation, causing some twists to be found there. The first site of fixation of the large colon is the cecocolic fold, which may explain a tendency for twists to be localized there; progression beyond this level bases the twist at the mesenteric root of the large bowel. Clinical signs are associated with rotations of over 180°, and torsions involving the cecal base are usually at least 360°.

At surgery or necropsy, the usual signs of strangulation obstruction are evident, including dilation and devitalization of the infarcted segment, and distension of the cecum if it is not twisted. Postmortem rupture of the diaphragm or abdominal wall may occur, due to tympany.

Intussusception involves the telescoping of one segment of bowel into an outer sheath formed by another, usually distal, segment of gut (Fig. 1.54). Any level of the gut with sufficient mesenteric mobility may be involved. The *cause* is usually not apparent, though linear foreign bodies, heavy parasitism, previous intestinal surgery, enteritis, and intramural lesions such as abscesses and tumors may be associated. It may also be a *terminal, agonal, or postmortem event*. The history is that of partial or complete intestinal obstruction, perhaps with bloody feces, and it is most common in young animals.

Intussusception is common in *dogs*, where most frequently it is ileocolic. It is much less common in cats. Intussusception is also

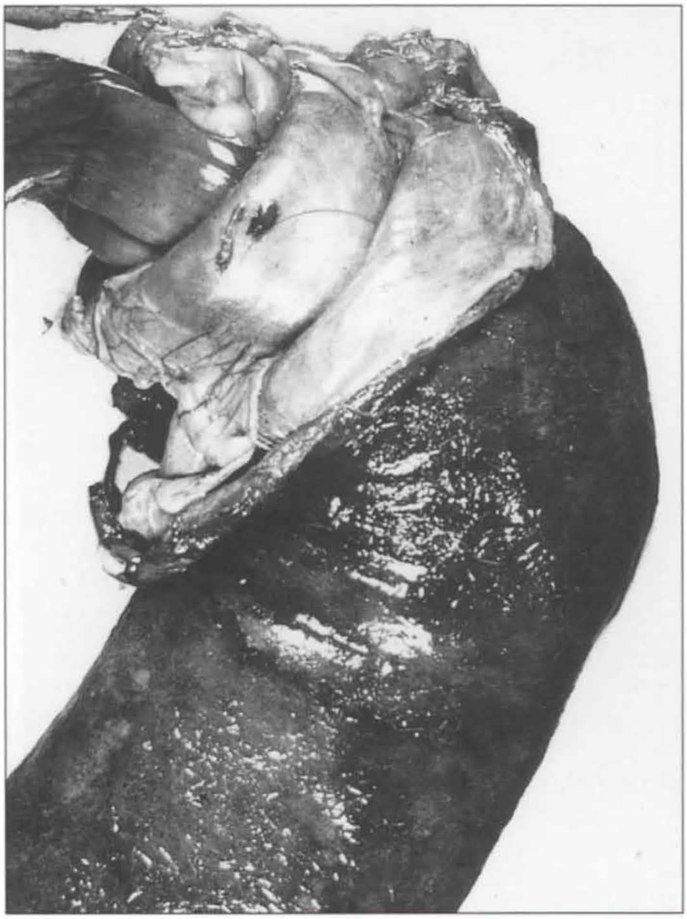

Figure 1.54 Intussusception of the intestine in a dog. Outer intestinal layer has been cut away to expose the edematous and congested infarcted mucosa of the strangulated portion of the intussusception.

moderately common in lambs, calves, and young horses, where it may involve small intestine, cecum, and colon.

The progressive invagination of the leading edge of the intussusceptum into the distal segment results in the *wall of the intussusception being comprised of three layers*: (1) the inner entering, and (2) middle returning, segment of invaginated bowel, and (3) the outer wall of the receiving segment of gut. It is limited in length by the increasing tension on the mesentery drawn into the lesion, to about 10–12 cm in small animals, and about 20–30 cm in large animals. This tension along one edge of the gut may cause the mass to become bowed or spiraled.

Tension and compression of mesenteric veins cause the intussusceptum, or a portion of it, to undergo *venous infarction*. It swells, with edema and congestion, and the adjacent apposed serous surfaces become adherent as fibrin and inflammatory cells effuse from the affected bowel. Adhesion quickly renders the intussusception irreducible. Necrosis and gangrene of the invaginated intestine usually develop, but sometimes the intussusceptum will slough, and the remaining viable segments will maintain continuity of the gut, or rarely, will form two adjacent blind ends. Intestine above obstructing intussusceptions may be dilated, and that below contracted and devoid of content. If obstruction is chronic or partial, there may be hypertrophy of the smooth muscle of proximal bowel. In horses, chronic ileocecal intussusception involves a relatively short (<10 cm) length of bowel. Incidental terminal, agonal, or postmortem intussusception is recognized by the relative absence of congestion, edema, and adhesion of the involuted segment of gut.

Cecal inversion, and cecocolic intussusception in the horse, with inversion of the cecum into itself, or into the right ventral colon, may result in ischemia of the cecum and possibly part of the involved colon; if partial, ischemia usually involves the more distal cecum.

Segmental ischemic necrosis of the small colon may occur in pregnant or postpartum mares, due to mesenteric tension from intussusception and rectal prolapse of the distal large bowel, or perhaps due to laceration of the mesocolon and associated vessels by the feet of the foal during parturition. Colic, and intestinal obstruction, necrosis, rupture, and peritonitis may follow.

Arterial thromboembolism

Ischemia of the gut due to arterial thrombosis and embolism is rare in domestic animals other than the horse. Mucosal and occasionally transmural focal or segmental infarctive lesions are seen in *Pasteurella* septicemia in lambs and in *Histophilus somni* bacteremia in cattle. Most cases of embolic disease are associated with bacterial infections that cause softening and lysis of thrombi and facilitate formation of emboli. This is particularly true for the lesions associated with strongyle migrations in horses, where lesions remain localized unless thrombi induced by the parasite become secondarily infected.

In **horses** it is associated with **endoarteritis**, mainly at the root of the cranial mesenteric circulation, caused by migrating larvae of *Strongylus vulgaris* (see Vol. 3, Cardiovascular system). Effective worm control programs have rendered this problem increasingly rare.

Candidates for a diagnosis of nonstrangulating infarction are animals in which the anatomic distribution of an ischemic lesion is incompatible with volvulus or other strangulation, or where physical evidence for incarceration or strangulation obstruction is not present in the surgical history or at autopsy, and where there is evidence of verminous arteritis. Typically, ischemic lesions of this type are limited to the "watersheds" at the periphery of the colic and cecal arterial circulatory fields – the pelvic flexure and the distal cecum – since collateral circulation within these circulatory fields is extensive.

Lesions limited essentially to the mucosa usually appear to be subacute, the result of ischemia of relatively short duration, and are ulcerative or fibrinonecrotic, usually with a hyperemic margin. They may be tens to many hundreds of square centimeters in area.

Transmural lesions represent ischemia of longer duration. Devitalized gray-brown intestine of normal thickness is interpreted to represent arterial obstruction without significant reflow, except along the boundary with viable tissue. Large edematous, congested, or hemorrhagic, full-thickness lesions, physically or anatomically inconsistent with strangulation, are interpreted as severe arterial obstruction, with subsequent reflow either by relief of the obstruction or by way of collaterals. Ischemic damage to vessels of the mucosa, submucosa, and perhaps deeper structures results in hemorrhage and edema when blood flow returns (Fig. 1.55). Ulcerative or fibrinonecrotic mucosal lesions are probably the result of transient ischemia, and superficial or mucosal damage, with subsequent reflow. Similar lesions may occur following relief of strangulation of short duration, and in nonsteroidal

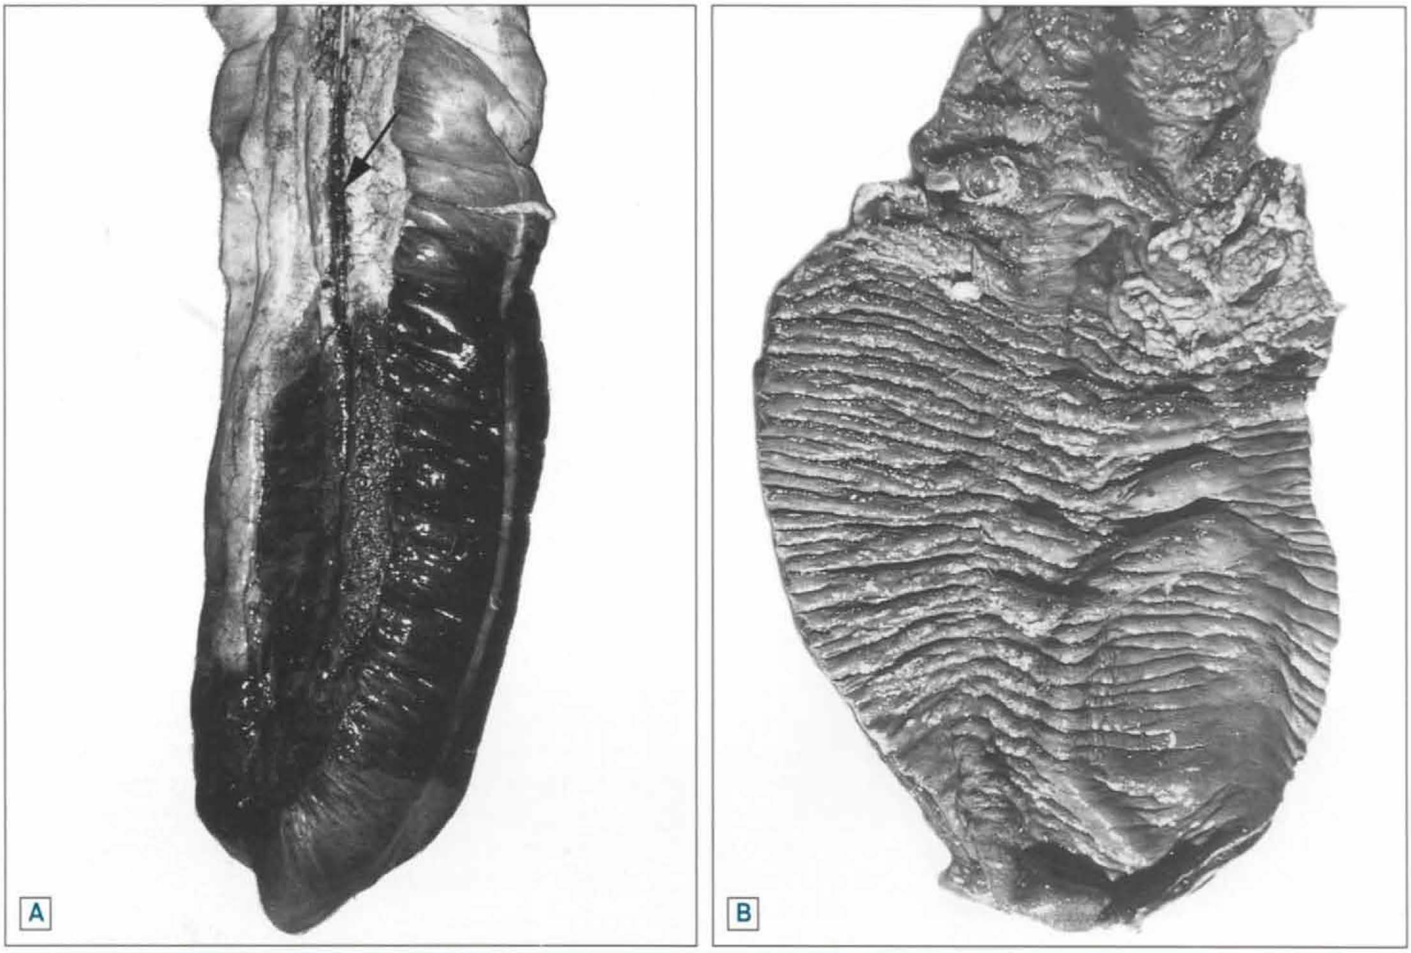

Figure 1.55 **A. Infarction of pelvic flexure** of the large colon of a horse. The colic artery contains a thrombus (arrow). Hemorrhage and edema of the serosa suggest that arterial thrombosis and infarction have been followed by reperfusion, with extravasation of blood from damaged vessels in the affected tissue. **B.** Mucosa of equine **cecum** that has undergone **ischemic necrosis** due to reduced arterial perfusion. Subsequent reflow has occurred and the infarcted mucosa is covered with fibrinonecrotic exudate. Irregular ulcers and foci of exudation are present on the mucosa along the proximal margin of the lesion (toward top).

anti-inflammatory drug toxicosis or salmonellosis, both of which, in part, involve mucosal microthrombosis.

Reduced perfusion

Ischemia due to reduced perfusion of the intestinal vascular bed is a *difficult and uncommon diagnosis*. Circumstances where it may be expected to occur include severe hypovolemic states, such as *hemorrhagic shock* in the dog, cat, and possibly other species; in animals, particularly dogs, with *disseminated intravascular coagulation* (DIC); in dogs with hepatic disease and *portal hypertension*; in *hypotensive shock* due to heart failure; and in animals with reduced mesenteric arterial perfusion, mainly horses with severe *verminous endoarteritis*.

In **"shock gut"** in dogs, and rarely, other species, associated terminally with heart failure, hemorrhage, hypovolemia, and DIC, part or all of the mucosa of the small intestine is deeply congested and the content is hemorrhagic. The pathogenesis of the lesion is related to reflex vasoconstriction in the mucosa and submucosa, shunting of blood away from the mucosa, dilation of mucosal capillaries, and reduction in rate of flow of blood through the villus. Countercurrent transfer of oxygen from the afferent to efferent vessels in the villus aggravates hypoxemia in the villus by increased shunting of oxygen to the efferent venule. Splanchnic pooling of blood, systemic arterial hypotension, and intestinal vasoconstriction occur in endotoxic shock in dogs, causing similar mucosal lesions. Microthrombosis associated with sluggish flow, DIC, and endotoxemia may contribute to mucosal ischemia by obstructing capillaries in the villi, and mucosal and submucosal venules. Microthrombi in these vessels in association with hemorrhagic mucosal necrosis suggest the possibility of ischemia due to "slow flow."

Transient or incomplete reduction in perfusion due to obstruction of the arterial blood supply has a similar effect on the mucosa. The obstruction may be due to *arteriospasm*, perhaps induced by vasoactive mediators such as thromboxane. Mucosa devitalized by hypoxia will become hemorrhagic with continued blood flow. Since the primary problem may not involve a systemic state as complicated as severe shock, the animal may survive long enough to develop an effusive ulcerated or pseudomembranous mucosa, with some prospect of stabilization or repair, if the lesion is not widespread. "Slow flow" due to reduced arterial perfusion with inadequate collateral flow may be expected to affect the "watershed" of a circulatory field preferentially. In the horse this may be the explanation for mucosal lesions at the pelvic flexure and apex of the cecum in which thromboembolism cannot be implicated, but in which mural thrombi in the cranial mesenteric root could have caused significantly reduced perfusion or flushed vasoconstrictive thromboxane into circulation.

Transient or noninfarctive "slow flow" has been proposed as a cause of intermittent colic due to verminous arteritis. It may also play a role in the development of functional obstruction and volvulus in horses with cranial mesenteric arterial lesions.

Ischemia at the periphery of the circulatory field of the caudal mesenteric artery may possibly predispose to rectal perforation in horses. The precarious perfusion of the mucosa at this site may contribute to ischemic ulceration and the development of *rectal stricture in swine*. In many cases this condition appears to be associated with *Salmonella* infection, and it is discussed further with porcine salmonellosis (p. 198).

Acute acorn poisoning in the horse may cause severe gastrointestinal edema and focal hemorrhage, with infarction and ulceration in the cecum and colon. Microscopic lesions in the small and large intestine are consistent with an ischemic pathogenesis, and microthrombi have been associated with mucosal infarcts in the large bowel, as well as in other organs.

Nonsteroidal anti-inflammatory drugs cause ulceration of the upper small intestine and colon, as well as oral and gastric ulceration, which seem to be related to ischemia, in horses and dogs. In horses, phenylbutazone, even at therapeutic dosages, can result in ischemic damage to the intestinal mucosa. It may be that intercurrent stress or dehydration contributes to the pathogenesis. The right dorsal colon is affected preferentially, resulting in the term "*right dorsal colitis.*" Lesions here are characterized by ischemia, often with marked edema and avascular necrosis. Lesions may be focal, linear, or extensive and segmental, involving the entire circumference of the bowel (Fig. 1.56). Depending on the duration and severity of the lesion, the mucosa may be congested and edematous, with superficial necrosis and fibrin exudation, or extensively eroded and ulcerated, with fibrinonecrotic exudate. Early in the process, superficial epithelial necrosis and progressive mucosal necrosis and inflammation are evident. *Microvascular injury*, with subsequent microthrombosis and ischemic ulceration, is considered by some to be the cause of the lesions in the stomach and intestine. This may be the result of direct phenylbutazone toxicity to the microvasculature. Vasoconstriction or depression of other cytoprotective effects, mediated by phenylbutazone inhibition of prostaglandin synthesis, could be the cause of the lesions. Animals may develop diarrhea and hypoproteinemia as a result of the extensive mucosal defects. Minor mucosal lesions may resolve; a sequel to severe colonic damage in horses is colonic stricture.

Lesions in the oral cavity associated with nonsteroidal anti-inflammatory drug administration are deep crateriform ulcers, with a clean granulating base. Concurrent with punched-out ulcers in the glandular mucosa, there may be chronic gastritis and atrophy of the mucosa with loss of differentiation of the cells in the fundus. In the upper small intestine, ulcers may be focal, linear, or segmental and annular. Microscopic lesions that may precede ulceration of the small intestine include mild to severe atrophy of villi, epithelial necrosis, mucosal inflammation, and fibrin exudation. Renal papillary necrosis is often concurrent, if animals are dehydrated.

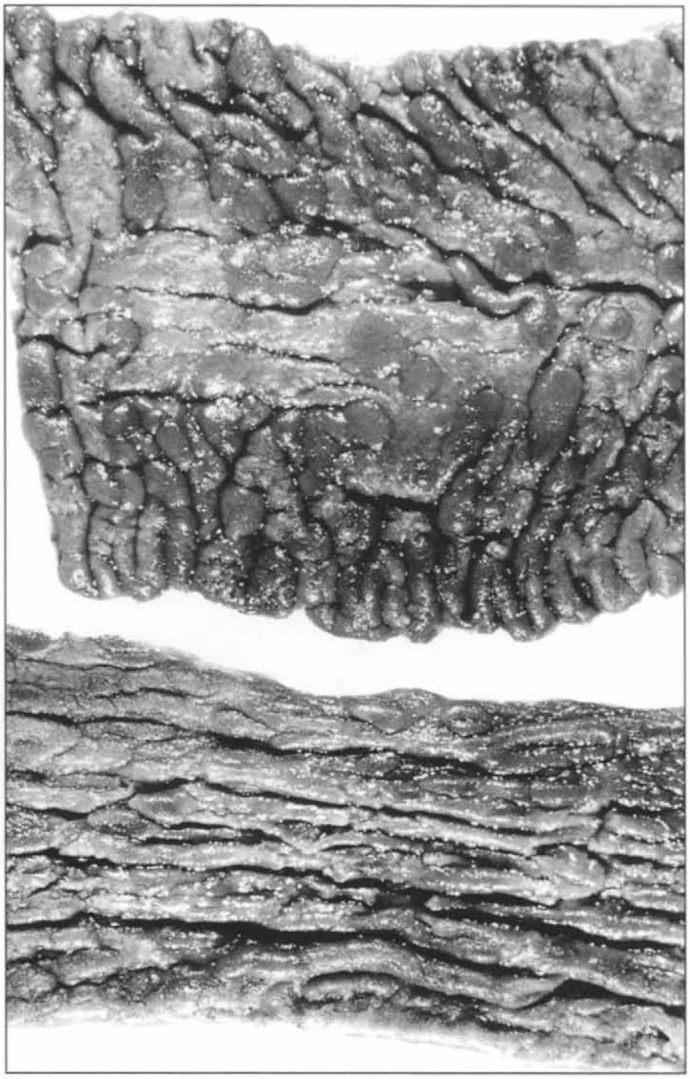

Figure 1.56 Fibrinonecrotic enterocolitis in a foal treated heavily with nonsteroidal anti-inflammatory drugs.

Miscellaneous conditions of the intestinal tract

Intestinal lipofuscinosis ("brown gut") in dogs is characterized grossly by *tan-brown discoloration of the intestinal muscularis* (Fig. 1.57). It may involve all areas of the gut, but is most common in the lower small intestine. The bladder and mesenteric and peripheral lymph nodes may also be affected grossly. Although the lesion may be incidental, it is usually associated with *chronic enteric and/or pancreatic disease*. Lipofuscinosis has been reported in Boxer dogs with histiocytic ulcerative colitis, but a definite correlation between the two conditions has not been established. A high prevalence of lipofuscinosis has also been reported in dogs that were fed rations high in polyunsaturated fats with a relative *deficiency of vitamin E*, and it is prevented by vitamin E supplementation. Any condition, such as exocrine pancreatic insufficiency, causing a reduction in the absorption of fats, and consequently of the fat-soluble vitamins, especially in the presence of polyunsaturated fatty acids in the diet, may predispose to lipofuscinosis.

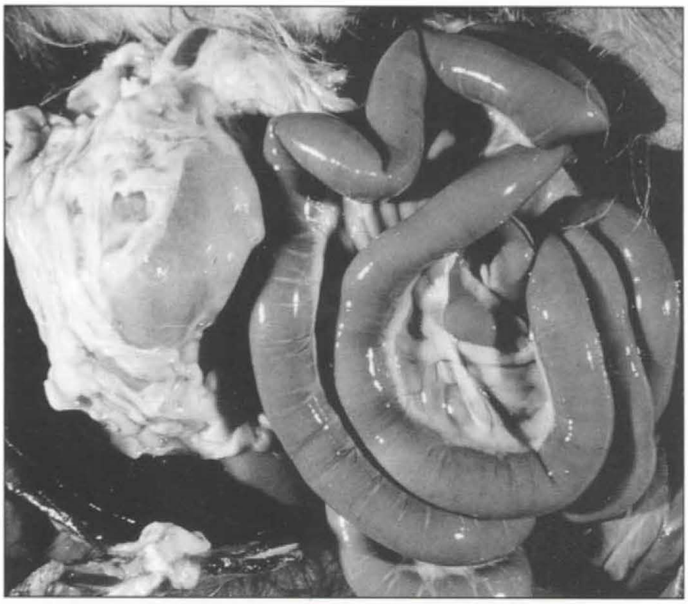

Figure 1.57 Intestinal lipofuscinosis (brown gut), discoloring the small intestine to a tan hue in a dog.

The microscopic lesions of brown gut are gray-to-brown granules in the perinuclear regions of smooth-muscle cells in both inner and outer muscle layers (Fig. 1.58). The granules stain as lipofuscin (periodic acid–Schiff-positive, sudanophilic, weakly acid-fast with Ziehl–Neelsen), and fluoresce dim yellow in paraffin section. The granules, termed *leiomyometaplasts*, are oxidized polymerized phospholipids which are highly resistant to further endophagocytic degradation. They are derived from excess cell membrane lipid peroxidation in vitamin E deficiency. Their propensity to accumulate, especially in gastrointestinal smooth muscle, is unexplained.

A distinct syndrome occurs in *Cocker Spaniel dogs* affected with generalized ceroid-lipofuscinosis, an inherited storage disease. In affected dogs, discoloration of intestinal smooth muscle is evident but, in addition, they have progressive hindlimb paresis and incoordination.

Muscular hypertrophy of the intestine was formerly a common finding in **swine**, but it appears to have diminished in prevalence in most areas. It may be found in apparently healthy animals at slaughter as a uniform thickening of the muscular coats of the *terminal ileum*. The segment involved always includes the most caudal portion, but it may extend a variable distance forward, usually 25–50 cm. The affected area is thickened and has the turgid feel of a rubber hose. The lumen is small and the mucosa is thrown into thick folds, but it is the muscle that thickens the wall. This condition must be differentiated from adenomatosis and necrotic ileitis, manifestations of enteropathy associated with *Lawsonia* in swine.

Rupture may occur, in association with impaction of dehydrated feed in the hypertrophic segment. The actual rupture may be a

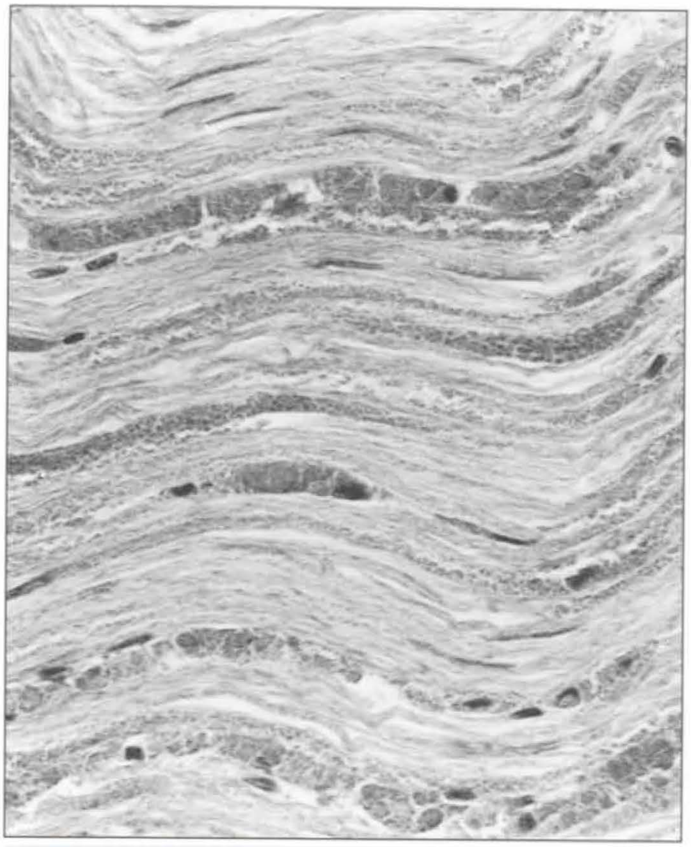

Figure 1.58 Granular accumulations of ceroid-lipofuscin pigment (leiomyometaplasts) in smooth-muscle cells in the small intestine of a dog with **intestinal lipofuscinosis**.

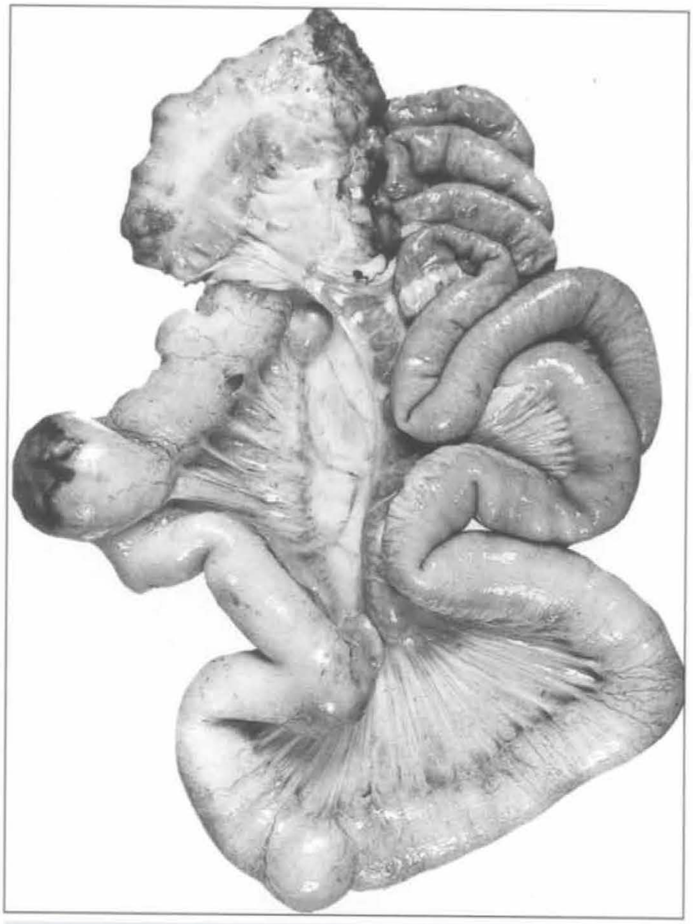

Figure 1.59 Multiple saccular dilations with impending perforation in **muscular hypertrophy of ileum** in a pig. (Courtesy of S Nielsen and J Am Vet Med Assoc.)

result of violent peristalsis, or diverticula may develop (Fig. 1.59), the mucosa undergoing necrosis with secondary bacterial inflammation. Perforation occurs at these weakened areas. While the underlying basis of this condition is obscure, it is likely that the muscular hypertrophy is secondary to a functional obstruction of the ileocecal orifice.

Muscular hypertrophy of the small intestine, of uncertain cause, but sometimes associated with *Anoplocephala* sp. tapeworms at the ileocecal orifice, also occurs in **horses** (Fig. 1.60). The association with tapeworm infection is uncertain because a considerable proportion of cases also show muscular hypertrophy of the *terminal esophagus*. The lesions are similar to those described in swine, except that the affected segment may occur at any point along the small intestine, and occasionally in the large intestine, although the *ileum is the most common site*. Horses with this condition may have chronic mild colic and anorexia or intermittent diarrhea with progressive loss of weight. Diverticula, and perforation or laceration of the thickened intestinal wall, may also occur.

Intestinal smooth-muscle hyperplasia has been described in a goat. Unlike the condition in horses and swine, the increased muscular thickness was jejunal rather than ileal.

Diverticulosis of the small intestine is a rare lesion that is sometimes associated with muscular hypertrophy in pigs and horses. It is characterized by the presence of saccular dilations, which are lined by intestinal mucosa, in the muscularis and subserosa of the small intestine. The diverticula tend to follow the pathway of blood vessels and are mainly located adjacent to the mesenteric attachment. Rupture of the diverticula causes peritonitis.

Intestinal emphysema is a rare condition found mainly in weaned *pigs*, in which it is usually an incidental finding in slaughtered animals, with no economic significance. It is characterized by numerous thin-walled, gas-filled cystic structures, a few millimeters to several centimeters in diameter, in the gut wall and on the serosal surface (Fig. 1.61). These are mainly located in the small intestine, although the large intestine, mesentery, and mesenteric lymph nodes may be involved. Microscopically, the cystic structures appear to be *dilated lymphatics* that are located in the lamina propria, submucosa, muscularis, subserosa, mesentery, and mesenteric lymph nodes. A pleocellular inflammatory reaction may be evident in the walls of the cysts. Although production of gas by bacteria has been implicated, the cause remains obscure.

Rectal prolapse most commonly occurs in *swine, sheep, and cattle*. It may occur in any animal that has *prolonged episodes of tenesmus or straining*, usually associated with colitis or urinary infection or obstruction. In pigs, rectal prolapse occurs as a herd problem when the ration contains *zearalenone*, an estrogenic mycotoxin produced by fungi of the genus *Fusarium*. The toxin causes marked swelling and congestion of the vulva and vaginal mucosa that may be followed by vaginal prolapse. Affected pigs strain continuously and rectal prolapse is a common complication. Rectal prolapse in sheep

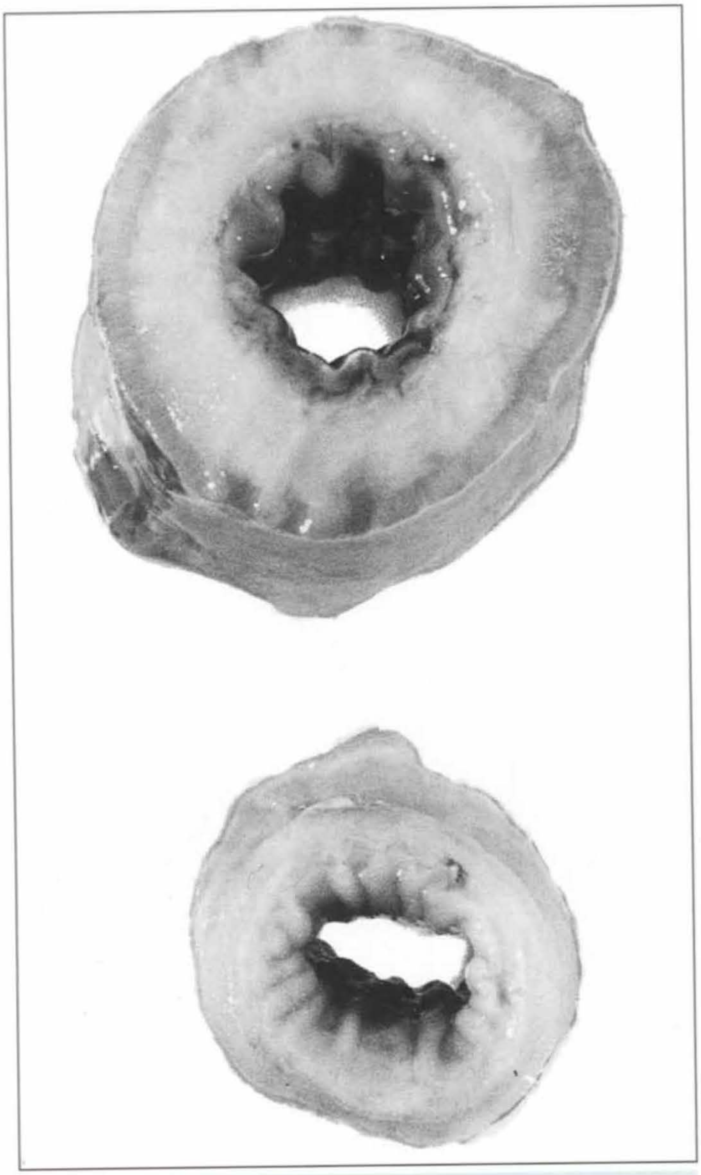

Figure 1.60 Ileal muscular hypertrophy in a horse. Normal equine ileum below.

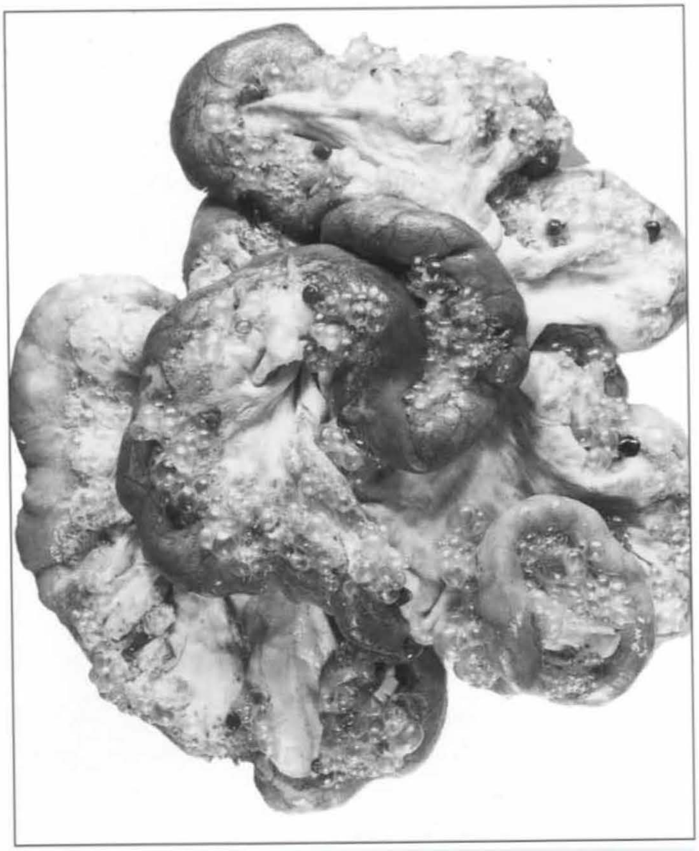

Figure 1.61 Intestinal emphysema in a pig.

may be the consequence of ingestion of estrogenic pastures, and is accompanied by other signs of hyperestrogenism (see Vol. 3, Female genital system).

The prolapsed rectum is edematous, congested, and there may be necrosis and ulceration of the everted mucosa. These lesions are ischemic in origin due to interference with venous blood flow from the prolapsed section. Only the mucosa, or all layers, may be involved in the prolapse. In swine surviving slough or amputation of the prolapsed tissue, *rectal stricture* may ensue. Rectal stricture is discussed further in the section on salmonellosis, below.

Malassimilation and protein-losing syndromes

In dogs, and to a lesser extent in horses, cats, and other species, usually idiopathic syndromes occur, variably signaled by *chronic diarrhea, weight loss, hypoproteinemia, and malabsorption. Intestinal biopsy, where feasible, is usually necessary to make a diagnosis and establish a prognosis.* These syndromes are typically characterized by abnormal lamina proprial inflammatory infiltrates (eosinophils, lymphocytes, and plasma cells, or granulomatous inflammation), neoplasia, especially lymphosarcoma, or amyloid, perhaps associated with villus atrophy. Lymphangiectasia may also produce a similar syndrome. Infectious causes of erosion or ulceration need to be considered, but are less common. In dogs giardiosis, and sequelae to severe parvoviral infections in animals recovered from the acute phase, may cause such a syndrome. In horses, chronic salmonellosis and *Lawsonia* are potential infectious causes of malassimilation and protein loss.

The limitations on the interpretation of biopsies noted in the section on normal form and function of the intestine must be

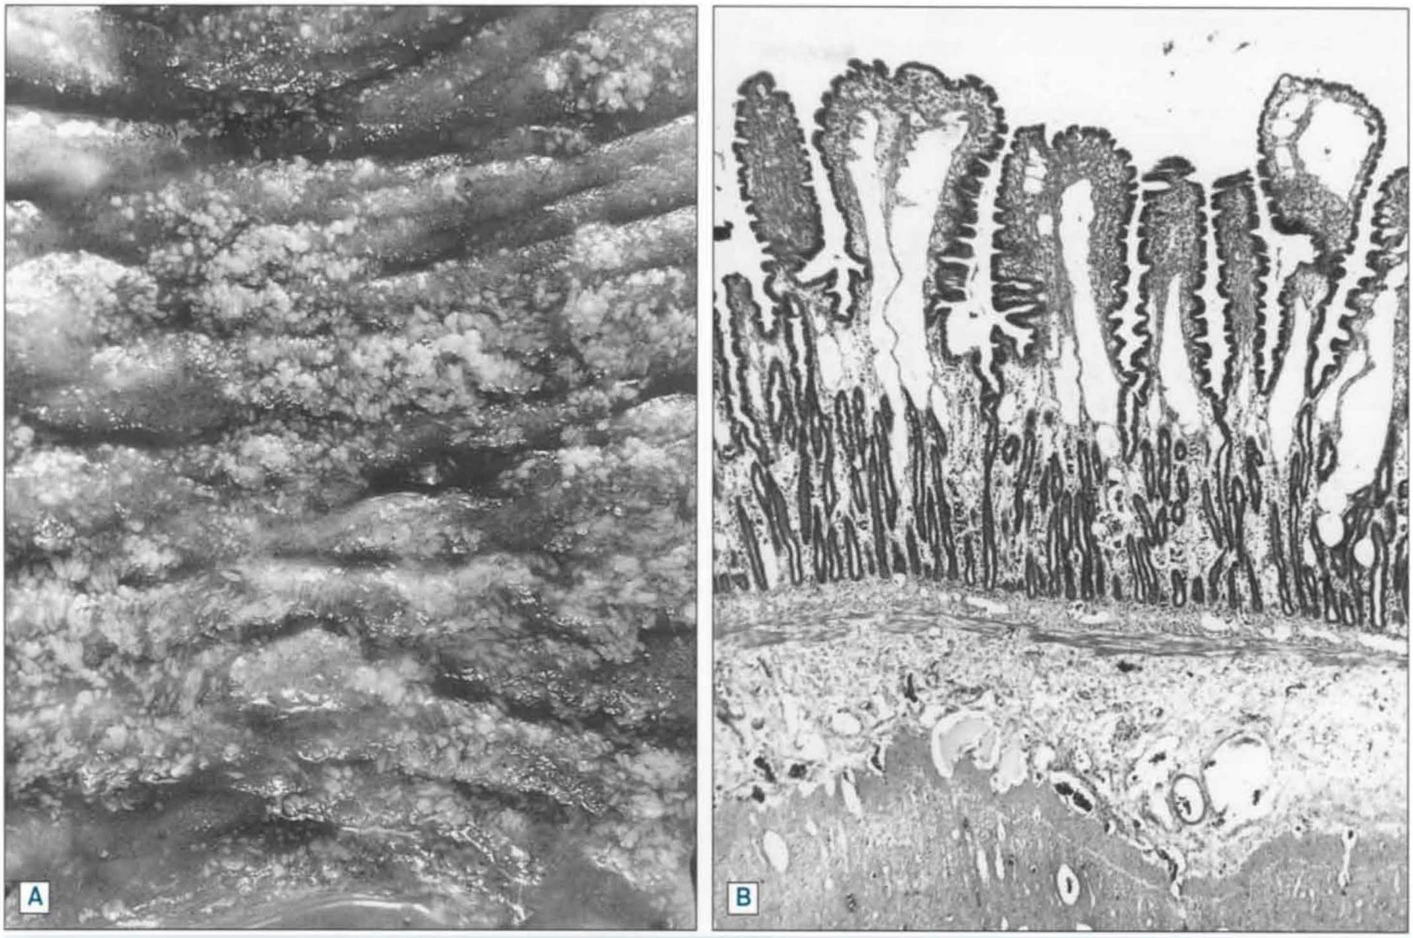

Figure 1.62 Lymphangiectasia in the small intestine of a dog. **A.** Mucosa, thickened by edema, is thrown in folds. Many villi contain white chyle-filled lacteals. **B.** Lacteals are dilated, lamina propria and submucosa are edematous, and lymphatics in submucosa and muscularis are open.

borne in mind. Neoplasia will be differentiated from inflammation, amyloidosis, and lymphangiectasia, and, rarely, characteristic lesions or an agent may be recognized, implicating an infectious process. If inflammatory bowel disease is recognized, associated or complicating problems, such as *Giardia* infection or bacterial overgrowth, should be sought. Associations with the dietary habits and history of the animal should also be investigated, since some cases may be associated with inappropriate responses to dietary antigen.

Lymphangiectasia

Lymphangiectasia has been described most commonly in the dog, where it is among the more common causes of malabsorption/protein-losing enteropathy; it has not been reported in cats. Breed predisposition seems limited to Yorkshire Terriers and the Norwegian Lundehund, in which lymphangiectasia is part of a syndrome of protein-losing enteropathy with inflammatory bowel disease and in which gastritis and gastric neoplasia may coexist. The disorder has also been reported in the horse. Lymphangiectasia is associated with a syndrome variably characterized by *chronic diarrhea, wasting, hypoproteinemia, lymphopenia, hypocalcemia, and hypocholesterolemia.* Peripheral edema, ascites, and hydrothorax result from hypoalbuminemia.

The lesion in the small intestine is *dilation of the lacteals, and often lymphatics* of the submucosa, muscularis, serosa, and mesentery (Fig. 1.62). Villi containing dilated chyle-filled lacteals may stand out grossly as white papillate foci in a thickened, transversely folded edematous mucosa. Serosal and mesenteric lymphatics may be prominent, white, and dilated. *Nodular white masses* up to 5–10 mm in size may be present on the serosa at the mesenteric border and along lymphatics; rarely, they are found on the liver, diaphragm, other abdominal organs, and pleura.

In section, villi may be of normal length or somewhat blunt or stubby, with some hypertrophy of crypts. The surface epithelium may appear normal or perhaps slightly attenuated, and lateral interepithelial spaces are often dilated. The lacteals in many villi are distended, and lymphatics in deeper portions of the mucosa, submucosa, and muscularis usually are. Occasional lipid-laden macrophages are present in and around lacteals and lymphatics; large focal accumulations of lipophages around lymphatics, sometimes with a local granulomatous response to lipid or saponified fat, form the white masses that may be seen grossly. A similar reaction may be present in the draining lymph nodes. The lamina propria is edematous, and the submucosa and deeper portions of the gut wall usually are. The proprial inflammatory cell population may be normal, or the numbers of lymphocytes, plasma cells, and eosinophils may be increased, as in chronic inflammatory bowel disease.

The cause of lymphangiectasia may be lymphatic obstruction. Many cases appear to be acquired, and some may be due to lymphosarcomatous or granulomatous infiltrates obstructing flow in mesenteric lymph nodes. Lipogranulomas along the lymphatic drainage are inconsistent features of lymphangiectasia, and are probably in response to chronic leakage of lipid-laden chyle, rather than a cause of lymphatic obstruction. Usually, no congenital or acquired obstruction of the lymphatic system is obvious, though several dogs with lymphangiectasia have had chylothorax associated with thoracic duct obstruction. Experimental obstruction of mesenteric lymphatics produces hypoproteinemia and lymphangiectasia, but not diarrhea and weight loss, suggesting that *the etiology of the clinical syndrome may be more complex than simple lymphatic obstruction.* Increased vascular permeability associated with chronic inflammatory bowel disease may also contribute to mucosal edema and lymphatic dilation.

Moderate malabsorption of lipid, and plasma protein loss into the gut, causes the signs associated with lymphangiectasia. Malabsorbed lipid may contribute to diarrhea via the effects of fatty acids on colonic secretion. Mucosal permeability associated with increased proprial hydrostatic pressure may cause filtration secretion and contribute to plasma protein loss. It has been proposed that dilated lacteals may rupture, releasing lymph into the lumen of the intestine. Hypocalcemia may be related to loss of the mineral bound to plasma albumin, and perhaps to vitamin D malabsorption, or formation of soaps with malabsorbed lipid in the gut lumen. Hypocholesterolemia is due to lipid malabsorption and effusion of plasma. Lymphopenia is thought to be the result of the loss of lymphocyte-rich lymph into the gut.

Amyloidosis

Amyloid deposition in the small intestine and stomach may occasionally be encountered in animals with systemic amyloidosis. Sometimes the gastrointestinal lesions predominate and contribute to the clinical syndrome. Significant intestinal amyloidosis leads to signs consistent with malabsorption and enteric protein loss. Usually there is no gross indication of the deposition of amyloid in the intestine. However, occasionally focal ulceration or hemorrhage may be noted. Microscopically, amyloid is seen beneath the epithelium or throughout the propria in villi, and perhaps around or within vessels in the submucosa (Fig. 1.63). It must not be mistaken for collagen deposition, which is most unusual in these locations, though a band of collagenous material is sometimes present at the base of the mucosa in cats. The pathogenic effects of amyloid in the intestine seem to involve either impaired movement of interstitial fluid into lacteals or perhaps increased permeability of capillaries, possibly explaining protein loss into the lumen.

Idiopathic inflammatory bowel disease

Some animals, mainly dogs, but less commonly cattle, cats, and horses, showing signs consistent with malabsorption and/or plasma loss into the gut, have microscopic lesions in the mucosa of the small intestine described as *chronic inflammatory bowel disease, lymphocytic-plasmacytic enteritis, filled-villi syndrome,* or *eosinophilic gastroenteritis.*

The latter phenomenon in cats and horses is often part of systemic eosinophilic syndromes affecting those species, considered separately below. In dogs, there is no proof that differentiation of eosinophilic gastroenteritis from chronic inflammatory bowel disease is clinically relevant, nor are there clear criteria for such differentiation, so the two will be considered together. In both dogs and cats, idiopathic mucosal colitis and gastritis may be present as components of chronic inflammatory bowel disease, perhaps with predominant signs reflecting gastric or colonic dysfunction; both are considered here. In contrast to the mucosal pattern of inflammation evident in these entities, inflammatory lesions of the large and small intestine of any species that include a significant population of macrophages usually adopt a transmural pattern, and may be associated with a specific etiology (e.g., *Mycobacterium*, *Histoplasma*) or represent a distinct syndrome (histiocytic ulcerative colitis of Boxers). They are described below with transmural granulomatous enteritis and with typhlocolitis.

Inflammatory bowel disease is a clinical syndrome for which it is difficult to develop a valid, objective histologic counterpart, and it should be a *diagnosis of last resort* made by the clinician after alternatives such as food intolerance, motility disorders, and infectious disease have been ruled out. However, the thoroughness of the clinical and laboratory investigation prior to the use of endoscopic biopsy is influenced by the amount of time and money available to evaluate what are often elusive functional entities. Endoscopic biopsies are often done early, after symptomatic medical therapy has failed to control clinical signs. It is probably not appropriate for a pathologist to issue a diagnosis of "inflammatory bowel disease;" it is more appropriate simply to list the histologic findings and to indicate that *the changes could be "compatible with" a clinical diagnosis of that syndrome.*

Regardless of the portion of the gastrointestinal tract under consideration, the histologic abnormalities are grouped under three broad headings: (1) *changes in mucosal architecture reflecting active or recent epithelial abnormality*; (2) *increased numbers of proprial leukocytes*; and (3) *fibrosis within the lamina propria.* Of these, the epithelial changes are the most reliable, yet the least prevalent. Subjective impressions of increased numbers of leukocytes within the lamina propria are the least reliable, but are the most widely used criterion for a diagnosis, simply because most biopsy samples do not have any other mucosal abnormalities. The pathologist, faced with substantial pressure to make some kind of diagnosis, may reach for the one observation that cannot be disproven (or proven): too many leukocytes.

In the **small intestine**, the cardinal finding is abnormally intense infiltrates of well-differentiated lymphocytes and plasma cells, and sometimes eosinophils, in the lamina propria of villi, between crypts and perhaps in the submucosa. However, normal intestine contains these types of cells and the distinction between normal and abnormal infiltrates is subjective, based on the position and number of cells in the villus. *A layer of lymphocytes, plasma cells, and perhaps neutrophils or eosinophils more than about four cells thick, in the deep mucosa, below the crypts and above the muscularis mucosae, is abnormal* (Fig. 1.64).

Villi may be normal, clubbed, or moderately to severely atrophic, and occasionally fusion of villi may be prevalent (Fig. 1.65). The surface epithelium may appear relatively normal, mucous metaplastic, or low columnar to cuboidal with an indistinct brush border. Intraepithelial lymphocytes may be common. Crypts may be hypertrophic and lined by numerous goblet cells; in other cases goblet cells are less obvious. There may be edema of the lamina propria and dilation of lacteals, suggesting concurrent lymphangiectasia, but usually the edema is not as severe as occurs with that lesion. In this and other conditions with increased inflammatory infiltrates or edema in the lamina propria, including lymphangiectasia, crypts may be obstructed and dilated, and contain mucus and a few exfoliated epithelial cells. This has been termed *cystic mucinous enteropathy*; it is merely a severe variant of lymphocytic-plasmacytic enteritis, and we see no benefit in expanding the nomenclature in an already-confused area. Occasionally, rupture of such crypts will be seen; lakes of mucus, reactive histiocytes, and occasional giant cells are present in the lamina propria (Fig. 1.66). Other distended crypts may contain casts of eosinophilic glycoprotein.

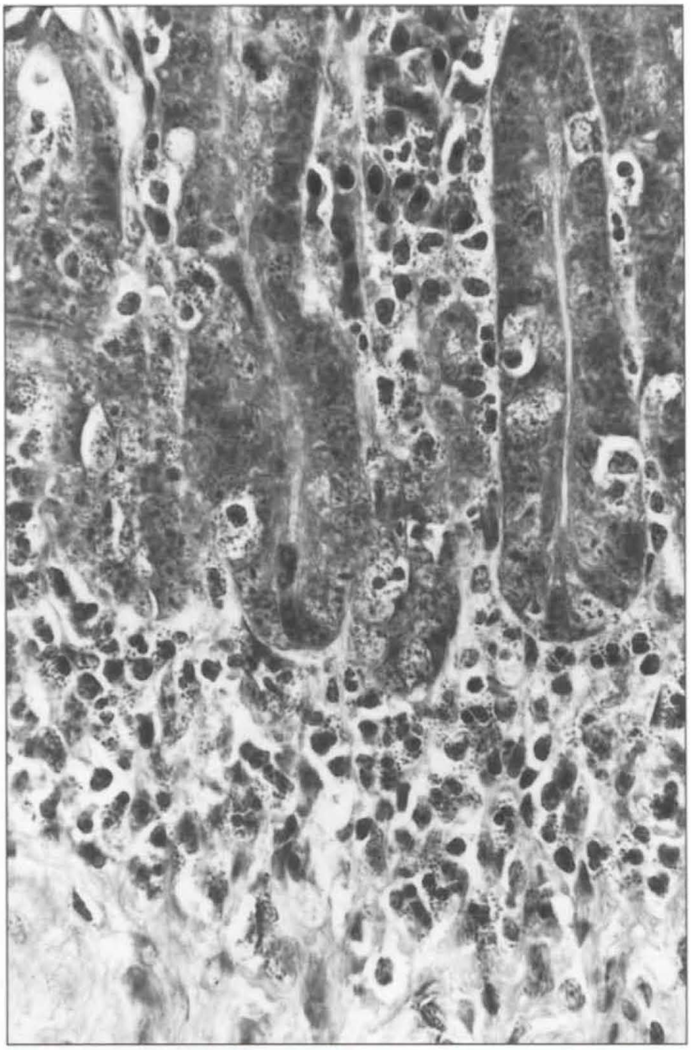

Figure 1.64 Eosinophilic enteritis in a dog. Numerous eosinophils infiltrating the epithelium of small intestinal crypts, adjacent lamina propria, and between the base of crypts and underlying muscularis mucosae.

Care should be taken to differentiate chronic inflammatory bowel disease from early intestinal lymphoma (see discussion of Malignant lymphomas, below). Some suggest that, in the Basenji at least, the former can evolve into the latter.

Idiopathic mucosal colitis is the colonic manifestation of chronic inflammatory bowel disease, and the *commonest form of colitis recognized in dogs.* It is etiologically nonspecific, occurring as chronic or chronic-active lymphocytic-plasmacytic or eosinophilic mucosal inflammation. Histiocytic ulcerative colitis is the distinctive pattern

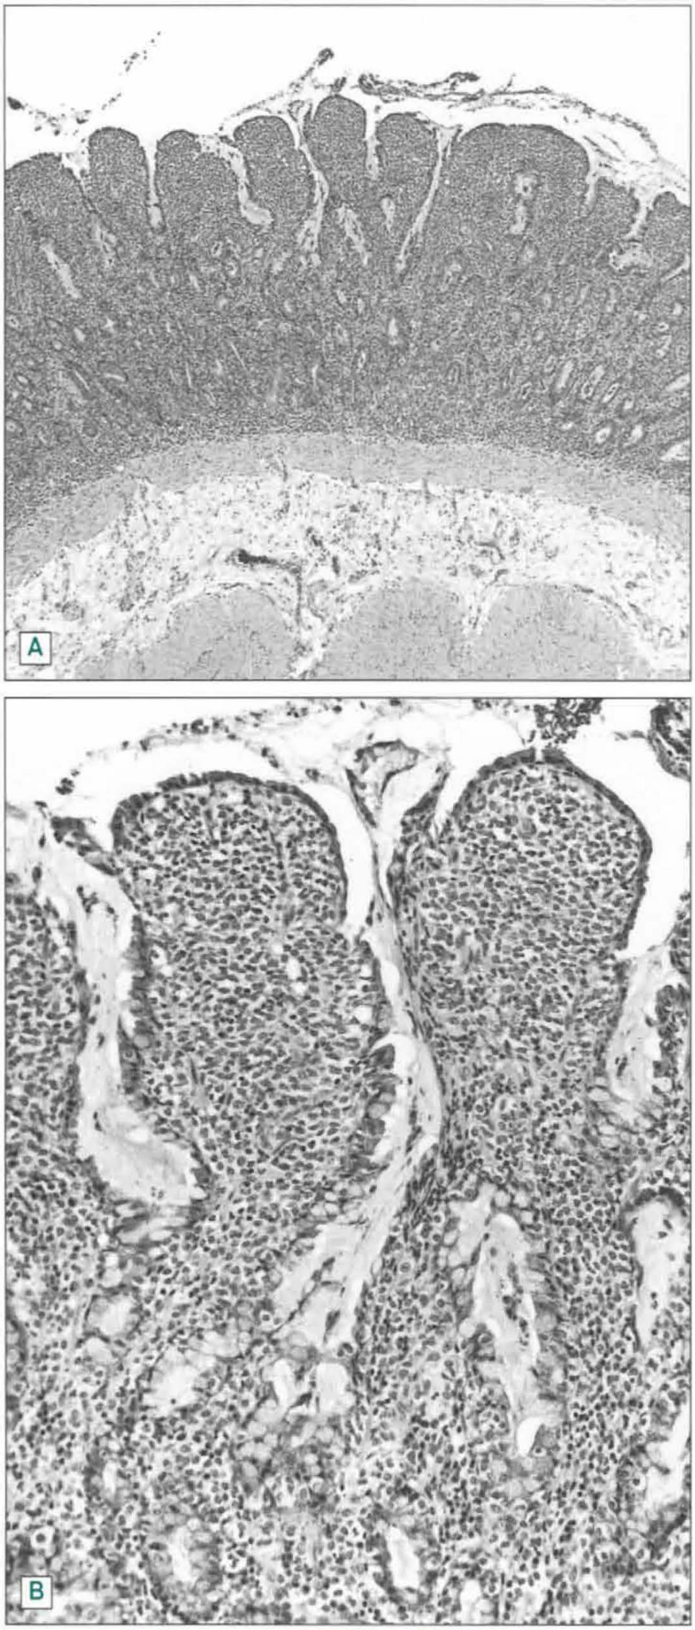

Figure 1.65 Lymphocytic-plasmacytic enteritis in a dog. **A.** Villi are stumpy, club-shaped, or fused. Excessive mononuclear infiltrate at all levels of the mucosa, including between the base of crypts and the muscularis mucosae. **B.** Blunt and club-shaped villi, cuboidal and attenuated surface epithelium, excess mucus secreted from crypts, and abnormal infiltrate of lymphocytes, plasma cells, and histiocytic cells in lamina propria.

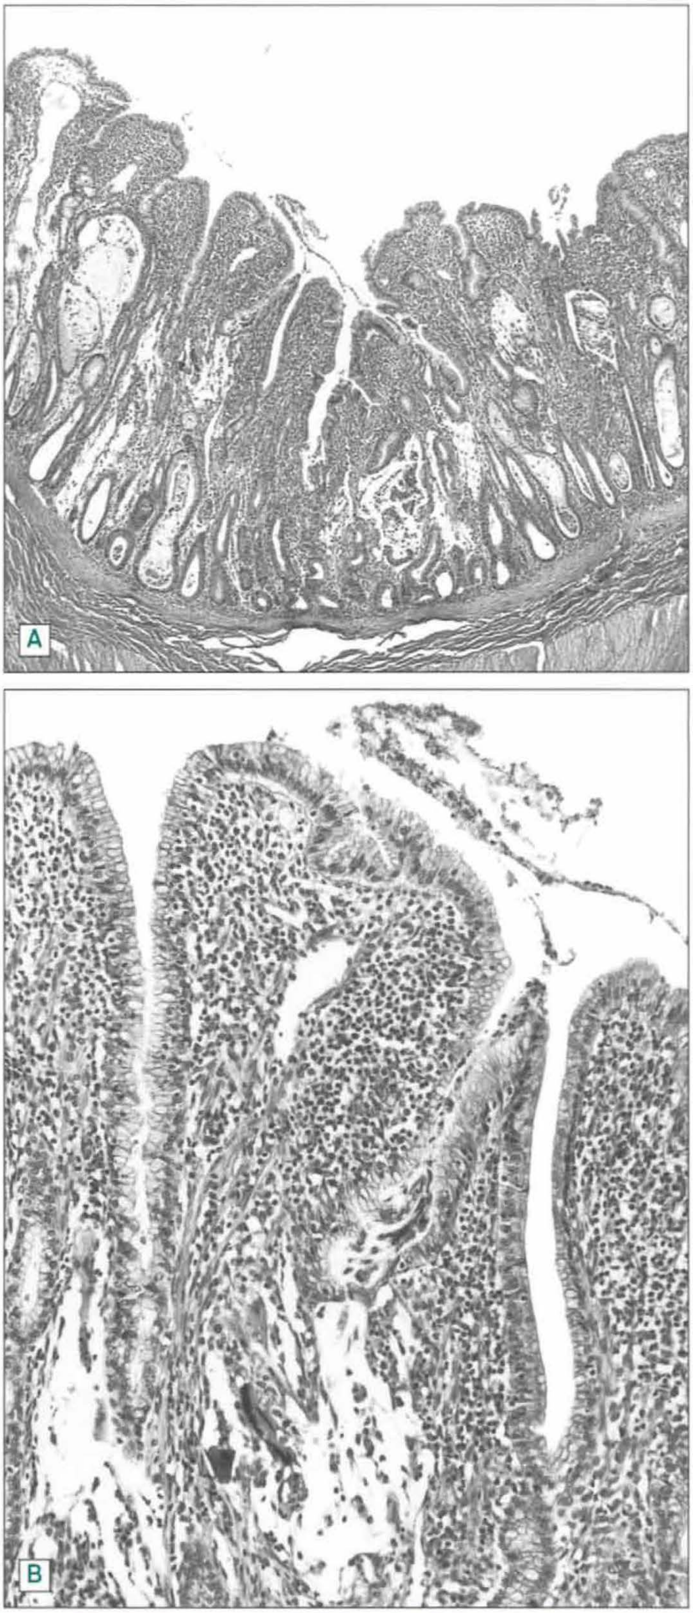

Figure 1.66 Small intestine of a dog with **malabsorption and intestinal protein loss. A.** Blunt and occasionally fused villi, mononuclear cells in lamina propria, and elongate, dilated, and mucus-filled crypts. Some distended crypts have ruptured, releasing mucus into lamina propria. **B.** Detail of (**A**) showing mucus in lamina propria due to rupture of a dilated crypt. Leak of cells and mucus from lamina propria and abnormal numbers of bacteria in lumen.

differentiated from it on microscopic grounds, along with rare cases of *Histoplasma* or protothecal colitis. Colitis is usually diffuse, so that even two or three endoscopic biopsies are probably enough to determine whether or not it is present.

Mild acute mucosal colitis, reflecting a grossly reddened friable surface visible on endoscopy, is characterized by congestion of superficial capillaries and venules, and proprial edema. Neutrophils infiltrate the superficial lamina propria around vessels, and transmigrate or pass between surface epithelial cells into the lumen. The population of lymphocytes and plasma cells in the lamina propria may not differ from normal, but there is generally a moderate increase in mononuclear cells, and perhaps eosinophils, which are usually rare in the superficial colonic mucosa, between glands. There are often few goblets on the surface and in glands, probably due to mucous discharge, rather than cell loss. Surface epithelium may be basophilic, low columnar, or cuboidal (Fig. 1.67A, B). Hyperplasia of epithelium in glands may be evident, and glands dilate. Inflammatory cells, mainly neutrophils, but perhaps lymphocytes, plasma cells, and eosinophils, may accumulate excessively along the mucosal side of the muscularis mucosae, as in inflammatory disease involving the small intestine. The lesions in mild acute colitis often seem mild in proportion to the severity of the clinical syndrome.

The *spectrum of inflammation* in colitis grades from acute towards an increasingly chronic infiltrate, which, along with edema, separates colonic glands and may accumulate deep in the mucosa between glands and muscularis mucosae (Fig. 1.67D). Neutrophils and eosinophils may be scattered among round cells in the propria, and transmigrating surface and glandular epithelium. Globule leukocytes may be prevalent. Accumulation of granulocytes and necrotic debris in the lumen of glands forms so-called *crypt abscesses*.

Greater severity of the lesion is reflected in attenuation and exfoliation of surface epithelium, and the development of *microerosions* on the mucosal surface (Fig. 1.67C). Inflammatory cells, mainly neutrophils, and tissue fluid effuse into the lumen through defects in the epithelium. Persistent erosion, or previous erosion in a healed mucosa, is marked by the development of a thin, horizontally arrayed layer of connective tissue in the superficial lamina propria. With increasing chronicity in colitis of mild or moderate degree, there may be deposition within the lamina propria of a collagenous stroma, throughout which inflammatory cells are interspersed, which separates glands abnormally throughout the mucosa. Downgrowth of glands into often-involuted submucosal lymphoid follicles may occur in chronic colitis.

Severe erosion and ulceration are usually associated with local acute inflammation and with a heavy, mainly mononuclear cell infiltrate in the lamina propria, and often in the submucosa. The ulcerated areas extend usually no further than the muscularis mucosae, and have a base of granulation tissue heavily infiltrated by neutrophils that effuse into the lumen of the bowel. The margin of surviving mucosa may overhang the ulcer. Crypt abscesses may be present in remaining mucosa, and all degrees of erosion and partial ulceration may be present. Idiopathic ulcerative colitis is uncommon, and does not seem as severe as histiocytic ulcerative colitis of Boxers; it rarely comes to autopsy. Severely affected dogs may be cachectic, probably due in part to enteric loss of plasma protein. The mucosa in ulcerative colitis is usually deep red, swollen, folded, and granular due to edema and cellular infiltrates; the depressions may be punctate or up to several centimeters across, roughly round or oval, irregular or elongate. Their margins may be tattered or puckered. Colonic lymph nodes may be enlarged and edematous.

In canine colitis, there is a broad three-dimensional spectrum: (1) in relative chronicity and density of the inflammatory infiltrate; (2) in the distribution of the infiltrate within the wall of the bowel; and (3) in the severity of the epithelial and mucosal change. Generally, milder lesions of superficial epithelium are associated with mild or moderate mucosal inflammation, which may be acute or chronic. In many cases of mild chronic mucosal colitis, the glands do not appear particularly hyperplastic. However, defective repair in the face of severe or ongoing injury may result in crypts that are tortuous or even nearly horizontal, and papillary hyperplasia of the epithelial surface. Severe erosion and ulceration are usually related to a more intense or heavy chronic inflammatory process, which may be limited to the mucosa, but which can extend into the submucosa. Truly granulomatous colitis is rare; when fully developed, perhaps as a component of regional enteritis involving the ileocecocolic area, or in histiocytic colitis of Boxer dogs, considered later, it is ulcerative and transmural. Occasionally, a granulomatous response to barium, or to other foreign material breaching the epithelium, may be observed in the mucosa and submucosa. *Atrophic colitis*, in which the mucosa is markedly thinned, with relatively inactive crypts and modest chronic or chronic-active interstitial inflammation, perhaps with notable interstitial fibrosis, is occasionally encountered.

Gastric changes in dogs or cats with clinically suspected inflammatory bowel disease are challenging to interpret, because of variation in normal microscopic anatomy within the stomach, and because gastric lesions are often patchy. As well, ingestion of chemicals and foreign bodies can create gastric lesions misinterpreted as being those of inflammatory bowel disease.

The stomach has a variety of *normal anatomic features and common background lesions* that have not been proven to have any functional significance. These include a dense band of hyalinized fibrous tissue (*lamina densa*) between the muscularis mucosae and the base of the crypts in cats, lymphoid nodules within the deep lamina propria of both dogs and cats, and a substantial amount of fibrous tissue within the lamina propria of the pyloric antrum. It is not clear whether some of these have any significance as signposts of previous disease. Background lesions that may or may not be correlated with some previous specific stimulus include globule leukocytes in the gastric epithelium of cats, and a combination of gastric proprial fibrosis, glandular atrophy, and glandular nesting within the fundic mucosa. While we assume (without proof) that such fibrosis and glandular atrophy are sequelae to previous inflammation or necrosis, such changes have not been correlated with gastric dysfunction or clinical illness.

Unlike the situation in the intestinal and colonic mucosa, *epithelial injury is not a prominent part of gastritis in dogs or cats.* It is rare to encounter erosion or ulceration as part of gastritis, and acute ulceration associated with chemical or mechanical injury to the stomach has little mucosal cellular infiltrate. It is therefore prudent to distinguish gastric ulceration from gastritis. Lesions compatible with a diagnosis of gastritis include leukocytic infiltrates in the superficial third of the mucosa, mucous metaplasia and hyperplasia in fundic glands, extensive lymphoplasmacytic and/or eosinophilic infiltrates deep in the mucosa, interstitial fibrosis, and associated atrophy of glands. The diagnosis of **gastric mucosal atrophy** must be made with great care because there is substantial difference in mucosal

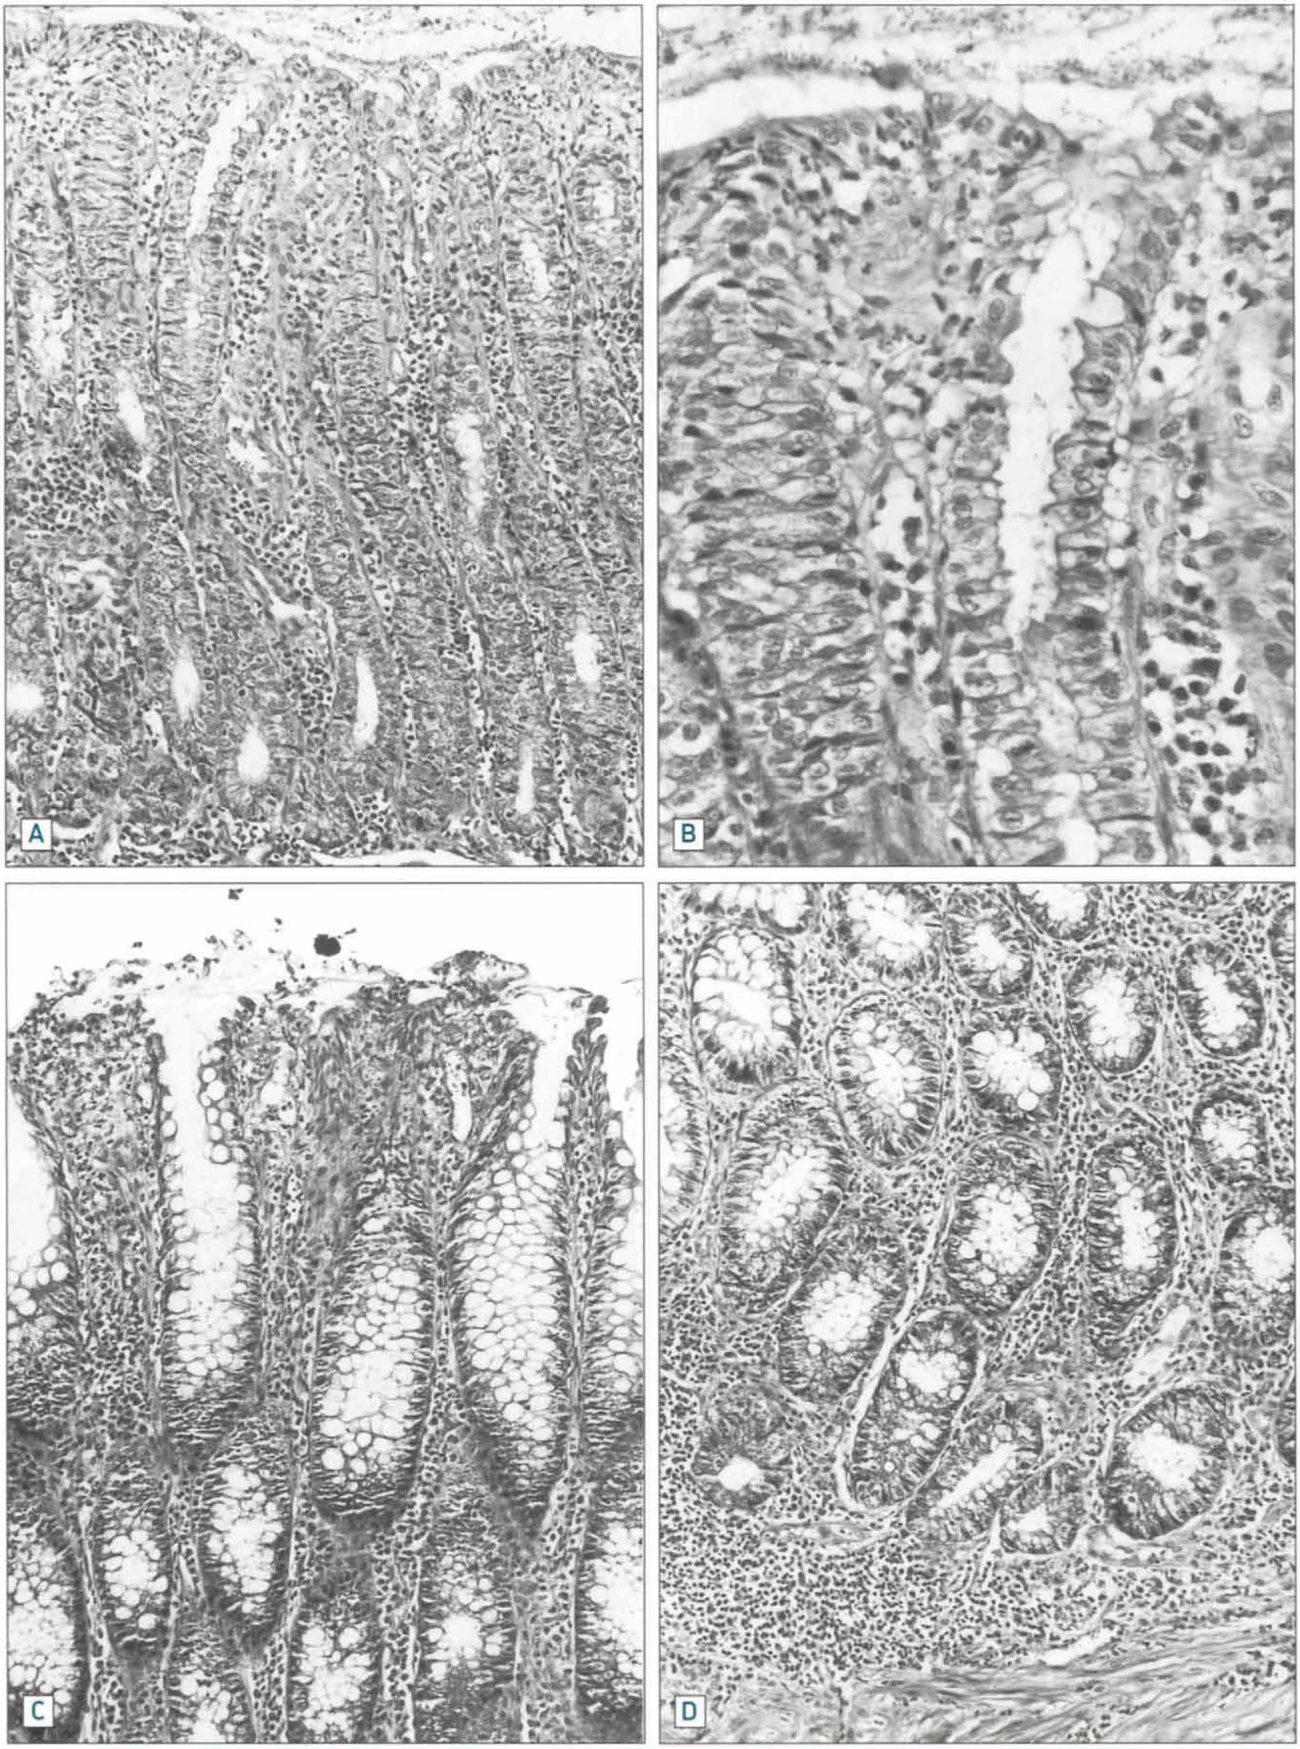

Figure 1.67 Mild acute colitis. **A.** Goblet cells are sparse or absent in glands and on the surface. Superficial epithelium is cuboidal and exfoliating in focal areas. **B.** Epithelium in glands is hyperplastic and crowded. The superficial lamina propria is edematous. **Chronic erosive colitis. C.** Hypertrophic glands are lined by goblet cells. The mucosal surface has widespread erosion and effusion of tissue fluid and neutrophils. **D.** Edema of superficial lamina propria. Deeper in the mucosa there is a moderately increased population of mononuclear cells and increased fibrous stroma. Cells extend between base of glands and muscularis mucosae.

thickness between various portions of the stomach, and even within the same anatomic region.

Most discussions of inflammatory bowel disease assume that the change in mucosal cellularity is primary and that characterization of that cellularity should provide the greatest insight into pathogenesis and therapy. However, assessment of mucosal cellularity is almost entirely subjective and has exceedingly poor interobserver agreement. There are no useful objective reference intervals for small intestinal mucosal cellularity because the range is so broad, and accurate identification of the different cell types is problematic. Characterization of the immunophenotype of lymphocytes in the small intestine has produced variable results that have yet to be usefully associated with the presence or absence of clinical signs.

Attempts to create more *objective grading systems* for the histologic assessment of inflammatory bowel disease have stressed the significance of architectural changes within the surface epithelium and lamina propria rather than relying exclusively on shifts in total or relative leukocyte populations. Such grading criteria include detection of villus or cryptal enterocyte injury (villus fusion, superficial ulceration, enterocyte flattening and basophilia, cryptal hyperplasia), as well as remodeling of mucosal architecture (separation of the crypts from one another or from the muscularis mucosae by edema, fibrosis, and/or leukocytes). However, these schemes still fail to resolve the dilemma of substantial overlap between "normal" and subjectively increased leukocyte numbers in mild inflammatory bowel disease in which there is no epithelial injury or architectural change.

Skepticism about the utility of estimating leukocyte numbers or identifying shifts in phenotype among mucosal leukocytes may not be so appropriate when looking at colonic and gastric inflammatory disease. Perhaps because of its lesser overall proprial cellularity in comparison with small intestine, or perhaps because of its greater accessibility to biopsy, the colonic mucosa was the first part of the canine intestinal tract to be subjected to morphometric grading of architectural changes and objective leukocyte counting, although application of such data is difficult. In comparison with small intestine, the normal range in leukocyte numbers is narrower and the overall population much smaller in both colon and stomach. This is particularly true of the granulocytes. *The presence of neutrophils within the lamina propria of any part of the intestine is probably abnormal*, and is probably a reliable marker for recent epithelial damage or permeability. Eosinophils have more variation, and often are present in very large numbers throughout the small intestinal mucosa. However, they are very sparse within the superficial half of the canine colonic mucosa, and are infrequent within the gastric mucosa.

Since the normal stomach has relatively few mucosal leukocytes, the pursuit of a diagnosis of gastritis based upon objective assessment of leukocyte numbers may be a credible goal. While it has been possible, by counting different types of leukocytes identified by routine histology and immunohistochemistry, to establish reference intervals for eosinophils, plasma cells, B cells, and T cells within various parts of the gastric lamina propria of healthy dogs, more than half of the round cells in the normal canine gastric lamina propria could not be precisely identified. Healthy dogs had an eightfold range in total mucosal cellularity, and the pyloric antrum was three times more cellular than the fundic mucosa. Although dogs with clinical signs of gastritis had an objective increase in eosinophils, plasma cells, and/or intraepithelial lymphocytes in many different combinations, it was difficult to correlate clinical severity or response to therapy with cellular or other parameters of gastric mucosal abnormality. There was no significance to whether the inflammation was limited to the superficial third of the mucosa or was found throughout, although the former was more common than the latter. In a second study of idiopathic gastritis, all cases were classified as lymphocytic, and T cells predominated. Eosinophils were not a significant component, and there was no observed regional variation in severity.

While it is certainly possible (or even probable) that precise identification and quantitation of the infiltrating leukocytes will emerge as significant when we have more precise ways of measuring clinical severity and response to therapy, currently there is no pragmatic clinical significance to distinguishing eosinophilic from lymphocytic gastritis, commenting on whether the lesions are superficial or more diffuse, or making any statement about histologic severity with respect to leukocytes or other aspects of mucosal architecture.

The etiopathogenesis of idiopathic inflammatory bowel disease is not understood in any animal species. The nature of the inflammatory infiltrate suggests that loss of tolerance to dietary antigen or antigens produced by the enteric microflora may be implicated. The common morphologic changes in the mucosa – of cryptal hypertrophy, villus atrophy, and, in severe cases, mucous metaplasia of surface enterocytes, may be side-effects of T-cell-mediated activity in the mucosa. Similar lesions occur in humans with celiac disease (gluten-sensitive enteropathy), which is T-cell mediated. An immunophenotypic investigation of inflammatory bowel disease in cats noted outcomes consistent with dysregulation of immunoinflammatory events. Major histocompatibility complex class II expression by proprial round cells and enterocytes was more pronounced than in the control population.

Lymphocytic-plasmacytic enteritis associated with *familial sensitivity to wheat protein* has been demonstrated in Irish Setters, but not in Basenji dogs, which as a breed seem predisposed to the problem. In Basenjis and in the Lundehund, syndromes of hypoalbuminemia, chronic diarrhea, and wasting occur with high prevalence, primarily attributable to lymphocytic-plasmacytic enteritis, with lymphangiectasia in some dogs. In the Basenji, chronic gastritis or hypertrophic gastritis may be associated, and malassimilation and plasma protein loss into the gut have been documented. Hypergammaglobulinemia commonly occurs in the late stages of the syndrome in Basenjis, and lymphosarcoma develops in some affected animals. In this sense, the syndrome resembles immunoproliferative small intestinal disease (α-heavy chain disease, or Mediterranean lymphoma), which is a disorder of IgA immunoblasts in humans. IgA plasmacytes do not dominate in the Basenji intestinal mucosa; though high circulating levels of IgA are present, it is not known if they are associated with abnormal α-heavy-chain protein. In cats, dogs, and horses, submucosal or transmural lymphoplasmacytic infiltrates may signal a precursor to lymphoma, and the infiltrating cell population must be carefully evaluated; a monomorphic population of lymphocytes, blurring of the proprial–epithelial interface by lymphocytic infiltrates, and mitotic activity suggest lymphosarcoma.

Animals with the gray Collie syndrome (cyclic neutropenia) may also have lymphocytic-plasmacytic enteritis (see Vol. 3, Hematopoietic system).

Eosinophilic enteritis in cats and horses

Eosinophilic enteritis in cats is rare, and appears to be one manifestation of a hypereosinophilic syndrome that may involve many organs in middle-aged or older cats. It is much more severe than eosinophilic gastroenteritis in dogs. Diarrhea, sometimes bloody, vomition, loss of appetite, and loss of condition may occur. Clinically, *intestinal thickening*, hepato- and splenomegaly, and enlarged mesenteric lymph nodes may be present, in association with circulating eosinophilia and hyperplasia of the eosinophil series in the marrow.

The postmortem picture reflects the clinical findings. Enlargement of the various organs, including liver, spleen, lymph nodes in many locations, and tan nodularities on the kidneys, is associated with *heavy infiltrates of usually well-differentiated eosinophils*. In the small intestine, the eosinophilic infiltrate may be transmural and is accompanied by grossly visible hypertrophy of the muscle layers (Fig. 1.68).

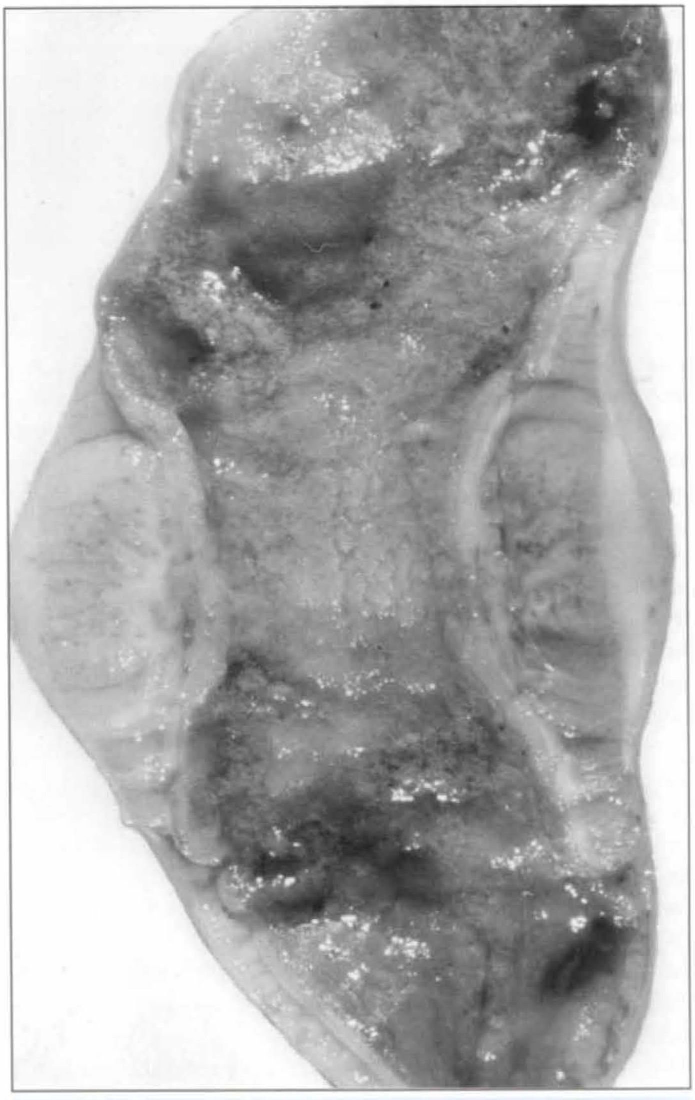

Figure 1.68 Eosinophilic enteritis in a cat. Foci of mucosal congestion, and segmental transmural thickening and hypertrophy of smooth muscle in an area heavily infiltrated by eosinophils.

Eosinophilic colitis may occur in some cases. Lymph nodes may have hyperplastic follicles and many mature eosinophils in sinusoids. Alternatively they may vary through eosinophilic lymphadenitis with fibrosis to complete obliteration of normal architecture and replacement by eosinophils in a fibrillar stroma extending through the capsule into surrounding tissue.

Chronic eosinophilic enteritis in horses has been described as part of a distinct *multisystemic epitheliotropic syndrome*, associated with eosinophilic granulomatous pancreatitis and eosinophilic dermatitis, among other lesions. Affected animals have weight loss, and diarrhea or unformed feces, associated with hypoalbuminemia, suggesting enteric loss of plasma protein. Reduced absorption of glucose occurs, but peripheral eosinophilia is absent. At autopsy, *mucosal and sometimes transmural thickening* may occur at any level of the alimentary tract from esophagus to rectum. Esophageal and gastric squamous mucosa is hyperkeratotic. Thickened mucosa is thrown into turgid transverse folds, or occasionally is fissured and roughened. Focal or diffuse ulcers may be present on the small and large intestine and focal caseous lesions up to 1.5 cm in diameter may be in the submucosa of the gut and common bile duct, as well as in an enlarged fibrotic pancreas.

Microscopically there is diffuse infiltration of the mucosa, submucosa, and often deeper layers of the enteric wall by eosinophils, mast cells, macrophages, lymphocytes and some plasma cells. Moderate to severe villus atrophy, fibroplasia in the lamina propria, and hypertrophy of the muscularis mucosae occur. Caseous foci in the mucosa and submucosa consist of central masses of eosinophils, sometimes surrounded by macrophages, giant cells, and occasionally fibrous tissue. Eosinophilic interstitial infiltrates and granulomas are described in the biliary and pancreatic ducts, pancreas, salivary glands, capsule, and outer cortex of enlarged firm mesenteric lymph nodes, and near portal tracts in the liver. The skin may be thickened and hyperkeratotic and the limbus of the hoof thickened and ulcerated. The eosinophilic dermatitis is described in Vol. 1, Skin and appendages.

Villus atrophy is common, but if large-bowel lesions are absent, there is no diarrhea. Chronic inflammation in the mucosa may explain protein loss and hypoalbuminemia. The cause of this syndrome is unknown. A hypersensitivity response to migrating parasitic larvae has been suggested, as has the possibility that undetected T-cell lymphoma secreting interleukin-5 may be responsible.

Granulomatous enteritis

The presence of chronic inflammatory infiltrates, including aggregates of histiocytes, and perhaps giant cells, in the lamina propria is the criterion for a diagnosis of **granulomatous enteritis**. With time, the inflammatory reaction typically follows lymphatics transmurally into the submucosa and through the muscularis to the serosa. The submucosa is usually edematous, and lymphatics are prominent. Granulomas may be present in the submucosa or at intervals along lymphatics. The affected lymph nodes are hyperplastic, usually with prominent sinus histiocytosis. Giant cells may be present in sinusoids, or granulomatous foci of various sizes may be evident. Sinusoids contain numerous neutrophils and perhaps eosinophils, and neutrophils may accumulate in the center of granulomas.

Granulomatous enteritis can potentially occur in *all species*. Johne's disease, other intestinal mycobacterioses, and *Histoplasma* enteritis are specific examples (see section on Infectious and parasitic diseases of the alimentary tract, below). Often the cause is not identified.

Transmural granulomatous enteritis is occasionally seen in **dogs** and **cats**. It is generally segmental and perhaps discontinuous in distribution, usually affecting the lower ileum, colon, and draining lymph nodes. Due to the extent of the attendant fibrosis, these lesions may be stenotic, and must be differentiated from invasive carcinoma. In dogs, there may be marked necrosis in the centers of granulomas and considerable fibrosis.

Idiopathic granulomatous enteritis as a cause of wasting and protein-losing enteropathy is most commonly seen as a sporadic problem in **horses**. Depending on the duration of the disease, animals may be markedly cachectic, have subcutaneous edema, especially of dependent areas, and there may be hydrothorax, hydropericardium, and ascites. Lesions in the horse usually affect the small intestine; stomach and large bowel are occasionally also involved. Mesenteric lymph nodes are usually enlarged, edematous, with mottled firm gray areas, fibrotic nodules, or, rarely, caseous or mineralized foci on the cut surface. Granulomatous pale, caseous, or calcified foci may be scattered in the liver.

The *microscopic lesion* may be patchy, regional, or diffuse, and it may be mucosal, or transmural, ultimately gaining the draining lymph nodes. Transmural inflammation is characteristically granulomatous. Villi are mildly to markedly atrophic with hypertrophy of crypts. The epithelium may vary from apparently normal to low columnar or cuboidal with an indistinct brush border. There may be leaks between cells on the surface, or microerosions may be present, through which neutrophils and proteinaceous exudate pass into the lumen. The lamina propria is edematous and contains scattered aggregates of histiocytes and perhaps giant cells, or, less commonly, more organized granulomatous foci. Neutrophils and eosinophils are distributed diffusely throughout the lamina propria, and may be concentrated in or near granulomatous foci. A heavy population of lymphocytes and plasma cells inhabits the lamina propria, and the infiltrate and edema may separate crypts abnormally from each other.

Rarely are agents identified in such lesions. *Mycobacterium avium* or environmental mycobacteria are occasionally incriminated. *Anaerobiospirillum* has been implicated as the cause of ileocolitis in cats.

Inflammation of the large intestine

The general reaction to injury of the cecal and colonic epithelium was considered earlier in the section on Epithelial renewal in health and disease.

Ischemia, obliteration of the proliferative epithelium by viruses or coccidia, severe inflammation in the mucosa, and necrotizing toxic insults from the lumen are responsible for the development of focal or diffuse ulceration of the large intestine. Inflammatory infiltrates in the lamina propria may be broadly classified as acute, chronic, or chronic-active, and granulomatous. They may be limited in distribution to the mucosa or be transmural, involving submucosa, muscularis, serosa, and frequently the draining lymph nodes. Typhlitis and colitis may be manifestations of a generalized or systemic disease; they may be part of an enterocolitis involving both small and large intestine; or they may be regional and limited to a segment of the intestine, often terminal ileum, cecum, and colon, or some shorter part of the large bowel.

The damaged colonic mucosa may provide the portal of entry for systemic bacterial invasion and for uptake of toxins. Increased mucosal permeability in the colon may permit enteric loss of plasma protein or of blood. Disordered large-bowel flora in hindgut fermenters may compromise uptake of volatile fatty acids and water. In any species, damage to the colonic mucosa may result in malabsorption of electrolytes and water, and perhaps net secretion. Colitis in each of the species will be considered in turn.

Colitis cystica profunda, the presence of dilated colonic glands protruding through the muscularis mucosae into the submucosa, is seen in several species, most commonly in *swine*. The cause is unknown; the lesion may be a sequel to colitis and local damage to the muscularis mucosae, or it may represent herniation into the space left by an involuted submucosal lymphoid follicle. Though the lesion has been seen with colitis in a variety of circumstances, especially in swine dysentery, it may also be found incidentally, with no specific etiologic association.

Typhlocolitis in dogs

Inflammation of the large bowel in dogs is usually associated with *diarrhea*, typically frequent, small in volume, mucoid or bloody, and often accompanied by tenesmus. By far the most common form encountered in dogs is **idiopathic mucosal colitis**, considered above in Idiopathic inflammatory bowel disease.

Severe acute necrotizing colitis and, less commonly, typhlitis, leading to *ulceration and perforation*, with subsequent peritonitis, has been associated with glucocorticoid administration, functional adrenal cortical tumors, and with trauma or surgery involving the spinal cord. Gastric ulceration may occur concurrently. The perforations usually occur in the antimesenteric border of the left colonic flexure or proximal descending colon, though they are reported from the cecum, ascending, transverse, and distal descending colon. The pathogenesis of the colonic lesions developing in these circumstances is unclear, but it does not seem to be associated with the interface between the cranial and sacral fields of autonomic nervous control, as has been proposed.

Necrotizing colitis, ulceration, and perforation may occur rarely in dogs in **uremia**. The mechanism is uncertain, but colonic damage may be the effect of high concentrations of ammonia evolved by urease-producing colonic flora from urea diffusing into the gut from the blood. The lesions are often associated with arteritis, and fibrinoid necrosis, mineralization, and destruction of the media are seen, especially in ruminants.

Trichuris vulpis, the whipworm of dogs, may cause mucosal colitis, which rarely evolves into a granulomatous transmural condition. Clinical trichuriasis is generally associated with a population of worms that extends from the usual site of infection in the cecum and proximal ascending colon into more distal parts of the large intestine. Ulcerative colitis in dogs is also rarely caused by ***Entamoeba histolytica***. Ulcerative, granulomatous transmural colitis is more common as one of the enteric manifestations of **histoplasmosis**. ***Prototheca*** is also a cause of distinctive but rare enterocolitis in dogs, and colitis characterized by a heavy mucosal infiltrate of macrophages, in which the agent may be found, is reported in **leishmaniasis**. ***Canine parvovirus*** causes colonic damage, but in virtually all cases, there are more severe lesions elsewhere, notably in the small intestine. ***Canine coronavirus*** has also been implicated as a cause of colonic, as well as small intestinal, lesions. These conditions are discussed fully in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Spirochetes may be present in the canine colon and their association with diarrheal disease is controversial. There is some indication that predisposing factors, particularly giardiasis, may result in heavy colonization of the mucosal surface, with resulting diarrhea. ***Campylobacter jejuni*** is isolated from dogs both with and without diarrhea, but has been implicated as an etiology of enterocolitis in some situations of outbreaks of diarrhea in dog colonies. In these cases, large aggregates of organisms can be visualized within crypt lumens.

Histiocytic ulcerative colitis is a distinctive histologic syndrome, which has been recognized in Boxers and the related French Bulldog. It is a chronic transmural ulcerative colitis characterized by the presence of large numbers of macrophages containing periodic acid–Schiff-positive granules, in the deep mucosa and submucosa, and in lymph nodes receiving drainage from the colon. Clinically affected animals are usually under 2 years of age. This condition causes typical large-bowel diarrhea, with mucus and blood; weight loss occurs and chronic cases may become cachectic, probably due to protein loss into the gut.

Grossly, the colon of dogs with advanced disease is variably thickened, folded, and perhaps dilated and shortened with some segmental or focal areas of scarring and stricture. Lesions on the mucosa may vary from patchy punctate red ulcers to more extensive irregular circular or linear lesions that may coalesce, leaving only a few islands of persistent mucosa on a granulating colonic surface (Fig. 1.69A).

Early *microscopic lesions* are those of mild nonspecific inflammation. Goblet cells disappear from the surface and glands. Microerosion of epithelium in the upper glands and on the surface is associated with local acute inflammation, migration of neutrophils into the epithelium, and effusion of neutrophils and tissue fluid into the lumen.

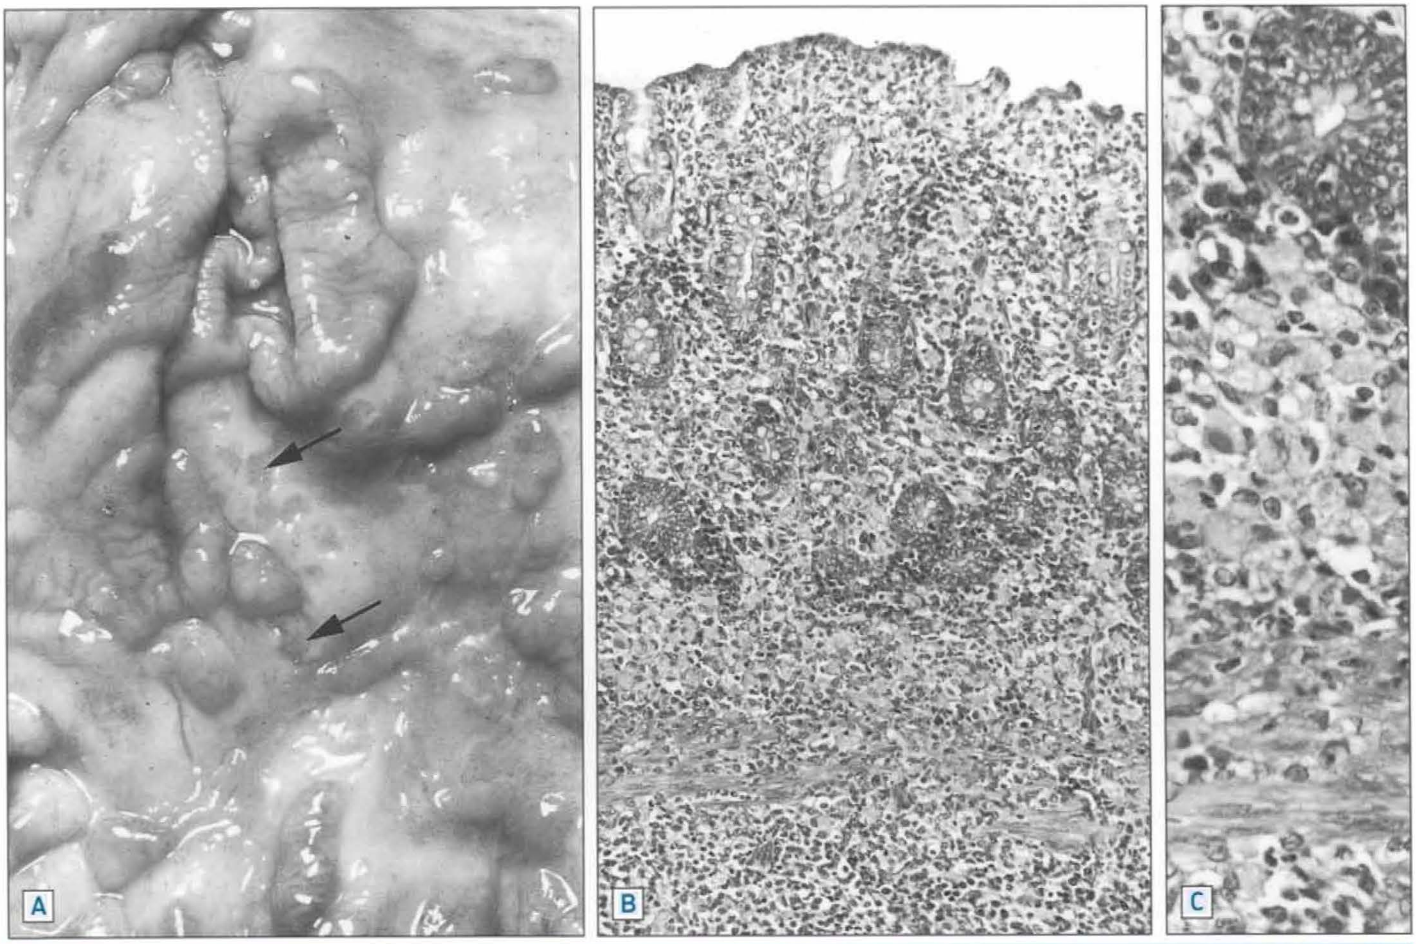

Figure 1.69 Histiocytic ulcerative colitis in a Boxer dog. **A.** Mucosa is thickened and edematous. There are numerous erosions (arrows). **B.** Accumulation of macrophages with abundant cytoplasm throughout mucosa, between base of glands and muscularis mucosae and in submucosa. **C.** Detail of macrophages in mucosa deep to crypts.

Macrophages in these areas may contain phagocytized necrotic debris and bacteria. In some areas the mucosa is thinned, and glands are relatively shortened, though lining epithelium appears hyperplastic. Macrophages with cytoplasmic vacuoles, which contain periodic acid–Schiff-positive material, are mainly deep in the lamina propria, raising the base of crypts from the muscularis mucosae, and in the submucosa (Fig. 1.69B, C). Sometimes they may be relatively sparse in the mucosa, and may be missed in small biopsy specimens if the submucosa is not sampled. These same cells may be found about lymphatics in the muscularis and the serosa, and they may be numerous in subcapsular, cortical, and medullary sinuses in the draining lymph nodes. The cecum is often involved, to a lesser degree, with similar lesions. Ulceration seems to progress from the superficial epithelial erosion and destruction of the basement membrane seen in early lesions. Ulcers usually do not progress beyond the submucosa, and they are lined by granulation tissue. The bed of the ulcer is necrotic, and numerous neutrophils and erythrocytes may be passing into the lumen.

The *cause* of the condition is unknown, as is the origin of the material in the characteristic vacuoles in macrophages. Ultrastructural study suggests that these are digestion vacuoles containing mainly remnants of phospholipid membranes. The material being digested may be phagocytized cell debris and microorganisms picked up in the superficial lamina propria and carried in "constipated" macrophages to deeper structures. The involvement of a variety of infectious agents has been postulated. It seems that a *defect in lysosomal function* may exist in some Boxer dogs that can lead to the accumulation of partially digested phospholipid membrane in macrophages, since similar histiocytes do not accumulate in ulcerative colitis in other breeds of dogs.

Colitis in cats

Colitis in cats is uncommon. **Idiopathic mucosal colitis**, similar to that described in dogs, occurs occasionally in cats, and has been included in the discussion of Idiopathic inflammatory bowel disease above. ***Tritrichomonas foetus***, associated with persistent large-bowel diarrhea and idiopathic mucosal colitis in cats under about a year of age, is considered in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Feline panleukopenia virus causes colonic lesions in about half the cases. They are similar to, but rarely as severe or widespread as, the lesions found in the small intestine. The relative paucity and mildness of lesions in the colon are related to the lower rate of epithelial proliferation in comparison with the small intestine. Panleukopenia is considered in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Mycotic colitis is occasionally seen in cats as a hemorrhagic ulcerative colitis in which focal or diffuse mucosal invasion by *Candida*, zygomycetes, or *Aspergillus* has occurred, sometimes causing microvascular thrombosis. These invaders occur mainly secondary to colonic damage and leukopenia caused by panleukopenia.

Clostridium piliforme caused mild mucosal colitis in several kittens with soft feces and vague central nervous disorder, but no other obvious intercurrent disease. The lesions were characterized by hypertrophy of crypts; exfoliation of epithelium into the lumen of crypts, which were dilated and lined by flattened epithelium; and a moderate chronic interstitial inflammatory infiltrate. Vegetative forms and spores of *C. piliforme* were recognized ultrastructurally in crypt epithelium. Lesions were not evident elsewhere. It has also occurred in kittens presumably immunocompromised by panleukopenia.

Necrotic colitis, a condition seen predominantly in older animals, is characterized by severe damage to colonic glands (Fig. 1.70). The cause is thought to be ischemia.

Transmural acute ulcerative colitis, with a heavy infiltrate of neutrophils, is the hallmark of ***Salmonella* Typhimurium** infection in cats, considered more fully with salmonellosis in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Anaerobiospirillum, associated with colitis in cats, is discussed in the section on Bacterial diseases of the alimentary tract, below.

Ulcerative colitis, grossly and microscopically similar to idiopathic ulcerative colitis of the dog, occurs very rarely in *cats*. Granulomatous or pyogranulomatous foci in the subserosa or submucosa may cause regional enterocolitis, characterized by fibrosis and serosal nodularity of affected segments, usually without severe mucosal defects. Fibrinoid arteritis causing hemorrhage and edema in the colonic submucosa, and ischemic necrosis of the mucosa, is also reported. The granulomatous syndrome is attributed to *Feline infectious peritonitis virus*, and there may be characteristic lesions in other organs.

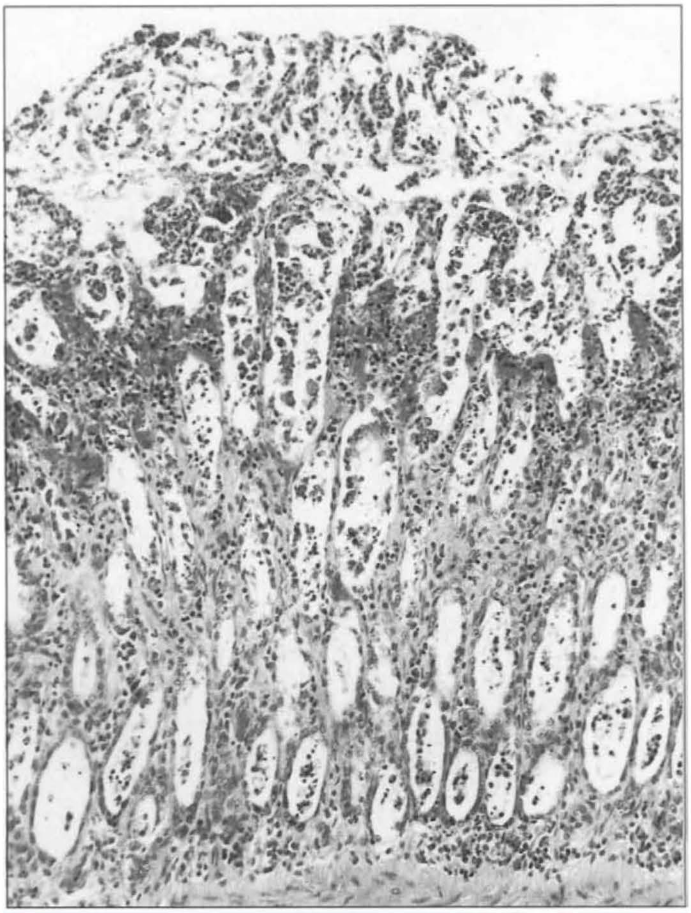

Figure 1.70 Necrotic colitis in a cat. Active necrosis on surface of mucosa. Glands are dilated, contain necrotic cellular debris, or are lined by extremely flattened epithelium. (Courtesy of JS Nimmo-Wilkie.)

Typhlocolitis in horses

The diagnosis of acute colitis in horses resolves into the differentiation of peracute and acute salmonellosis, Potomac horse fever (equine monocytic ehrlichiosis), and intestinal clostridiosis. Colitis must also be differentiated from the sequelae of intestinal accidents, nonsteroidal anti-inflammatory drug intoxication, and thromboembolism involving the large bowel.

Equine intestinal clostridiosis is increasingly well defined as an entity. Previously, many of these cases were lumped into an umbrella

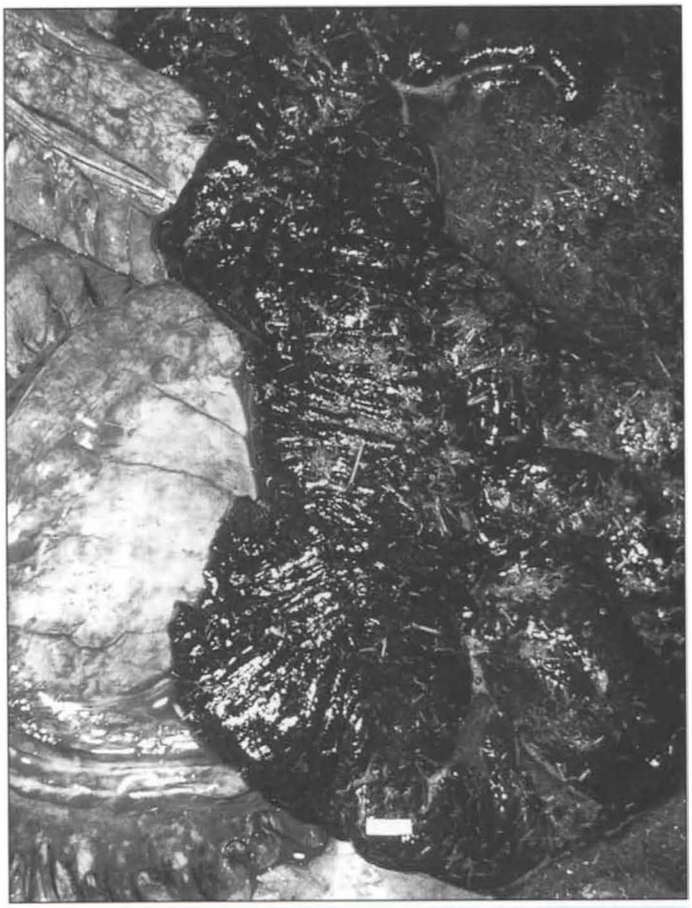

Figure 1.71 Acute colitis, probably clostridial, in a horse. The mucosa is very congested and edematous.

category, "*colitis X*," a severe acute colitis in which all known etiologic agents were ruled out. At necropsy the animal is dehydrated, and there may be subcutaneous and serosal petechial hemorrhage. The blood is dark and clots poorly. Enteric lesions are virtually limited to the large bowel, which is distended, with abnormally fluid content. The serosa of the cecum and large colon may appear cyanotic from congestion and hemorrhage in the mucosa (Fig. 1.71) and perhaps submucosa. The deeper tissues of the intestinal wall are not compromised, as is usually the case in volvulus and often in thromboembolic infarction. The mucosa and submucosa are commonly markedly edematous, and edema is often present at the mesenteric attachment of the gut and in the cecal and colic lymph nodes. The mucosa may appear brown and necrotic with focal fibrinohemorrhagic exudate on the surface. More commonly, it is deeply congested with focal hemorrhage, but blood is rarely present to significant degree in the contents. Gross lesions in other organs are those consistent with circulatory or endotoxic shock.

The microscopic lesions in the large bowel include superficial or full-thickness necrosis of the mucosa, associated with dilation and perhaps thrombosis of small mucosal and submucosal venules. There is hemorrhage and edema in the mucosa, and the submucosa is markedly edematous, with dilated lymphatics. Variable numbers of bacilli are associated with these lesions. Some neutrophils may be evident in the mucosa or submucosa, and fibrin may be effusing from the damaged mucosal surface in less advanced cases. Submucosal lymphoid follicles show evidence of recent severe lymphocytolysis. Congestion, microvascular thrombosis, and hemorrhage may be found in a variety of other organs, especially the adrenal cortex.

Clostridium perfringens type A is the most common clostridial species associated with this syndrome. Most horses carry this organism within their intestines. In addition, *C. difficile* has been associated with equine clostridial colitis. Equine intestinal clostridiosis may occur after *dysbacteriosis*, instigated by antibiotic therapy (especially the tetracyclines), stress, or changes in feeding regimens. With overgrowth of *C. perfringens* type A, β_2 toxin-secreting *C. perfringens* type A or *C. difficile* exotoxins cause severe acute mucosal damage. There is a positive association between the disease and the presence of *C. perfringens* enterotoxin and/or *C. difficile* toxin.

Subacute and chronic diarrhea in horses almost always involves the large intestine, with or without concomitant small-bowel involvement. ***Salmonella*** typhlocolitis must be suspected in such cases. Salmonellosis in horses may have an extremely variable course and pathologic manifestations (see section on Infectious and parasitic diseases of the alimentary tract, later in this chapter). **Potomac horse fever** usually results in diarrhea that does not exceed 10 days in duration; at necropsy there is congestion and ulceration of the mucosa of the large bowel, and enlargement of mesenteric lymph nodes. Suppurative ulcers involving lymphoid tissue in the typhlocolic mucosa, and cecal and colic lymphadenitis, characterize enteric infection with ***Rhodococcus equi*** in foals. **Histoplasmosis** has been reported once in a horse with salmonellosis and ulcerative colitis. Extensive mucosal involvement by **larval cyathostomes and strongyles** and, rarely, ulcerative typhlitis due to **anoplocephalid tapeworms**, may also cause diarrhea and wasting; they are discussed under specific parasitisms.

Ciliate protozoa may be seen in the colonic mucosa of horses dead of a variety of enteric and nonenteric problems; the tissues are frequently autolytic, are rarely inflamed, and the protozoa are terminal or postmortem invaders. Intralesional protozoa have, however, been reported in a horse with diffuse eosinophilic colitis.

Chronic diarrhea and possibly cachexia may also result from persistent ulceration of the cecum or colon due to **ischemic mucosal lesions**. These may be the product of arterial thromboembolism and slow flow, or less likely, corrected strangulation with reflow. Use of *nonsteroidal anti-inflammatory drugs* has also been associated with cecal and colonic ulceration and plasma protein loss. "*Right dorsal colitis*," in which ulcerative lesions are limited to the named part of the large bowel, may be associated with colic, and acute or chronic diarrhea. This syndrome and others associated with the use of nonsteroidal anti-inflammatories are considered with ischemia due to reduced perfusion (see section on Intestinal ischemia and infarction, above).

The specific cause of extensive ulceration may be difficult to determine. Smaller chronic ulcers and widespread subacute erosion and ulceration are most likely the result of salmonellosis, rather than ischemia. A history of administration of nonsteroidal anti-inflammatories, and the presence of lesions in the renal papilla, mouth, and upper alimentary tract, suggests intoxication by those agents.

Typhlocolitis in swine

The differential diagnosis of typhlocolitis in swine mainly revolves around identifying swine dysentery and other spirochetoses, *Salmonella* enterocolitis, and *Lawsonia intracellularis* infection.

Swine dysentery, caused by *Brachyspira hyodysenteriae*, involves only the cecum and spiral colon. It is a catarrhal to mildly fibrinohemorrhagic erosive mucosal typhlocolitis. The colonic content is fluid and usually blood-tinged. A similar but milder disease, **intestinal spirochetosis**, is associated with *B. pilosicoli*, which causes distinctive microscopic lesions as it colonizes the apex of surface epithelium. ***Salmonella* enterocolitis**, mainly due to *S.* Typhimurium, is a fibrinous, erosive to focally ulcerative condition, mainly of the cecum and colon, but perhaps involving the small intestine, especially terminal ileum. The content is fluid but usually not bloody. Mesenteric lymph nodes are prominent. ***L. intracellularis*** infection is readily recognized by the consistent concurrent involvement of the terminal ileum by adenomatosis, with or without hemorrhage, or by necrotic ileitis.

Postweaning colibacillosis is characterized by catarrhal to mild fibrinohemorrhagic enterocolitis in piglets after weaning.

Fibrinohemorrhagic typhlitis is caused by heavy infestations with ***Trichuris suis***, especially in weaned pigs with access to pastures and yards. Under similar circumstances, ***Eimeria*** infection may rarely cause ileotyphlocolitis.

Rectal stricture appears to be a product of ischemic proctitis, probably related in many cases to infection with *S.* Typhimurium.

Details of these conditions are discussed in the section on Infectious and parasitic diseases of the alimentary tract, later in this chapter.

Typhlocolitis in ruminants

Diagnostic considerations in cattle over 2–3 months of age with acute to subacute fibrinohemorrhagic typhlocolitis include salmonellosis, bovine viral diarrhea, rinderpest (in enzootic areas or populations at risk), coccidiosis, adenoviral infection, and winter dysentery (coronavirus). Lesions of the oral cavity and upper alimentary tract may be expected, but are not necessarily present, in **bovine viral diarrhea** and **rinderpest**. ***Bovine coronavirus*** causes microscopic lesions in colonic crypts in cattle with **winter dysentery**; mild fibrinous typhlocolitis may be seen grossly. **Salmonellosis** affects all age groups from neonate to adult and may frequently involve both small and large intestine in catarrhal to fibrinohemorrhagic enteritis; mesenteric lymph nodes are usually enlarged. **Coccidiosis** may involve ileum and large intestine; it can usually be diagnosed by mucosal scraping at autopsy. ***Bovine adenovirus*** infection may cause severe hemorrhagic colitis, with few lesions elsewhere. **Arsenic**, other **heavy metals**, and **oak or acorn poisoning** may also cause hemorrhagic typhlocolitis and dysentery. Rarely, **trichuriasis** causes hemorrhagic mucosal typhlitis in calves.

Chronic fibrinous or ulcerative typhlocolitis may occur in salmonellosis, bovine viral diarrhea, and coccidiosis.

Granulomatous typhlocolitis associated with chronic diarrhea and wasting may occur in **Johne's disease**, concurrently with granulomatous ileitis and mesenteric lymphadenitis. The mucosa of the large bowel in these cases is thickened and rugose. Impressions of affected mucosa or ileocecal lymph node will contain acid-fast bacilli. Johne's disease in sheep and goats is usually associated with wasting, but often not diarrhea. The large bowel may be involved in a minority of cases; the ileum is consistently affected.

In **sheep**, hemorrhagic typhlocolitis may be present in animals with **bluetongue** and **peste des petits ruminants**; it is rarely the only lesion. **Salmonellosis** may cause fibrinohemorrhagic enteritis in lambs and pregnant ewes, and typhlitis caused by **trichuriasis** will occur rarely, although the presence of parasites in small numbers is common in weaners. **Coccidiosis** may be implicated in hemorrhagic ileotyphlocolitis in lambs and kids, though the small intestine is usually more commonly and severely involved. In goats, enterotoxemia due to *C. perfringens* type D may cause mild to moderately severe fibrinohemorrhagic typhlocolitis. Uremia may cause hemorrhagic lesions associated with vasculitis in the cecum and colon.

Neoplastic and proliferative lesions of the stomach and intestine

Tumors of the lower gastrointestinal tract are *not common* in domestic animals. However, they are relatively prevalent among surgical biopsy submissions from dogs and cats, in sharp contrast to their rarity in horses and food-producing animals. Malignant neoplasms are more common than benign tumors, and, excepting lymphosarcoma, *most are carcinomas*. Polyps are generally hyperplastic rather than neoplastic. The exceptions are rectal polyps in dogs, which are adenomas or carcinomas. Highly malignant scirrhous adenocarcinomas of the stomach and intestine occur in all species. *Lymphosarcoma* is the most common malignant tumor of mesenchymal origin in most species. It may arise in the gut, although involvement of this area is often part of multicentric disease (see Vol. 3, Hematopoietic system). The third major category of gastrointestinal tumors is *stromal*, mainly phenotypically smooth muscle or undifferentiated.

Elaborate classification schemes have been proposed based on histologic or immunophenotypic characterization with, in many cases, little evidence that they are relevant to the biological behavior of the tumor or its response to therapy. Furthermore, there is often so much variation within these lesions that it is difficult to make them conform to arbitrary categories. However, it is important to recognize the range in appearance inherent in the various neoplasms, so that they may be diagnosed correctly, in a clinically meaningful way.

Table 1.1 Major neoplasms and tumor-like proliferative lesions of the lower gastrointestinal tract of domestic animals[a]

Epithelial
- Benign
    1. Papillary adenomatous hyperplasia
    2. Gastric pyloric mucosal hypertrophy
    3. Canine rectal papillary adenoma
- Malignant
    1. Gastrointestinal adenocarcinoma
    2. Neuroendocrine carcinoma (carcinoid)
    3. Gastric squamous cell carcinoma

Stromal
- Benign
    1. Leiomyoma
- Malignant
    1. Leiomyosarcoma
    2. Gastrointestinal stromal tumor

Round cell
- Benign
    1. Plasmacytoma
- Malignant
    1. Malignant lymphoma
    2. Mast cell tumor
    3. Malignant plasmacytoma

Neoplasms metastatic to the gastrointestinal tract

[a] *Since most of these tumors are histologically and behaviorally similar regardless of where they occur in the lower gastrointestinal tract, where appropriate the tumor name can simply be preceded by the adjective* gastric, intestinal, or colonic.

The 2003 World Health Organization *Histological Classification of Tumors of the Alimentary System of Domestic Animals* lists over 50 specific neoplastic entities and over 15 additional tumor-like lesions of the lower gastrointestinal tract. *The pragmatic classification of neoplasms and proliferative lesions outlined in* Table 1.1 *is considerably simpler.* This classification, and the discussion arising from it, is based upon several fundamental principles:

Any classification of neoplasms should be:

- the simplest that is compatible with our current understanding of tumor biology, including therapeutic and prognostic information;
- based upon easily observed and objective features to allow a high degree of interobserver agreement when in use; and
- easily adaptable in response to new information about significant differences in behavior or response to therapy.

There appears to be no significant difference in the histologic appearance or the biological behavior of the various neoplasms based on their site of origin in the lower gastrointestinal tract, i.e., there is no reason to consider colonic adenocarcinomas (or lymphomas) separately from small intestinal or gastric adenocarcinomas. Prefixes such as "gastric" or "colonic" are used as descriptive anatomic terms to aid in communication of results.

Gastrointestinal adenocarcinomas

The prevalence and distribution of gastrointestinal adenocarcinomas vary among species, although they are common in none. In dogs, gastric carcinomas predominate; small intestinal and colonic carcinomas are relatively uncommon. In contrast, gastric carcinoma is almost unknown in cats, but small intestinal and colonic adenocarcinomas are relatively common. In other species, where they are generally rare, gastrointestinal adenocarcinomas also involve mainly small intestine.

The microscopic appearance is similar, regardless of species or location. A few develop as tubular and papillary proliferations of differentiated columnar epithelial cells projecting into the intestinal lumen. This is perhaps most commonly seen with colonic carcinomas in cats. Such lesions are distinguished from rare papillary adenomatous hyperplasia because *they have at least some invasion into the lamina propria, submucosa, or tunica muscularis.* Such invasion cannot be appreciated with endoscopic biopsies, and these papillary carcinomas sometimes cannot be distinguished from benign adenomatous hyperplasia or papillary adenomas without full-thickness surgical biopsies. This becomes particularly relevant when trying to distinguish the very common rectal papillary adenoma from the occasional, truly malignant, papillary carcinoma arising in the distal colon or rectum of dogs.

The earliest recognizable histologic lesion, regardless of the location, is *local effacement or obliteration of glandular mucosal architecture at the site of origin by proliferating polygonal mucus-producing epithelial cells.* These cells infiltrate the lamina propria, and then invade sequentially through the submucosa and tunica muscularis, infiltrating into lymphatics, and sometimes veins. They penetrate the serosa and exfoliate into the peritoneal cavity to establish neoplastic implants on omentum and mesentery. The tumor also spreads early via lymphatic and venous routes, so that even surgical excision on discovery is rarely curative, because it is too late to prevent metastasis.

The microscopic appearance of the invading tumor can be quite variable, and usually more than one histologic subtype occurs within the same neoplasm. There is no proven prognostic or therapeutic significance to the different histologic patterns. *Most are scirrhous, mucus-producing carcinomas* that can create mucus-filled epithelial lakes throughout the intestinal wall, accompanied by what is often a great deal of fibrous stromal proliferation. The degree of cytologic maturation may be high, yet the diagnosis of carcinoma is obvious, given the transmural invasive behavior. Less commonly, the tumor cells invade in a tubular or acinar pattern, which tends to be less scirrhous, or as scattered individual anaplastic epithelial cells, accompanied by a great deal of desmoplastic fibrous tissue, so that recognizing carcinoma (in contrast to stromal malignancy or postinflammatory reactive fibrosis) may be challenging. In almost all cases, however, the tumor cells produce mucus, which may be revealed by periodic acid–Schiff staining. Formation of *signet ring cells* (an epithelial cell with the nucleus displaced to the periphery by a single large clear cytoplasmic vacuole) is relatively common.

The histological diagnosis is easy with a *full-thickness biopsy.* The submucosal and transmural portions of the tumor are routinely larger and more readily identified as malignancy than the mucosal portion of the tumor, which endoscopic biopsies may not capture.

Alternatively, especially when large deep ulcerative lesions are biopsied endoscopically, only the necrosis, inflammation, and fibrosis that accompany neoplastic cells may be captured. On the other hand, a false-positive diagnosis may be made when attempting to distinguish early carcinoma (especially gastric carcinoma) from dysplastic repair of recent ulceration; in such cases, a full-thickness biopsy to detect invasion is more reliable than the best endoscopic sample.

Adenocarcinoma of the stomach is most frequently reported in **dogs**, usually in animals <10 years of age. It is the most common gastrointestinal adenocarcinoma in dogs, and the most common gastric neoplasm in that species. Males predominate in the population with gastric cancer, and over half of gastric adenocarcinomas in dogs occur in the pyloric region. In the Lundehund, there may be a relationship to the chronic gastritis common in that breed, but otherwise no causal association is recognized in dogs.

Grossly, some gastric neoplasms appear as nonulcerating, firm thickenings involving most of the gastric wall and causing loss of the normal rugal pattern on the mucosal surface. Others are more localized plaque-like thickenings that tend to obliterate rugae and ulcerate centrally. Ulceration occurs in over half of canine gastric adenocarcinomas. Surface proliferation or irregularity other than ulceration is very uncommon in gastric carcinoma in dogs. Cut sections through the stomach wall invaded by carcinoma reveal edema and pale, firm fibrous tissue. Induration or plaque-like pale masses may be evident on the serosa, where the pale outline of infiltrated lymphatics may be prominent. Widespread gastric mural fibrosis and thickening, the result of desmoplasia induced by the malignant epithelium, cause "*linitis plastica*," the so-called "leather bottle" appearance.

Gastric carcinomas in dogs infiltrate the stomach wall aggressively, invading lymphatics, and they have usually metastasized to the local lymph nodes, and often to distant organs, particularly lung, liver, and adrenal, by the time they are diagnosed.

Rare cases of gastric adenocarcinoma are described in **cats**. They adopt tubular and diffuse patterns, and behave typically, but are so rare that a diagnosis of carcinoma should only be made on a full-thickness surgical biopsy or necropsy specimen. Endoscopic samples suggestive of gastric carcinoma in cats are almost always foci of adenomatous hyperplasia upon further investigation.

Gastric adenocarcinoma in **cattle** is exceptionally uncommon, but when it occurs it resembles similar tumors in other species.

Intestinal adenocarcinomas are uncommon in **dogs**; they occur most frequently in the proximal small intestine and large bowel of animals averaging 8–9 years old. Some investigators have reported a slightly higher prevalence of intestinal carcinomas in males, with a breed predisposition in Boxers, Collies, Poodles, and German Shepherds. Weight loss, persistent vomiting, anorexia, emaciation, and abdominal distension are the most common signs when the tumor is located in the small intestine. Dogs with colorectal tumors have large-bowel diarrhea, tenesmus, hematochezia, and dyschezia. Many dogs with intestinal carcinomas are anemic on account of hemorrhage from ulcerating tumors.

Macroscopically, the tumors appear as gray-white, firm, sometimes annular, stenotic areas that commonly affect the entire thickness of the intestinal wall (see Fig. 1.48). These tumors often do not ulcerate, and they usually do not project into the lumen of the gut. Papillary or polypoid intestinal adenocarcinomas do form intraluminal masses, which tend to involve larger segments of the intestine, suggesting horizontal spread. There is dilation of the gut proximal to stenotic and obstructive tumors and there may be hypertrophy of the intestinal muscularis proximal to such neoplasms.

These tumors metastasize widely, mainly via the lymphatics (Fig. 1.72). Involvement of the small intestine leads to metastases mainly in the mesenteric lymph nodes, less commonly to other abdominal nodes, liver, spleen, and lungs. Histological evidence of metastasis at the time of resection of small intestinal tumors predicts a markedly reduced postsurgical survival time, but even dogs without such evidence may succumb to metastatic disease, albeit with longer survival.

Colonic adenocarcinomas metastasize to colonic, iliac, and other pelvic and abdominal nodes. Metastases may also occur in most abdominal organs and the lungs. Implantation on serosal surfaces may result in obstruction of omental and diaphragmatic lymphatics, leading to ascites. In a few cases, malignant cells may spread retrograde in the lymphatics of the abdomen and pelvic limbs, causing edema of the abdominal wall and legs. Dogs with annular colorectal

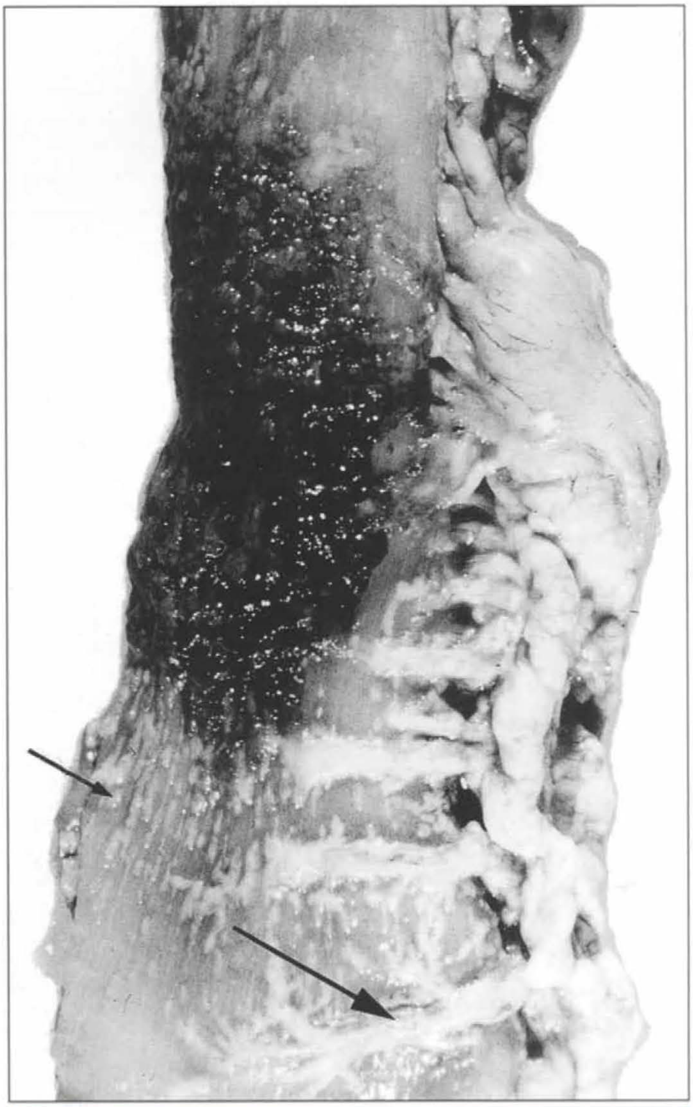

Figure 1.72 Adenocarcinoma of rectum in a dog. Serosal hemorrhage, and plaque-like masses of desmoplastic fibrous tissue and neoplastic cells on the serosa (small arrow) and along serosal lymphatics draining to the mesentery (large arrow).

carcinomas have a much shorter survival period compared to dogs that have a single, pedunculated polypoid tumor in this location. The etiopathogenesis of colonic carcinomas in dogs is uncertain, but there appears to be progression to malignancy from benign adenomatous lesions in at least some instances. β-catenin and cyclooxygenase-2 are overexpressed in malignant colonic epithelial cells in some cases, as they are in humans.

In **cats**, intestinal adenocarcinoma is less prevalent than lymphosarcoma, but it is relatively more prevalent in cats than in dogs. Carcinomas of the intestine are more prevalent in Siamese cats than in other breeds. As in dogs, a higher prevalence of this tumor has been reported in males than females. The mean age of cats with intestinal carcinomas is 10–11 years.

The ileum is the most common site affected, followed by the jejunum. Carcinomas occasionally arise in the large intestine, and when the tumor is located at the ileocecal junction, both the large and small intestine are usually involved. The clinical signs and gross appearance are similar to those in dogs.

The microscopic appearance of intestinal carcinomas in cats is typical (Fig. 1.73), except that osteochondroid metaplasia of the stroma may be a feature. The rare carcinomas involving the large intestine have tended to be papillary, better differentiated, and less scirrhous than carcinomas involving the small intestine.

Intestinal adenocarcinoma is relatively common in **sheep** in New Zealand, the UK, Iceland, Scotland, Norway, and southeastern Australia; in New Zealand and Australia, there is a high prevalence in breeds used for fat lamb production. The cause of the high prevalence is unknown, but may be related to exposure to bracken fern or other unidentified carcinogens. Other associations, such as heavy use of certain fertilizers, and pastures with the weed *Cynosaurus cristatus*, have been reported from New Zealand. Tumors occur mainly in animals 5 years of age or older. Clinically, affected sheep lose weight and have abdominal distension due to ascites, but most cases are incidental findings at slaughter.

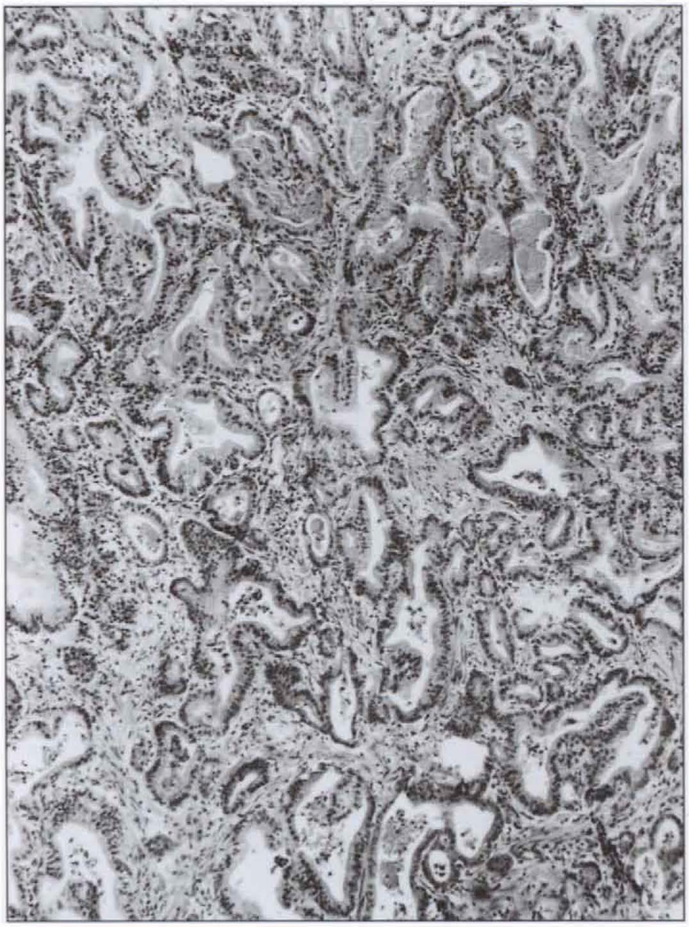

Figure 1.73 Well-differentiated **intestinal adenocarcinoma** in a cat.

The tumors are usually located in the middle or lower small intestine, rarely in the colon (Fig. 1.74). They are dense, firm, white masses, 0.5 to several centimeters long and up to 1 cm thick, which may form annular constrictive bands at the affected site. Cauliflower-like growths may be evident on the serosal surface. Polyps or plaques may protrude into the lumen, but ulceration of the mucosa is uncommon. The distal edge of the tumor is generally well demarcated. There is dilation of the intestine proximal to the lesion. Metastatic implantations on serosal surfaces are common and these appear as opaque to white plaques or diffusely thickened areas, which must be differentiated from mesothelioma. Obstruction of serosal lymphatics by tumor emboli may lead to ascites. Lung and liver metastases are rare.

Microscopically, the tumor is characterized by solid sheets or nests of well-differentiated to highly anaplastic polyhedral, cuboidal, or columnar epithelial cells that may form irregular acinar structures. They may be distributed singly, or in small aggregates, and are often difficult to detect in the heavy fibrous desmoplastic response (Fig. 1.75). The neoplastic cells infiltrate the bowel wall along lymphatics, vessels, and nerve trunks, through to the serosal surface, whence they spread to the mesenteric lymph nodes. This is apparently followed by retrograde lymphogenous metastasis to the gut wall proximal to the primary tumor. These secondary tumors are particularly responsible for constriction of the gut lumen. Sclerotic masses with anaplastic epithelial cells, many of which are periodic acid–Schiff-positive, are located on the serosal surfaces of the abdominal organs but rarely infiltrate the parenchyma. Argentaffin cells may form part of some intestinal carcinomas, especially in lymph node metastases. Mineralization and osseous metaplasia may develop in the stroma.

Intestinal carcinomas are generally rare in **cattle**, **goats**, **horses**, and **swine** (Fig. 1.76), with the exception of those associated with bracken fern, papillomavirus, and upper alimentary cancer in cattle (see section on Neoplasia of the esophagus and forestomachs, above). A high prevalence of intestinal **adenomas** is associated with these tumors in cattle. Three types are recognized: (1) a sessile plaque; (2) an adenomatous polyp; and (3) a more proliferative adenoma of the ampullae where the bile and pancreatic ducts open into the duodenum. Intestinal carcinomas are usually an incidental finding at meat inspection. The location, morphology, and routes of metastasis are similar to those described for sheep, except that serosal lesions are less obvious. Hematogenous spread to the liver, lung, kidney, uterus, and ovaries may occur in cattle.

Adenomatous hyperplasia/papillary adenoma/polyps

Adenomatous hyperplasia occurs as focal papillary or papillotubular proliferation of surface epithelium anywhere in the gastrointestinal tract. In the stomach (Fig. 1.77), it is to be distinguished from chronic hypertrophic pyloric gastropathy, discussed with pyloric obstruction.

The most common site is the distal rectum of middle-aged **dogs**, within 10 cm of the anal–rectal margin. Given a variety of names, such as *adenomatous hyperplasia, papillotubular adenoma, colorectal polyp, or adenoma*, and *polypoid carcinoma in situ*, we refer to it as **rectal papillary adenoma**. It occurs in dogs of almost any age, and is usually a single nodule easily managed by adequate surgical excision. Tenesmus, prolapse of the polyp, rectal bleeding following defecation, chronic dyschezia, and diarrhea are the most common signs. There is a single case of paraneoplastic leukocytosis associated with such a tumor. Some, but not all, surveys indicate that this tumor is more common in males.

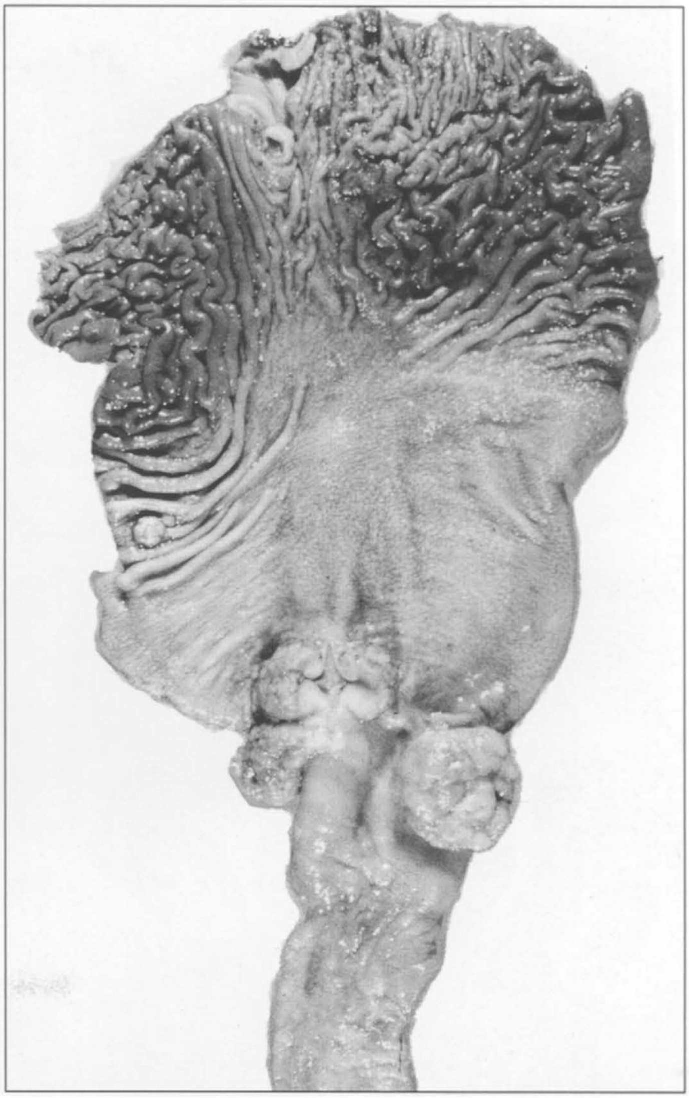

Figure 1.77 Mucosal polyps at the pylorus and along the greater curvature of the stomach of a dog.

Macroscopically, the tumor is usually sessile or slightly pedunculated (Fig. 1.78), varying from 1 cm to several centimeters in diameter. It may be firm or friable and hemorrhagic; the mucosal surface is often ulcerated.

Microscopically, the polyp may have a predominantly tubular or papillary growth pattern (Fig. 1.79). In well-oriented specimens, the tubular pattern is characterized by branching crypts that are lined by generally well-differentiated columnar-to-cuboidal pseudostratified epithelial cells. The papillary type consists of villus-like projections of proprial connective tissue that are covered by a layer of pseudostratified columnar epithelial cells. There may be cytoplasmic basophilia, loss of nuclear polarity, and prominent nucleoli in epithelium in both types of polyps. The number of mitotic figures varies, often within the same polyp. These tumors often appear to originate in the superficial

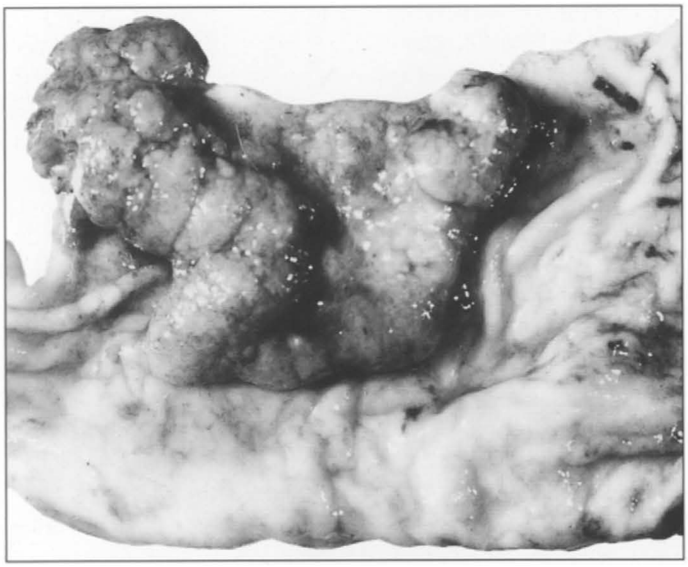

Figure 1.78 Rectal papillary adenoma in a dog.

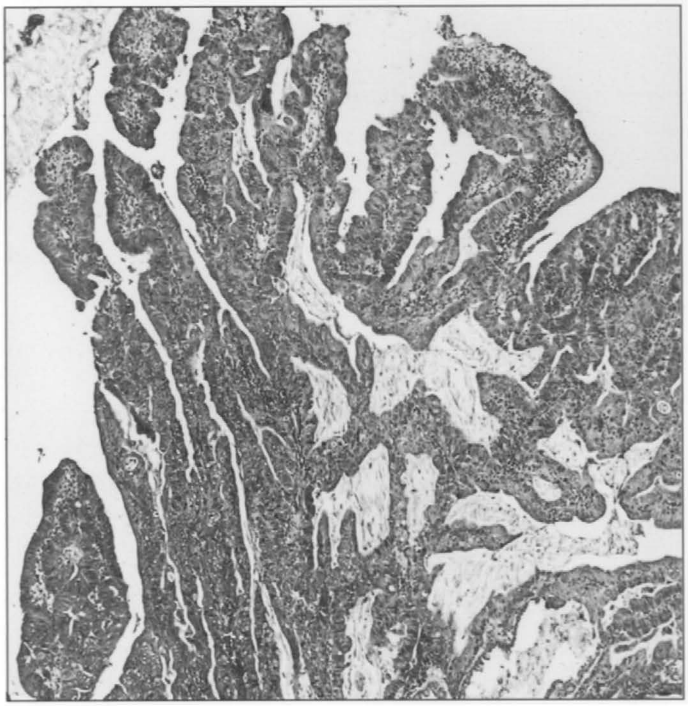

Figure 1.79 Rectal papillary adenoma in a dog, showing tubulopapillary microscopic architecture.

portion of the crypts, deeper portions of which may remain normal, with tubules or slender papillae of hyperchromatic tumor cells above them. The stalk of the tumor is highly vascular and is continuous with the lamina propria or submucosa of the rectum. The tumors are generally well demarcated from the adjacent normal mucosa. The amount of mucin in the epithelium varies considerably, and it is often absent, especially in more dysplastic cells. Some polyps have a malignant appearance histologically. These are characterized by the presence of anaplastic epithelial cells in situ in the mucosa, and, in some cases, invading the propria and adjacent submucosa (Fig. 1.80).

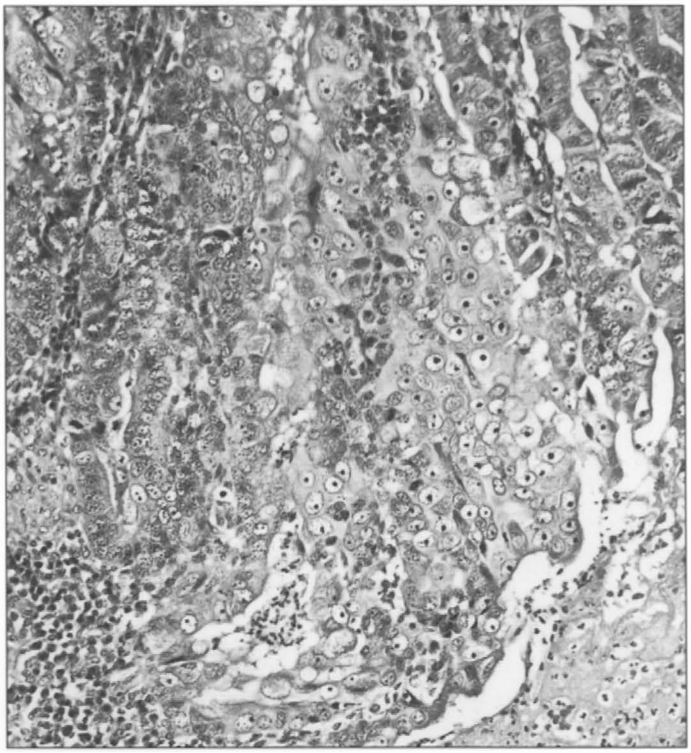

Figure 1.80 Invasive carcinoma arising from the base of a rectal polyp in a dog.

There is limited information on the *biological behavior* of these tumors. In dogs, adequate surgical removal usually results in complete recovery. Some are interpreted at presentation as carcinoma in situ, based on cytologic characteristics, and deep biopsies and/or complete excision of these polyps are essential to rule out local invasion or infiltration of lymphatics, which should be sought in specimens with epithelial morphology suggesting malignancy. Polyps that are more than 1 cm in diameter tend to have cells with a more anaplastic appearance, and recurrence is most probable in cases interpreted as carcinoma in situ, those with multiple masses, or those with more diffuse colonic involvement.

In other species, polypoid and adenomatous tumors are uncommon. Benign adenomatous polyps are reported in the stomach and duodenum of **cats**, predominantly middle-aged males of Asian breeds. They are presented with vomition, hematemesis, and possibly anemia. Excision is curative. These lesions can be confused with papillary adenocarcinomas if sampled only by endoscopic biopsy.

In **cattle**, intestinal polyps are usually an incidental finding, except in those cases where they are large enough to cause partial obstruction. The tumors are raised, often pedunculated, gray-to-brown masses on the mucosal surface. They may occur singly, in grape-like clusters, or they may be scattered. Microscopically they resemble benign rectal polyps in the dog, but they may be capable of malignant transformation (see above).

Adenomatous polyps frequently occur in **sheep** with intestinal carcinoma. Hyperplastic polyps occur in the small intestines of **lambs** and **goats** with chronic coccidiosis (see section on Infectious and parasitic diseases of the alimentary tract, later in this chapter).

Multicentric small intestinal polyposis has been associated with protein-losing enteropathy in a **horse**. The proliferative lesions caused by *Lawsonia intracellularis* in horses and swine may impart a polypoid appearance to the intestinal mucosa grossly, and microscopically should not be mistaken for adenomatous neoplasia.

Gastrointestinal neuroendocrine carcinomas (carcinoids)

Carcinoids arise from neuroendocrine cells that are scattered in the mucosa of a wide variety of organs, including the stomach and the intestine. These cells secrete low-molecular-weight polypeptide hormones such as secretin, somatostatin and cholecystokinin, or they are part of the amine precursor uptake decarboxylation (APUD) group, producing compounds such as serotonin (5-hydroxytryptamine).

Carcinoid tumors of the gastrointestinal tract are *rare* in domestic animals. They have been reported mainly in aged dogs and very rarely in the cat, cow, and horse. In **dogs**, most carcinoids are located in the duodenum, colon, and rectum, and only rarely in the stomach and lower small intestine. Clinically, they may cause intestinal obstruction, and anemia due to ulceration and hemorrhage. Associated diarrhea in some cases can speculatively be attributed to hypersecretion of functional polypeptide hormones. Rectal carcinoids may protrude from the anus and resemble adenomatous polyps.

Macroscopically, carcinoids are usually lobulated, firm, dark-red to cream-colored masses a few millimeters to perhaps 2 cm in diameter. They seem to arise deep in the mucosa, often forming submucosal or subserosal nodules, perhaps with ulceration of overlying mucosa, and infiltrating transmurally and into the mesentery.

Microscopically, carcinoids have a *distinct endocrine appearance*. Round or oval to polyhedral cells have abundant finely granular eosinophilic or vacuolated cytoplasm and vesiculate nuclei with prominent nucleoli. They form nests, ribbons, rosettes, or diffuse sheets in the mucosa, submucosa, and muscularis. A fine vascularized fibrous stroma often divides the tumor masses into pseudoalveolar arrays. Amyloid may be present in intercellular and perivascular spaces. Uninuclear megalocytes and multinucleate giant cells are present occasionally.

A *diagnosis* of carcinoid is based on the endocrine histologic pattern, cytoplasmic argentaffinic and argyrophilic granularity, immunohistochemical identification of specific secretory products, and the typical ultrastructural appearance. The histochemical reactions may be negative, especially in rectal carcinoids, and they may also be lost during fixation in formalin or by autolysis prior to fixation, as may immunohistochemical reactivity. These cells are routinely positive with immunohistochemical staining for neuron-specific enolase and chromogranin, as are most neuroendocrine tumors, and then with one or more of the specific immune probes related to the peptides being produced. An increased concentration of specific secretory products may be detected in circulation.

Electron microscopic examination helps to differentiate carcinoids from intestinal mast cell tumors. Carcinoid cells have dense, round-to-oval, membrane-bound secretory granules in the cytoplasm, which vary in diameter from 75 to 300 nm. They have abundant rough endoplasmic reticulum and the plasma membrane forms interdigitating processes. Carcinoid cells are Schiff-negative and do not show metachromasia with Giemsa stains.

Data on biological behavior of intestinal carcinoids in dogs are limited. Most cases reported have been malignant. There may be extensive invasion of the gut wall and veins, with metastasis, especially to the liver. The few cases that have been described in other species have features similar to those described in dogs.

Goblet-cell carcinoids (adenocarcinoids, mucinous carcinoids) are tumors that are most commonly found in the appendix of humans, with features of both carcinoids and adenocarcinomas. There is a single report of such a tumor in the rectum of a dog. Microscopically, goblet-cell carcinoids have distinct areas of mucinous adenocarcinoma and carcinoid that may merge. The carcinoid component is most prominent in the primary tumor and the metastases.

Gastric squamous cell carcinomas

Squamous cell carcinomas derived from the mucosa of the pars esophagea are the most common gastric tumor in **horses**. They occur predominantly in middle-aged or older animals, which are usually presented in an advanced state, with unexplained anorexia, occasionally dysphagia, and weight loss sometimes progressing rapidly to emaciation. At autopsy there may be peritoneal effusion, and there is usually evidence of the neoplasm as plaques of proliferative or scirrhous tissue on the serosa of the stomach. There may also be peritoneal implants, especially on intestine, testes, omentum, parietal abdominal surfaces and diaphragm; direct extension to adjacent organs including liver, spleen, and diaphragm, with progression to the pleural space; and sometimes distant metastases, usually in liver and lung. The appearance of the tumor on serosal surfaces resembles mesothelioma, with smooth creamy plaques or nodules up to 2–4 cm in diameter.

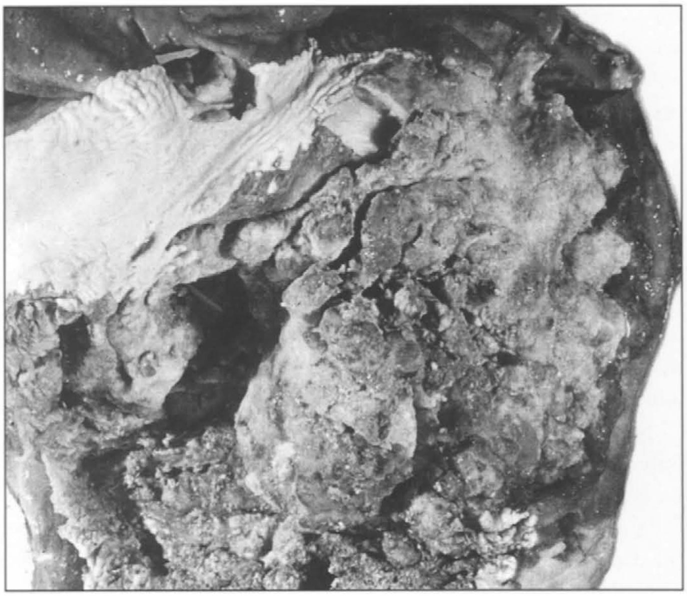

Figure 1.81 Fungating and ulcerative **squamous cell carcinoma** arising from the gastric squamous mucosa of a horse.

The origin of these lesions is usually a fungating cauliflower-like mass 10–40 cm in diameter, with superficial fissures, projecting above the surface of the pars esophagea (Fig. 1.81). Sometimes these lesions are superficially more ulcerative than proliferative. Necrosis and hemorrhage are evident in the tumor mass, which is usually well demarcated from adjacent normal squamous mucosa. Occasionally the tumor extends into the distal esophagus, and may obstruct it. Microscopically, these neoplasms are typical squamous cell carcinomas, invading in cords or nests of cells through the gastric wall. They induce desmoplasia, imparting a scirrhous, firm texture and appearance to the thickened gastric wall and to the peritoneal and pleural implants. One such tumor has been reported as a cause of pseudohyperparathyroidism in a horse.

A squamous cell carcinoma is reported arising from the pyloric gland mucosa in a dog.

Malignant lymphomas

Gastrointestinal lymphomas occur in most species and are common in **cats**. These neoplasms may be primary, or part of the systemic or multicentric form of the neoplasm (see Vol. 3, Hematopoietic system). Primary lymphoma of the intestine includes cases having malignant lymphocytic infiltrates in the intestine, with or without involvement of the abdominal organs or bone marrow, but with no lesions in the thorax or peripheral sites.

Malignant lymphoma is the most common gastrointestinal neoplasm in companion animals, more prevalent in cats than in dogs. It can be segmental within any portion of the gastrointestinal tract, or diffuse. While the gastrointestinal tract may be involved in advanced multicentric lymphoma in dogs, such cases are rarely submitted for biopsy because the diagnosis has already been made based on lesions elsewhere. Most samples submitted for histologic assessment are from cases suspected of having primary gastrointestinal lymphoma. In cats, almost all cases examined at biopsy are primary within the stomach or intestine.

In both species, spread outside intestine is usually to mesenteric lymph nodes and to liver, and less commonly beyond. In liver, the neoplasm infiltrates in a characteristic portal pattern that should not be mistaken for chronic portal hepatitis or lymphocytic cholangiohepatitis. In lymphoma, the tumor cells often form layers 10–20 deep in the portal tract, and cholangiolar proliferation, fibrosis, and hepatocellular atrophy are absent. In advanced hepatic disease, the cells will also surround central veins. Although scattered tumor cells may occur within the sinusoids, a primarily sinusoidal distribution of lymphocytes signals lymphocytic leukemia rather than intestinal lymphoma.

The classification of lymphomas in animals is complex, integrating distribution, histologic and cytologic appearance, and immunophenotype. Most categories are based on lymphomas discovered in lymph nodes or skin; as a group, intestinal lymphomas have received little detailed investigation in this context. Most of the controversy about intestinal lymphoma is related not to its diagnosis, but rather to the relationship (if any) between its classification and subsequent behavior, including response to therapy; currently no clear association is evident.

In **dogs**, intestinal lymphoma can affect animals from adolescence to old age, with a male sex bias. Nonspecific signs of enteric disease and weight loss may be acute or occur over a period of weeks to months. Hypoproteinemia, probably associated with enteric protein loss, occurs in ~30% of affected dogs.

The tumors are located in the small intestine, stomach, and colon in that order of frequency. They are soft-to-firm, cream-colored masses located in the submucosa that may protrude into the gut lumen. The overlying mucosa may be ulcerated. The masses can be nodular to diffuse and several sections of the gut are usually affected. The mesenteric nodes are often enlarged and the liver is frequently involved at the time of presentation.

The majority of primary gastrointestinal lymphomas in dogs are *epitheliotropic T-cell tumors* based on immunohistochemical reactions, the remainder being mixed, B-cell, or indeterminate. Microscopically, in typical cases of epitheliotropic intestinal lymphoma, the mucosal, submucosal, and muscular architecture is effaced by a population of monotypic large lymphocytes with variable nuclear morphology and obvious mitotic activity. The crypts literally "disappear" as they become infiltrated by neoplastic cells.

The lesions of *very early lymphoma* are more challenging. They are distinguished from chronic inflammatory bowel disease by the *relatively monotypic lymphocyte population* and by the *intraepithelial infiltration of lymphocytes* that obscures the distinction between lamina propria and epithelium. Even with these criteria, differentiation of early neoplastic from inflammatory disease can be problematic, since residual plasma cells, eosinophils, and benign lymphocytes of the normal lamina propria persist among the neoplastic lymphocyte population. Similarly, not all cases of intestinal lymphoma exhibit epitheliotropic growth, and there is overlap between neoplastic epithelial invasion and the increase in intraepithelial lymphocytes that is commonly seen with inflammatory disease. The key is not just the presence of the lymphocytes, but the *obliteration of the proprial:epithelial boundary*. Once the lymphoma effaces crypts or invades submucosa, diagnosis should not be problematic, but full-thickness biopsies from several areas of the intestine may help differentiate chronic inflammatory bowel disease from intestinal lymphoma.

Lymphoplasmacytic enteritis in the dog, particularly the Basenji, may represent a prelymphomatous stage similar to immunoproliferative small intestinal disease in humans. The latter is characterized by diffuse lymphoplasmacytic infiltration of the small intestinal mucosa that results in malabsorption, and predisposes to the development of primary enteromesenteric lymphoma.

In **cats**, the situation is substantially more complicated. There are at least three histologic categories of gastrointestinal lymphoma. However, no correlation is evident between immunophenotype and ultimate biological behavior or response to treatment. It is also fairly common in cats to have sharply segmental disease, and some such cases can be cured by surgical excision.

Small-cell lymphocytic villus lymphoma is an epitheliotropic T-cell lymphoma that typically begins at the base of the villi within the small intestine of old cats. Clustering of suspiciously monotypic small hyperchromatic lymphocytes within the lamina propria just at the base of villi is an exceedingly common observation in cats 15 years of age and older. It is not clear whether this is incipient lymphoma or a normal finding. The number of such cells may vary substantially from villus to villus. As these clusters seem to expand, the lymphocytes infiltrate into the overlying epithelium, obliterating the distinction between lamina propria and epithelium. Unlike inflammatory bowel disease, such lesions may be very patchy, and there is no concurrent increase in plasma cells or eosinophils. With time, the lymphocyte population appears to expand throughout the lamina propria and then transmurally. The syndrome shares substantial clinical overlap with inflammatory bowel disease in that it is often slowly progressive and it is usually not accompanied by clinical signs related to neoplastic infiltration of liver, spleen, or lymph node, even though there is often microscopic tumor within those organs. The extent of microscopic disease within the intestine is usually much greater than the macroscopic impression at the time of surgery.

Large-cell/lymphoblastic lymphoma, in contrast, is characterized by a rapidly progressing transmural lesion that is usually accompanied by clinically palpable intestinal masses and by markedly enlarged mesenteric lymph nodes. Cats of any age may be affected. Most of these are reported as B-cell tumors, although not all investigators concur, and the majority of these high-grade lymphomas have not been subjected to immunophenotyping. The tumor resembles canine lymphomas, in that there is usually transmural effacement of intestinal architecture, and obliteration of the structure of affected mesenteric lymph nodes. Many cases differ from canine lymphomas, however, in having marked cellular pleomorphism. The tumor cells may have fairly abundant cytoplasm, nuclear cleavage, and up to twofold anisokaryosis. Descriptive names like "histiocytic" lymphoma for some of these more anaplastic variants are no longer appropriate, since immunophenotyping is available to identify the cells more precisely. Lesions are often sharply segmental and the primary lesion can be completely excised. However, the high prevalence of metastatic disease makes surgical cures rare.

Large granular lymphoma is usually a rapidly progressive intestinal lymphoma of cats. The tumor cells are either T cells or natural killer cells. These are medium-to-large lymphocytes with pleomorphic nuclei with frequent clefting. The distinctive features are the large red cytoplasmic granules, and perforin immunoreactivity. In the presence of cleaved nuclei, the large granules may be mistaken for those of eosinophils, but they are larger, rounder, and are more intensely eosinophilic. The cytologic characteristics have also caused such tumors to be attributed to globule leukocytes in the past. The granular cells are not present as a pure population. They are often intermingled with other lymphocyte types and with macrophages, so these invasive and destructive transmural lesions are sometimes confused with transmural granulomatous disease or mast cell tumors. These tumors progress rapidly, with widespread dissemination and even leukemia, and they may perforate affected areas of intestine.

In the **horse**, alimentary lymphoma is a relatively common tumor; most are attributed to *B lymphocytes*. It occurs mainly in young adults. Affected horses lose condition, likely due to malabsorption and protein loss; in addition they may be anemic, icteric, and have mild intermittent bouts of colic. Diarrhea is inconsistent. Serum albumin can often be decreased, but they are frequently hypergammaglobulinemic.

Macroscopic lesions in horses are usually located in the small intestine, and these are characterized by local to diffuse thickening of the gut wall with prominent rugae on the mucosa. Nodules or plaques with fibrous adhesions may be evident on the serosa. The mesenteric nodes are markedly enlarged. Other nodes may be enlarged, but to a lesser extent. Microscopically, there is diffuse lymphoid infiltration of the lamina propria and submucosa, usually extending transmurally to the serosa. There is marked villus atrophy to the point of complete loss of villi and crypts. Plasmacytoid cells are regularly present in the lamina propria but less numerous in the submucosa. Similar lymphoid cell infiltration involves the mesenteric nodes and the perinodal connective tissue. Other lymph nodes are involved in about half the cases. A plasmacytoid or plasmacytic reaction and occasional giant cells are also present in the nodes. The neoplastic lymphoid cells are probably of B-cell origin and "home" into the gut-associated lymphoid tissue and the lamina propria of the small intestine.

An immune-mediated type of *dermatitis* has been associated with both chronic inflammatory (granulomatous and eosinophilic enteritides) and lymphomatous lesions in the gut in horses.

Epitheliotropic T-cell lymphomas resembling those in dogs, and ulcerating large granular lymphomas caused by T cells, somewhat resembling those described in cats, also occur infrequently in horses. A T-cell lymphoma occurred concurrently with multisystemic eosinophilic epitheliotropic disease in a horse, prompting the suggestion that undetected T-cell lymphoma secreting interleukin-5 may underlie that syndrome. Paraneoplastic eosinophilia has also been associated with intestinal lymphosarcoma in the horse.

In **cattle** and **sheep**, alimentary lymphomas are generally part of the adult multicentric form of the disease, and the intestinal lesions resemble the effacing tumors described in other species. More important in cattle is lymphosarcoma of the abomasum, which is common in adult cattle. Diffuse mucosal and submucosal lymphocytic infiltrates or nodular proliferations may occur. Strategically placed pyloric tumor may cause obstruction. Diffuse lesions, thickening the gastric wall, frequently ulcerate, and hemorrhage from such ulcers, as melena, is a common sign. The lymphoid infiltrates are recognizable as firm gray-white tissue in the submucosa and mucosa. Involvement of abomasal lymph nodes is disproportionately slight.

In **swine**, diffuse gastric lymphosarcoma occurs. The wall of the stomach is thickened by submucosal lymphocytic infiltrates, which sometimes invade the mucosa locally in many areas, producing nodular elevations that may ulcerate. B-cell lymphomas involving the Peyer's patches have also been detected at meat inspection in swine.

Gastrointestinal mast cell tumors

These tumors are *uncommon*. They occur in aged dogs, and occasionally in cats, with signs such as vomition, diarrhea, and melena. They are seen in biopsies as invasive round cell tumors that can resemble carcinoids, lymphomas, and gastrointestinal stromal tumors; *definitive diagnosis requires histochemical and possibly immunohistochemical investigations*. Primary mast cell tumors of the gastrointestinal tract are comprised of mucosal mast cells, which differ from connective tissue mast cells, such as those found in skin, in having few granules, which usually do not stain well in formalin-fixed tissue. Abnormal mast cells do not appear in circulation in animals with these tumors.

Mast cell tumors are most commonly seen in stomach, and least common in the colon. Affected areas in the mucosa are tan-colored, firm, thickened, possibly ulcerated, and may be 1 cm to several centimeters in size. The tissue architecture is effaced by a population of granular round cells accompanied by variable numbers of eosinophils. They generally grow in infiltrative cords, but occasionally form endocrine-like packets surrounded by a delicate fibrovascular stroma. There is a wide range in the cytologic appearance. Some tumors are populated by fairly mature mast cells with abundant cytoplasmic granularity easily demonstrated with toluidine blue. Others are populated by anaplastic and pleomorphic round cells or spindle-shaped cells, sometimes with giant nuclei or forming syncytia, in which cytoplasmic granules with metachromatic staining, while present, may be difficult to observe. Those with abundant metachromatic granules must be differentiated from connective tissue mast cell tumors metastatic to the gastrointestinal tract, in which case lesions should be sought in skin and elsewhere. There can be marked variation in the number of eosinophils in the tumor, and they are not definitive, since eosinophils are also common in some intestinal lymphomas, and as part of the background cell population in normal lamina propria.

Gastrointestinal mucosal mast cell tumors are differentiated using a suite of histochemical and immunohistochemical characteristics. They have at least a few *metachromatic granules* when stained with toluidine blue, and many tumors have at least some cells that stain with alcian blue. They stain *immunohistochemically positive* for mast cell tryptase and c-KIT (CD117), but negatively for CD3 (distinguishing them from most T-cell lymphomas), cytokeratin (distinguishing them from carcinomas), and chromogranin and synaptophysin (distinguishing them from carcinoids). Gastrointestinal stromal tumors should be positive for c-KIT, but cytology and lack of metachromatic granules when stained with toluidine blue differentiate them.

Ultrastructurally, the cytoplasm of gastrointestinal mucosal mast cell tumor cells contains many membrane-bound granules that appear as single or fused vesicles. Fine fibrillar material forms a loose network within these vesicles. A few tumor cells contain electron-dense fibrillar granules or intermediate forms. The crystalline electron-dense granules that are present in connective tissue mast cells, such as those from the skin, are rarely evident.

Metastases occur most often in the mesenteric lymph nodes, followed by the liver, spleen, and, rarely, the lungs. Ulceration of the gastrointestinal mucosa occurs commonly with systemic tissue mast cell tumors in cats and with large cutaneous mastocytomas in dogs, due to histamine stimulation of acid production by gastric parietal cells. Gastrointestinal ulceration is not a feature of mucosal mast cell tumors of intestinal origin, except perhaps as a result of mucosal effacement by the tumor.

Extramedullary plasmacytomas

Plasmacytomas of the lower gastrointestinal tract are *uncommon neoplasms in dogs*, and rare in cats and other species. They are encountered most frequently in the submucosa of the distal colon and rectum of dogs, where they are associated with signs of large-bowel diarrhea and bleeding.

Histologically, they resemble plasmacytomas of the skin, oral cavity, or larynx. The tumor is formed by solid packets of pleomorphic round cells with various degrees of plasmacytoid maturation, especially at the periphery of the tumor. There is frequent nuclear hyperchromasia and convolution. The cells are typically arranged in solid endocrine-like packets of 10–20 cells surrounded by a delicate fibrovascular stroma, and there may be AL amyloid deposition among the tumor cells. A few syncytial plasmacytoid or histiocytic cells may be evident. The majority of the tumor growth is submucosal, with a little bit of overflow into the deep half of the lamina propria. Most tumors have a discrete local growth habit amenable to surgical cure. A small proportion exhibit more aggressive behavior, including invasion of tunica muscularis, and some spread to regional lymph nodes and spleen, perhaps producing a monoclonal gammopathy.

Intestinal stromal tumors

The intestinal stromal tumors include leiomyoma, leiomyosarcoma, gastrointestinal stromal tumor, and very uncommon examples of almost every other type of stromal neoplasm, including hemangiosarcoma, nerve sheath tumors, fibroma and fibrosarcoma, osteosarcoma, and even lipoma. Ganglioneuromas have been described in dogs, a sow, horse, and a kitten. Other mesenchymal tumors include fibrous histiocytoma in a cow and histiocytic sarcoma in a dog.

Leiomyoma, **leiomyosarcoma**, and **gastrointestinal stromal tumor** are considered together, since recognition of the latter prompted re-evaluation of the criteria for diagnosis of leiomyosarcoma; older literature should be read with this in mind. Together, they are more common in dogs than other types of mesenchymal tumors except lymphosarcoma, and they also occur with some frequency in horses. Smooth-muscle tumors occur uncommonly in cats, equally prevalent in stomach, small intestine, and colon. They occur only rarely, if at all, in other species.

Leiomyoma and leiomyosarcoma represent the two extremes of a morphologic continuum, which included, toward the malignant end of the spectrum, tumors now classified as gastrointestinal stromal tumor. The latter are thought to be derived from interstitial cells of Cajal, or from a stem cell precursor to both those cells and smooth-muscle cells, and they are distinguished by expressing KIT (CD117) antigen. While some may contain smooth-muscle actin, they rarely express desmin. Leiomyomas and leiomyosarcomas, on the other hand, do not express KIT, and should express smooth-muscle actin, and desmin. *Immunohistochemical reactivity is the definitive means of differentiating these tumors*, but may be adversely affected by autolysis and duration of fixation, which must be considered in such studies. However, leiomyomas can be recognized based on their histology and cytology.

In **dogs**, as a group these tumors occur in older animals, in many of which they may be asymptomatic and incidental. Signs can include weight loss, lethargy, anorexia, anemia due to intestinal hemorrhage, abdominal pain, palpable abdominal masses, diarrhea, vomition, and dehydration or other signs of gastrointestinal obstruction. Based on limited studies in which the immunophenotype of stromal tumors of the gut has been determined, leiomyomas are most common and tend to occur in the esophagus and stomach of predominantly male dogs. Gastrointestinal stromal tumors are the next most common, and may occur in the stomach and intestine, with a tendency to predominate in the large bowel; sex distribution is equal. They have a spectrum of behavior from benign to malignant, and include tumors that were diagnosed as leiomyosarcomas prior to revision of terminology. Leiomyosarcomas are seemingly least common, and tend to occur in the intestine, with no apparent sex predisposition.

The majority of symptomatic tumors of this type are expansile nodules arising in the muscularis externa and can be cured by surgical excision, as is certainly the case with leiomyoma. However, a minority, perhaps up to 30%, of the other types have metastasized by the time that they are discovered.

Leiomyomas are sharply circumscribed masses of well-differentiated smooth-muscle cells, and generally lie beneath an intact mucosa, although they may deform the serosal or mucosal profile, and ulceration, perhaps related to pressure necrosis, can occur. They are comprised of swirling bundles of uniform fusiform cells, with abundant eosinophilic cytoplasm, and a central nucleus with blunt ends; usually no mitotic figures are evident. Areas of coagulative necrosis may occur in the tumor mass.

Leiomyosarcomas often resemble leiomyomas grossly, but they are invasive rather than circumscribed, and may ulcerate mucosa. The cells resemble those in leiomyomas in general cytology, but there is usually some degree of anisokaryosis, multiple nucleoli, scattered bizarre nuclei, and obvious mitotic activity. There may be necrosis in the mass and a mild lymphocytic or eosinophilic inflammatory infiltrate.

Gastrointestinal stromal tumors may be demarcated and grow by expansion, sometimes forming exophytic nodules on the serosal surface, or they may be transmural and invasive. Overlying mucosa, while usually intact, may ulcerate. They are usually comprised of spindle cells arranged as interlacing fascicles, or in a storiform (whorling or matted) pattern, with oval nuclei, and a somewhat basophilic cytoplasm with indistinct boundaries. A minority of cases may have somewhat epithelioid tumor cells arranged in trabeculae or solid sheets, perhaps with a somewhat myxoid intercellular matrix, often infiltrating between normal smooth-muscle fascicles. Epithelioid tumors are thought to reflect some degree of neural differentiation, while a storiform pattern is considered to reflect a poor degree of differentiation. There may be nuclear pleomorphism in all patterns of tumor, and mitotic figures are usually evident, and may be common. Hemorrhage or necrosis may be present within the tumor, and lymphocytic and/or eosinophilic infiltrates can occur.

The difficulty in determining the *prognosis* of these tumors in dogs has not changed with the recognition that the great majority are gastrointestinal stromal tumors, rather than leiomyosarcomas. No objective criteria or nomenclature differentiate benign from malignant gastrointestinal stromal tumors. In humans, larger tumor size and high mitotic activity are considered to be poor prognostic indicators, but there are no data substantiating these tendencies in animals.

Invasion into the mucosa causes ulceration and cavitation on the luminal surface (Fig. 1.82), which may lead to perforation of the

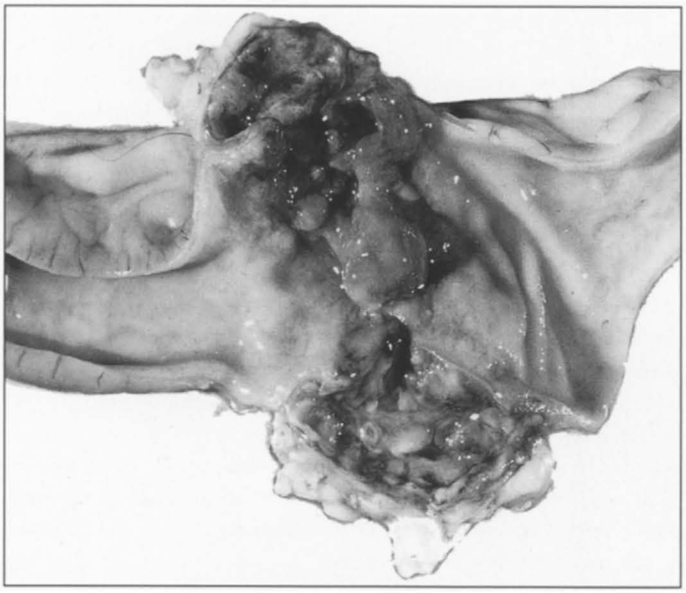

Figure 1.82 Annular ulcerating **leiomyosarcoma** in a cat.

bowel. Even in the absence of perforation, microorganisms from the gut lumen may cause local abscessation and secondary septic peritonitis in which there is intermingling of suppuration, granulation tissue, and tumor cells. Based on studies carried out prior to revision of the nomenclature, tumors in cecum and colon, where gastrointestinal stromal tumors predominate, were determined to have a relatively high metastatic risk. They may metastasize to the mesenteric nodes, mesentery, and liver, but in general, these tumors have a more favorable prognosis after complete resection than other malignant neoplasms of the lower gastrointestinal tract.

The large intestinal tumors may also cause *paraneoplastic hypoglycemia*, due to the production of insulin-like growth factors, that may precipitate the search for a neoplasm. Production of erythropoietin, resulting in erythrocytosis, has also been documented.

In old **horses**, tumors of the intestine have been described that in many cases meet morphologic or immunohistochemical criteria for gastrointestinal stromal tumor, as it has been described above. Most are encountered incidentally, at surgery, meat inspection, or necropsy, but tumors of this type, or previously diagnosed as leiomyomas, may cause intermittent bouts of colic that become more frequent with time. They occur in the stomach, small intestine, and most frequently in the cecum and colon, as encapsulated, moderately firm, multinodular, pale tan, or hemorrhagic masses in the muscularis or subserosa, protruding on the serosal surface, or rarely, as somewhat pedunculated tumors projecting from the serosa or into the lumen. They may vary from 1 to >10 cm in diameter, and are usually solitary, but occasionally may be multiple. Malignancy, if it occurs, must be rare; it is not described.

APPROACH TO THE DIAGNOSIS OF GASTROINTESTINAL DISEASE

The diagnosis of gastrointestinal disease is facilitated by knowledge of the entities that may be expected in a particular species and age group, and the clinicopathologic syndromes with which they are associated. *In the next section, etiologic entities associated with various syndromes in the domestic species are briefly summarized.* The salient diagnostic features of some conditions, or the steps required at necropsy to confirm a diagnosis, are mentioned. The diseases causing gastritis, and those causing typhlocolitis in all species, have been discussed in previous sections. They are only briefly reiterated here in a general context. Further information on the pathogenesis and diagnosis of most infectious and parasitic conditions is found in the next section.

Diarrhea in neonatal ruminants, swine, and horses

Diarrhea causing dehydration, metabolic acidosis, and electrolyte depletion is an important cause of morbidity and mortality in neonatal piglets, calves, lambs, and kids, and to a lesser extent in foals. Some classes of agents occur in most species of large animals, and mixed infections may occur; these include *Escherichia coli*, coronavirus, rotavirus, and *Cryptosporidium*. These, and some other less common agents, produce diarrhea in neonatal animals, the etiology of which cannot be readily differentiated on clinical grounds or on the basis of gross examination at necropsy.

Undifferentiated diarrhea of neonatal animals requires etiologic diagnosis if appropriate advice is to be rendered on prevention and management of the problem. Many of the agents involved are transiently present, or produce villus atrophy that is obscured by autolysis, hindering diagnosis. To overcome these obstacles, *one or more live untreated animals in the early phase of clinical disease, and representative of the herd problem, must be examined.* They should be killed and examined immediately using a necropsy procedure modified so that specimens of small intestine are fixed within a few minutes of death, and so that appropriate samples of tissue and content are quickly collected for etiologic investigation.

The presence of specific microscopic lesions, and their distribution in the intestine, may suggest an etiology. Culture or application of rapid immunologic methods to gut content and fixed or frozen tissues may identify a bacterial or viral agent. *Cryptosporidium* and coccidial agents may be identified in Giemsa-stained mucosal scrapings as well as in tissue sections. The prevalence of diarrhea in neonates, and the main agents associated, can be expected to vary considerably on the basis of locality, climate, and season, and the management system, as well as by species.

In all species, neonatal animals succumbing to the effects of undifferentiated diarrhea are overtly *dehydrated.* The eyes are sunken in the orbits, the skin lacks elasticity, and the subcutis is tacky. There is usually fecal staining on the perineum, but a rare acute case may dehydrate without significant diarrhea. Scouring animals may continue to suck during the early phase of their illness, a milk clot or curd may be present in the stomach, and internal fat depots may be adequate. Animals that lose interest in feed due to more chronic disease, and those taken off nutrients, may have serous atrophy of fat and appear cachectic. The small intestine is flaccid, dilated, and often thin-walled, and fluid content is present throughout the full length (Fig. 1.83). The content is usually watery and clear green-yellow. It often separates into two phases, the more solid of which appears to consist of small masses of clotted milk or mucus. Sometimes the content is more homogeneous and creamy in texture. In animals examined some time after spontaneous death, this appearance is due to postmortem slough of epithelium. The large intestine similarly contains fluid, creamy or pasty content, usually white or yellow. The mucosa of the small intestine may appear glistening and mildly congested; that in the large intestine is usually unremarkable. The forestomachs in ruminants that have been tube-fed, or in which the reticular groove has apparently failed to close, may contain sour fermented milk or milk replacer and the mucosa may be mildly reddened. The abomasal mucosa of some calves may contain scattered focal stress-associated hemorrhages. In piglets, urates, precipitated as the result of dehydration, may be present in the renal medulla and pelvis.

In each species, undifferentiated diarrhea of neonates may be caused by other agents, in addition to the common bacterial, viral, and protozoal causes cited above. Conditions distinguishable at necropsy from undifferentiated diarrhea, and caused by a further array of pathogens, are also found in most species. The spectrum of agents associated with diarrhea in neonates of each species will be considered below.

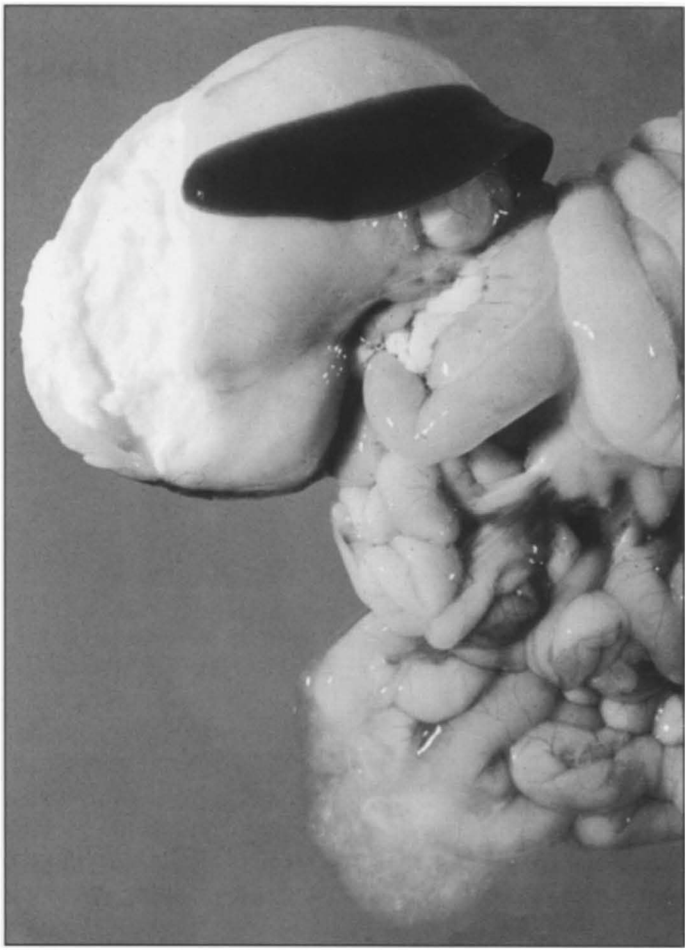

Figure 1.83 The stomach and intestines of a piglet with **undifferentiated neonatal diarrhea**; clotted milk fills the stomach, the small intestine is flaccid, and filled by floccular fluid content, with no gross evidence of inflammation.

Diarrhea in calves

About 10 infectious agents have been associated with undifferentiated diarrhea in calves under about 3 weeks of age, and a further four or five syndromes associated with diarrhea in neonates can often be recognized at necropsy. Frequently, combinations of several of these agents occur together, or in sequence. The consequences of combined infections experimentally often appear to be more severe than infections with individual agents. The diagnosis of these infectious problems in a herd can be complex, and examination of more than one animal early in the course of disease is desirable. Noninfectious diarrhea and emaciation, resulting from the use of nutritionally inadequate milk replacers containing heat-denatured protein, must also be considered and eliminated when examining artificially reared animals.

Enterotoxigenic *E. coli* *is probably the most common single cause of undifferentiated neonatal diarrhea in calves.* Little or no overt morphologic change may be evident in tissue section, though bacteria are seen attached to the surface of enterocytes on villi. The disease usually occurs within the first week of life, and is confirmed by specific immunofluorescent techniques in smears and frozen sections, or by culture and characterization of the organism as enterotoxin-producing. Enterotoxigenic colibacillosis is distinct from the less-common **enteropathogenic colibacillosis**, caused by attaching-effacing organisms, and from **septicemic colibacillosis** and other gram-negative infections occurring in hypogammaglobulinemic neonates. Occasional cases of **enterohemorrhagic colibacillosis**, caused by **Shiga toxin-producing *E. coli*** and producing fibrinohemorrhagic enterocolitis, occur in calves, usually in the second week of life.

Bovine coronavirus and ***Rotavirus*** are responsible for a significant proportion of neonatal calf diarrhea, alone, together, or in combination with other agents. Disease due to these viruses may begin at any time in the first 1 or 2 weeks of life. Both produce villus atrophy by causing lysis or exfoliation of surface enterocytes. *Bovine coronavirus* also commonly causes microscopic, and occasionally gross, lesions in the colon. Both agents may be confirmed by demonstration of virus in feces, or viral antigen in infected epithelium.

Cryptosporidium, a minute apicomplexan protist, is commonly associated with undifferentiated diarrhea and villus atrophy in calves. It is most common in animals about 4–20 days of age. Cryptosporidia are recognized in the brush border of epithelium on villi, and in mucosal smears and fecal smears or flotations.

Giardia, a flagellate protist, has been implicated as an etiologic agent in diarrhea of calves and other young ruminants, but giardiosis is infrequently diagnosed in this context.

Bovine torovirus (Breda virus 2), in genus *Torovirus*, family Coronaviridae, has been recovered from diarrheic calves; though antibody is common in some surveys, disease seems rare. The pathogenesis and lesions caused by the Breda agent are similar to other coronavirus infections, though some crypt cell necrosis is reported in the small intestine.

Astrovirus infections usually appear to be subclinical, and their implication as a cause of diarrhea in calves is rare. Astrovirus infects enterocytes on the villus surface, causing lysis or exfoliation of cells, and transient villus atrophy. Several **noroviruses** (family Caliciviridae, genus *Norovirus*; formerly "Norwalk-like viruses"), or bovine enteric caliciviruses (BEC), have been identified from the feces of diarrheic calves, including norovirus Jena, Newbury agents 1 and 2, and the Nebraska BEC.

Enteroviruses are commonly isolated from the feces of clinically normal animals, and they are likely not associated with significant disease, though diarrhea has occurred in some experimental studies. **Birnavirus** has also been isolated from the feces of diarrheic calves, but with no proof of pathogenicity.

A **bovine enteric syncytial virus**, a group B rotavirus, was identified as a cause of diarrhea in calves in a beef herd. Experimentally, it causes diarrhea, and distinctive syncytia formed by enterocytes on the sides of villi are present in tissue sections of the small intestine.

Bovine parvovirus infects cells in crypts of Lieberkühn in the small and large bowel, and may cause mild to moderate diarrhea, particularly in the postweaning period. Mild necrosis and exfoliation of cells in crypts may occur in the small intestine, with some villus atrophy and fusion.

Bovine viral diarrhea virus can be implicated in enteritis of calves as young as a week or so of age, on the basis of microscopic lesions in the small intestine and colon similar to those found in older animals, and by virus isolation, or antigen or genome identification.

Chlamydophila* infection** is very rarely recognized in association with enteritis. It may be acutely necrotizing and exudative microscopically. ***Strongyloides infection may also cause villus atrophy and diarrhea in calves as young as 2–3 weeks of age. Enterotoxigenic ***Bacillus fragilis*** has been suggested as a cause of diarrhea in neonatal calves, but its role is unproven.

A number of other syndromes are usually distinguishable on the basis of gross lesions at necropsy in diarrheic calves. ***Clostridium perfringens* types B and C** are usually associated with acute hemorrhagic enteritis and dysentery; infection with these organisms is rare.

Salmonellosis, usually due to *Salmonella* Typhimurium, or perhaps *S.* Dublin or *S.* Muenster in enzootic areas, occurs in calves as young as 4 or 5 days of age. It is especially common in stressed calves weaned to milk replacer and moving through sales barns as vealers. Salmonellosis may mimic undifferentiated neonatal diarrhea, perhaps in association with rotavirus, coronavirus, or *Cryptosporidium*. Or it may cause acute fibrinous enterocolitis, with septicemia in a proportion of cases.

Bovine herpesvirus 1 (infectious bovine rhinotracheitis virus) in calves under 2 weeks of age may produce gastrointestinal lesions associated with generalized infection; more commonly the enteric lesions occur alone or dominate the picture. Characteristic foci of necrosis in the mucosa of the forestomachs, perhaps associated with focal ulceration of the abomasum and crypts of Lieberkühn, are the typical findings.

Mycotic rumenitis and abomasitis are complications secondary to infectious bovine rhinotracheitis in calves, or possibly following abomasal venous infarction in salmonellosis.

Diarrhea in other neonatal ruminants

Undifferentiated diarrhea in neonatal lambs is mainly associated with enterotoxigenic ***E. coli***, ***Rotavirus*** and ***Cryptosporidium***; ***Giardia*** may contribute, but its significance is poorly defined. **Astrovirus** has been found in lambs and experimentally produces diarrhea. An **adenovirus** antigenically related to *Ovine adenovirus-2* is reported as a cause of enteritis in goat kids. **Salmonellosis** may occur rarely in young lambs. **Septicemia** is more commonly associated with certain serotypes of ***E. coli***, which may be the cause of "watery mouth" in lambs. ***Bacteroides fragilis***, producing enterotoxin, has been implicated as a cause of diarrhea in neonatal lambs. Causes of undifferentiated diarrhea in young goats are poorly defined, but the problem appears to be minor under usual conditions of husbandry. A similar spectrum of agents may be expected and sought.

Lamb dysentery, due to *Clostridium perfringens* type B in lambs and kids under 8–10 days of age is usually recognized at necropsy as severe hemorrhagic enteritis, occasionally with necrotic ulcers.

Coccidiosis due to *Eimeria* spp. in lambs and in kids may occur in animals as young as 3 weeks of age. Raised white plaques or polypoid masses of infected epithelium are found in the terminal ileum, perhaps associated with hemorrhage.

Strongyloides may also be associated with diarrhea in ruminants only a few weeks old.

Diarrhea in neonatal swine

The agents commonly implicated in undifferentiated diarrhea in piglets under 3 weeks of age are enterotoxigenic ***E. coli***, coronavirus (transmissible gastroenteritis), *Rotavirus*, and *Isospora suis*.

Enterotoxigenic colibacillosis typically occurs in piglets under a week of age, and causes no specific gross or microscopic lesions, other than organisms adherent to the brush border of enterocytes. **Rotavirus** and ***Transmissible gastroenteritis virus*** (TGEV, coronavirus) infections cause villus atrophy, in contrast to most types of *E. coli*. ***Isospora suis*** tends to occur in piglets over 5–6 days of age. It is associated with villus atrophy, and in a minority of cases, necrotic enteritis in the distal small intestine. Meronts or gamonts may be found in mucosal smears, and in epithelium on atrophic villi in section.

A number of other agents are less commonly associated with undifferentiated neonatal diarrhea in pigs. ***Porcine epidemic diarrhea virus*** (coronavirus 777) infection is similar to TGEV infection. **Nongroup A rotaviruses**, antigenically distinct from group A *Rotavirus*, produce similar lesions experimentally; group B cause epithelial syncytia, in addition. **Adenovirus** infection, most commonly evident as intranuclear inclusion bodies in epithelium on the dome over Peyer's patch in tissue sections, may be implicated as a cause of villus atrophy in occasional cases. **Enteroviruses**, **astroviruses,** and **calicivirus** have poorly defined significance as pathogens in piglets, though a calici-like virus causes villus atrophy in gnotobiotic pigs. ***Cryptosporidium*** infects the large and small intestine in swine, where it seems to play a minor role as an enteric pathogen. ***Salmonella*** and ***Klebsiella***, though rarely implicated as pathogens, can cause villus atrophy and diarrhea in neonatal pigs, and some strains of ***E. coli*** with the same capacity are rarely encountered. ***Bacteroides fragilis*** is also rarely associated with diarrhea. None of these bacterial infections are common in piglets. ***Strongyloides ransomi***, transmitted in the milk, may infect young piglets, causing villus atrophy, malabsorption, protein loss, and diarrhea.

Hemorrhagic and necrotizing enteritis due to ***Clostridium perfringens*** type C in piglets in the first week of life is readily recognized at necropsy. ***C. difficile*** also causes diarrheal disease in piglets in this age group, with a distinct suite of gross and microscopic lesions.

Diarrhea in foals

In the young foal, undifferentiated diarrhea may be associated with ***Rotavirus***, ***Cryptosporidium***, and ***Strongyloides***. Enterotoxigenic *E. coli* and coronaviruses are not proven pathogens in foals. ***Actinobacillus equuli*** may cause severe diarrhea and hemorrhagic enteritis, with lesions of bacteremia evident in other organs at necropsy. **Salmonellosis** in foals may be seen as fatal diarrhea with few gross lesions, or as fibrinous enterocolitis and septicemia, similar to that seen in older horses. ***Escherichia coli*** and ***Klebsiella pneumoniae***, with occasional gram-positive infections, are common causes of neonatal septicemia, predisposed by failure of passive transfer of immunoglobulin. Fibrinonecrotic enterocolitis in foals under a week of age may be due to ***Clostridium perfringens* type B or C**, or ***C. difficile***. ***Rhodococcus equi*** may cause chronic diarrhea and wasting in foals. Pyogranulomatous ulcerative lesions of the large bowel, and purulent mesenteric lymphadenitis, often associated with chronic purulent bronchopneumonia, are characteristically found in *R. equi* infection. ***Enterococcus* (*Streptococcus*) *durans***, an enteroadherent coccus, has been associated with diarrhea in foals. Moderate atrophy of villi covered with adherent gram-positive cocci is characteristic; the large bowel is not colonized. ***Strongyloides westeri*** is capable of causing diarrhea in young foals occasionally. **Tyzzer's disease**, which is restricted to foals under about 6 weeks of age, may be associated with diarrhea. However, the liver lesion dominates the pathologic picture.

Gastroenteritis in cattle over 3 weeks of age

Acute or subacute gastroenteritis associated with systemic disease and, usually, upper alimentary lesions, may be due to **bovine viral diarrhea/mucosal disease**, **rinderpest**, and **malignant catarrhal fever**. In the latter disease, lymphadenopathy occurs, and gross lesions may be expected in other organ systems. **Acute salmonellosis** occurs as enterocolitis with enlarged mesenteric lymph nodes, but without upper alimentary lesions. **Arsenic poisoning**, **oak poisoning**, and consumption of **mustard seed** or **superphosphate fertilizer** may cause acute hemorrhagic gastroenteritis. Acute diarrhea and enterocolitis, sometimes hemorrhagic, may be caused by **adenovirus** infection in calves and feeder animals. **Coccidiosis** in calves over 3 weeks of age and older cattle usually causes dysentery and fibrinohemorrhagic typhlocolitis. **Winter dysentery**, an erosive colitis caused by *Bovine coronavirus* infection, is only occasionally fatal. Diarrhea due to **grain overload** is associated with lesions of chemical rumenitis and usually with a history or evidence of excess carbohydrate intake. **Hemorrhagic bowel syndrome** (jejunal hemorrhage syndrome) with segmental jejunal mucosal necrosis and hemorrhage, and functional or mechanical obstruction of the gut causing severe abdominal discomfort of sudden death, is discussed with *Clostridium perfringens* type A, with which it has been circumstantially associated.

Gastrointestinal parasitism may be associated with acute or chronic diarrhea and wasting in calves and young cattle at pasture. The nematode fauna is usually mixed, but certain genera of helminths may dominate in particular epizootiologic circumstances. Most important is ***Ostertagia***, which causes abomasitis with mucous metaplasia and hyperplasia. Intestinal nematodes such as ***Strongyloides*** and ***Nematodirus*** may cause diarrhea in calves at pasture or in semiconfinement. ***Trichostrongylus*** and ***Cooperia*** in adequate numbers are commonly pathogenic for pastured animals. ***Toxocara vitulorum*** may have some significance in warm climates.

Enteritis is often not grossly recognized in the small bowel at necropsy of animals with intestinal helminthosis. The pathologist needs, therefore, to have a high index of suspicion to come to a diagnosis in some cases. To make a firm diagnosis of intestinal helminthosis it is necessary to demonstrate substantial populations of nematodes by worm count in intestinal content or digests, and ideally to observe villus atrophy in tissue sections of infected intestine. These findings should be associated with a compatible syndrome – in the case of *Ostertagia*, *Strongyloides*, and the intestinal trichostrongyles, inefficient weight gain or wasting, and usually diarrhea. The hematophagous genera ***Haemonchus*** and ***Bunostomum*** cause anemia and hypoproteinemia, and associated poor growth but without diarrhea. ***Oesophagostomum radiatum***, in the colon, may result in anemia, hypoproteinemia, and diarrhea as well as causing nodule formation in the gut wall. ***Trichuris*** may also cause occasional significant hemorrhagic typhlitis, wasting, and diarrhea.

Subacute-to-chronic diarrhea and poor growth or emaciation in cattle may also be due to **copper deficiency**, **chronic bovine viral diarrhea**, **salmonellosis**, **yersiniosis**, **chronic coccidiosis**, and, in cattle over about 2 years of age, **Johne's disease** (paratuberculosis). **Congestive heart failure** and other causes of portal hypertension may also cause chronic diarrhea in individual animals.

Gastroenteritis in sheep and goats over 3 weeks of age

The major causes of diarrhea and ill-thrift in sheep and goats at pasture are parasitic. The main helminth species causing this syndrome are ***Ostertagia***, ***Nematodirus***, and ***Trichostrongylus***. The genera and species involved vary with the geographic area and climate, and perhaps seasonally, as well as with the age group and other local epizootiologic factors. Larval **paramphistomes** will also cause enteritis in lambs in enzootic areas. ***Strongyloides*** may affect lambs up to several months of age, even those held in confinement. Where it occurs, ***Nematodirus*** is usually a disease of lambs 1–3 months of age. **Trichostrongylosis** usually affects lambs 3 months to yearling age. ***Oesophagostomum columbianum*** may cause significant disease in sheep, as well as causing nodule formation in the intestinal submucosa. ***Trichuris*** typhlitis is an uncommon problem in sheep, as is ***Chabertia*** infection of the colon. ***Bunostomum*** and especially ***Haemonchus*** cause marked anemia and hypoproteinemia without diarrhea. Hemonchosis is a particular problem in lambs and kids at pasture or held in semiconfinement in warm humid climates. It is also important in ewes and does during the postparturient period, or spring, when retarded larvae emerge synchronously from the abomasal mucosa, and mature.

Coccidiosis is a problem mainly in lambs and kids reared in confinement, on feedlot or heavily stocked on pasture. Villus atrophy due to mixed-species infections may be responsible for ill-thrift and diarrhea in older animals, while *Eimeria arloingi* and *E. christenseni* or *E. ovina* and *E. ahsata* may be responsible for mortality in very young kids and lambs respectively.

Acute enterocolitis and septicemia due to ***Salmonella* Arizonae** infection may occur in lambs and sheep. **Yersiniosis** causes fibrinous enterocolitis and caseous mesenteric lymphadenitis. **Grain overload** may cause acute diarrhea in feedlot lambs and in sheep offered supplemental feed. Diarrhea may also be associated with ***C. perfringens* type D enterotoxemia** in sheep and goats, though animals may die very acutely. Where it occurs, ***Peste-des-petits-ruminants virus*** causes acute severe enteritis with upper alimentary lesions in sheep and goats.

Johne's disease causes a syndrome of wasting, usually without diarrhea, in sheep and goats; in goats, caseous mesenteric lymphadenitis may occur. **Schistosomiasis** may cause ill-thrift in sheep in enzootic areas.

Terminal (regional) ileitis of lambs is a syndrome characterized by reduced weight gain, diarrhea, and apparent abdominal pain, usually in 1–4 month-old animals. It is reported from the UK, continental Europe, and North America. At necropsy, animals are typically in poor body condition, with evidence of diarrhea. There is marked enlargement of the caudal small intestinal mesenteric lymph node. The terminal small intestine is thickened, with transmural edema, and a corrugated appearance on the serosal aspect. The mucosa is reddened, and thrown into thick transverse nodular folds. There may be superficial erosion and fibrin exudation. The mucosa of the cecum and spiral colon may also be grossly thickened.

Microscopic lesions are always evident in the ileum, decreasing in frequency and severity with distance cranial and caudal to the ileocecal orifice. In the small intestine, there is moderate to subtotal villus atrophy, associated with hypertrophy of crypts, hyperplasia of crypt epithelium, and a heavy mixed inflammatory cell infiltrate in the lamina propria. Microerosions or ulcers may be present, through which neutrophils exude. In the large intestine, the crypt epithelium is hyperplastic, causing thickening of the mucosa, which is infiltrated by a mixed, mainly mononuclear, inflammatory cell population, and is thrown into folds superficially. Peyer's patches and submucosal lymphoid aggregates are hypertrophic, with lymphoid hyperplasia.

The lesion is compatible with a chronic immunoinflammatory response in the bowel, and it may be due to *Border disease virus*.

Gastroenteritis in swine over 3 weeks of age

Rotavirus and ***Transmissible gastroenteritis virus*** may be responsible for villus atrophy and diarrhea in susceptible pigs of any age, though significant mortality is generally restricted to neonates and nursing pigs. Considerable morbidity but low mortality occur in the later suckling, weanling, and feeder age groups. **Postweaning diarrhea** is associated with villus atrophy of uncertain etiology; it is discussed with villus atrophy in the section on epithelial renewal in health and disease, above. ***Escherichia coli*** causes postweaning enterocolitis, and Shiga toxin-producing strains of *E. coli* produce "**gut edema**," causing sudden death or nervous signs in weaner and feeder pigs. No mucosal lesions are evident, but edema of the gastric submucosa and mesocolon may be found, among other lesions.

Enterocolitis due to ***Salmonella***, ***Lawsonia intracellularis*** infection, **swine dysentery**, and **intestinal spirochetosis** generally occur in weaner and feeder swine, though proliferative hemorrhagic enteropathy, swine dysentery, and intestinal spirochetosis occasionally involve suckling animals older than about 3 weeks of age. The differential diagnosis of these conditions and **trichuriasis** has been discussed previously in the section on typhlocolitis in swine. **Coccidiosis**, other than that in neonates due to *Isospora suis*, is rare in swine. Occasional ileitis or, less commonly, typhlitis is caused by infection with several species of *Eimeria*.

Porcine circovirus type 2 (PCV2) has been associated with watery diarrhea and weight loss, often accompanied by pneumonia, in weaned pigs. Grossly, the mucosa of the distal small intestine and colon is thickened. Microscopically, a prominent lymphoplasmacytic/histiocytic infiltrate is evident in the lamina propria and submucosa. There is lymphocytolysis and atrophy of follicles in gut-associated lymphoid tissue, and irregular basophilic intracytoplasmic inclusions characteristic of PCV2 infection are evident in macrophages in lamina propria and lymphoid tissue. Immunohistochemical staining for circoviral antigen stains these inclusions, which are presumably phagocytosed viral inclusions from lytic-infected lymphocytes. Similar inclusions are evident in bronchiolar epithelium and alveolar macrophages in lungs affected with bronchointerstitial pneumonia. Other lesions characteristic of PCV2 infection, including lymphadenopathy, hepatitis, and interstitial nephritis, are also present.

Hemorrhage into the intestine may occur in **proliferative hemorrhagic enteropathy** and **mesenteric torsion**, and should be differentiated from the melenic content found in animals with **esophagogastric ulcer**.

Ascaris suum may contribute to diarrhea and ill-thrift in weaner and feeder pigs. The thorny-headed worm ***Macracanthorhynchus hirudinaceus*** may, under rare circumstances, cause ill-thrift or intestinal perforation. Submucosal nodules in the intestinal wall may be caused by ***Oesophagostomum*** infections, which are otherwise usually relatively inconsequential in swine. Thin-sow syndrome has been attributed to **gastric hyostrongylosis**.

Enteritis in horses

Most of the significant gastrointestinal diseases of horses are discussed elsewhere, including salmonellosis, *Lawsonia*-associated proliferative enteropathy, clostridial colitis, antibiotic-associated diarrhea, Potomac horse fever, granulomatous enteritis, and parasitism. The reader should consult portions of the chapter dealing with displacements, obstruction, ischemic disease of the bowel, syndromes associated with malassimilation and protein-losing enteropathy, and typhlocolitis, for discussions putting these conditions into a diagnostic context. The capacity of the equine large intestine probably compensates for the additional fluid load posed by diseases of the small intestine that in other species might be expected to produce diarrhea. Horses presented with a syndrome reflecting hypoproteinemia, usually without diarrhea, may have *Lawsonia* infection, chronic salmonellosis, chronic inflammatory bowel disease or granulomatous enteritis, or enteric lymphosarcoma.

"**Proximal enteritis**," also known as *ulcerative duodenitis*, is characterized by signs of upper small intestinal ileus, including depression and nasogastric reflux. There is debate about including ulcerative duodenitis of foals, associated with gastric ulcers, in the syndrome. We do so here, on the grounds of similar lesions in advanced cases.

At surgery or necropsy, there is fibrinous enteritis or ulceration involving the duodenum, and a variable amount of more distal small bowel. The lesions may be segmental and circumferential, only a few centimeters long, or more diffuse, involving much of the small intestine, but sparing the ileum. The affected segment of bowel may be thickened, congested, or hemorrhagic on the serosal aspect, and there may be fibrinous peritonitis with adhesions, and pancreatitis. Perforation may occur. If the lesion is of some standing, there may be significant stricture at the site. Affected animals often have a distended stomach, with abnormally fluid content, and gastric ulcers, particularly of the pars esophagea. Perforation or rupture of the stomach may occur. Duodenal lesions should always be sought in foals with gastroesophageal ulceration.

Microscopically, there is edema and congestion, with progressive necrosis from the tips of villi in early lesions, advancing to mucosal or transmural acute fibrinonecrotic enteritis, grading to the development of granulation tissue and fibrosis in the bed of more chronic ulcerative lesions.

The etiology is undetermined. Clostridia, *Salmonella*, mycotoxicosis, and ischemia associated with the use of nonsteroidal anti-inflammatory agents have been proposed, but not firmly implicated. The segmental, often circumferential, nature of the lesions is compatible with ischemia, perhaps complicated by secondary bacteria.

Fibrinous enteritis in the small bowel may also occur in blister beetle intoxication. Enterocolitis associated with use of nonsteroidal anti-inflammatory drugs is discussed in the section Intestinal ischemia and infarction.

Enteritis in dogs

Rotavirus and ***Canine coronavirus*** infection appear to be causes of uncommon, generally nonfatal, diarrhea in young dogs. A variety of other viral agents have been associated with diarrhea in dogs, usually on the basis of electron microscopic observations or virus isolation from feces. These include **astroviruses**, **adenovirus**, and **paramyxovirus**, as well as **calicivirus** and **herpesvirus** antigenically related to *Feline calicivirus* and *Feline herpesvirus*. The pathogenic significance of these agents is unclear.

Canine parvovirus 2 is by far the most significant cause of gastroenteritis in the dog. It is distinguished by the severe fibrinohemorrhagic enteritis usually evident at necropsy, and the radiomimetic microscopic lesions in the gastrointestinal mucosa, lymphoid, and hemopoietic tissues. Dogs with **canine distemper** often develop diarrhea; *Canine distemper virus* apparently does infect the intestinal cryptal epithelium. However, the enteric lesions of canine distemper have not been well described.

Salmonella infection is common, but salmonellosis and enteritis due to other gram-negative bacteria such as ***Yersinia*** is rare in dogs. **Proliferative enteritis** associated with intracellular bacteria is discussed under *Lawsonia*. ***Enterococcus durans*** has been associated with diarrhea in dogs. "**Salmon poisoning**" in the Pacific Northwest of the USA is due to rickettsial infection transmitted by the fluke *Nanophyetus*.

Hemorrhagic enteritis is associated with **clostridial overgrowth**, and may also be due to **reduced perfusion**, and **coagulation defects**, which may be congenital, part of disseminated intravascular coagulation, or due to anticoagulant rodenticide intoxication. **Castor beans** (*Ricinus communis*) contain ricin, a glycoprotein known to cause gastroenteritis, vomiting, diarrhea, and occasionally death.

Ascarid infection in puppies may be associated with ill-thrift, diarrhea, and, in heavy infestations, occasionally with death. **Hookworms** may cause anemia, hypoproteinemia, and ill-thrift, or, in neonatal puppies, occasional acutely fatal infection. ***Isospora*** infection may cause diarrhea in puppies, and occasional mortality. **Giardiasis** is associated with chronic diarrhea in some dogs.

Syndromes of malabsorption and protein loss associated with granulomatous or eosinophilic enteritis, "filled villi," and lymphangiectasia have been discussed elsewhere. The differential diagnosis of colitis, including idiopathic colitis, parasitic colitis, protothecosis and histoplasmosis, *Campylobacter*, and spirochetal colitis, has been discussed previously in the section on typhlocolitis in dogs. Ulcerating or widely infiltrating **colonic neoplasms** may be associated with diarrhea.

Enteritis in cats

With the exception of **feline panleukopenia**, enteritis in cats is relatively rare. ***Feline leukemia virus*** has been associated with a syndrome of cryptal necrosis in the intestine, resembling panleukopenia, but without lymphoid or bone marrow depletion. **Astrovirus**, enteric **coronavirus**, **calicivirus**, **rotavirus**, and other viruses are reported from the feces of cats, but are only rarely associated with diarrhea, and even less frequently associated with mortality. A **torovirus** has a questionable association with a syndrome of diarrhea and bilateral protrusion of the nictitating membrane. Diarrhea is a common sign in cats with ***Feline immunodeficiency virus*** infection, and may occur in cats with *Feline leukemia virus* infection. Bacterial infections such as **salmonellosis**, **shigellosis**, **yersiniosis**, **helicobacteriosis**, and **Tyzzer's disease** are unusual, as is significant parasitic enteritis due to **helminths**, ***Cystoisospora***, ***Toxoplasma***, ***Giardia***, or ***Cryptosporidium***. Chronic inflammatory small-bowel disease and the forms of colitis occasionally encountered in cats have been considered in previous sections.

INFECTIOUS AND PARASITIC DISEASES OF THE ALIMENTARY TRACT

Viral diseases of the alimentary tract

Foot-and-mouth disease

Foot-and-mouth disease (FMD) is a highly contagious viral infection of all cloven-hoofed animals. It is a problem of worldwide concern, being enzootic in large areas of Africa, Asia, and parts of Europe and South America. Presence of the virus imposes serious trade restrictions that effectively thwart the development of a healthy agricultural economy.

FMD is an acute febrile condition characterized by the formation of vesicles in and around the mouth, on the feet, teats, and mammary glands. The disease is not notable for high mortality, except in sucklings, but morbidity is very high, with a concomitant loss of productive efficiency.

FMD virus (FMDV) belongs to the genus *Aphthovirus* (aphtha = ulcer) in the Picornaviridae family. The virus is highly resistant under many circumstances, but is inactivated by direct sunlight, due to drying and increase in temperature, and by moderate acidity (pH < 5.0). The acid production that accompanies rigor mortis in carcasses and meat inactivates the virus. However, the alteration in pH is not dependable and the virus survives in offal, viscera, lymph nodes, and bone marrow for an indefinite period under refrigeration. Next to the movement of infected animals, contaminated animal products are likely the most common mechanism of spread. It may survive on hay and other fomites for several weeks.

The resistance of FMDV is of epidemiological significance, especially where control policies involve slaughter rather than vaccination. The importance of a carrier state in the epidemiology of FMD is uncertain. The carrier state has been observed in cattle, sheep, goats, and African buffalo (*Syncerus caffer*), but not in pigs. The carrier state may persist for up to 2 years postinfection in cattle, even in animals with a significant level of serum-neutralizing antibody. Sheep and goats are considered to be a frequent inapparent source of dissemination of the virus. African buffalo can carry FMDV for at least 5 years. Field outbreaks have been associated with buffalo–cattle contact in Africa, but these appear to be rare. Although Asian water buffaloes (*Bubalus arnee*) may be affected in FMD outbreaks, it is not known whether they remain carriers.

Of equal importance to the persistence of the virus is its *antigenic heterogeneity and instability*. There are seven principal antigenic serotypes, namely, the classical A, O, and C types, and SAT-1, SAT-2, SAT-3, and Asia-1. These can be distinguished by serologic tests. Six of the seven serotypes (O, A, C, SAT-1, SAT-2, SAT-3) are known to occur in Africa, four (O, A, C, Asia 1) in Asia, and three (O, A, C) in Europe and South America, although recent pandemics are blurring these geographic distinctions. These serotypes are sufficiently different immunologically that *infection with one type does not confer resistance to the other six*. Within these seven major types there are antigenic subtypes, each different, to variable degrees, from the parent type. Generally, the subtypes cross-immunize to a useful degree, but exceptions do arise and become recognizable, especially when vaccination fails. *Antigenic drift* can also be demonstrated experimentally; new subtypes can be produced by passing the virus in immune or partially immune animals, or by growing the virus in vitro in the presence of immune serum. There are presently over 70 distinct antigenic strains of the virus of natural origin.

As well as differences and variability in antigenic characters, strains of the virus differ in virulence, and a given strain is probably able to vary in virulence. Certainly, comparing different outbreaks, there is considerable variation in the severity of the disease produced in a given host species. Virulence also varies among species. Although the vast majority of strains will affect a wide range of species, there have been occasional viruses that show a distinct predilection for one species. An example is the porcinophilic strain that originated in China in the late 1990s and spread to Taiwan, destroying the swine industry there.

The main portal of entry and primary site of viral multiplication are the pharynx and lung. Subsequent to the first round of replication, there is widespread viremic dissemination to surface epithelium, with subsequent development of lesions in sites of mechanical or physiologic stress, such as oral and pedal epithelium, or teats in lactating animals. FMDV probably gains entry to these areas via Langerhans cells, with replication in a contiguous group of cells in the stratum spinosum. The resulting cellular degeneration and lysis result in an **epidermal vesicle**, *which is the hallmark of the disease.*

Virus is present at high titer in the vesicular fluid, and is present in large amounts in expired air from acutely infected animals, which is the main source of spread – pigs in particular liberate large quantities of airborne virus. Virus persists in lesions for 3–8 days after the appearance of significant neutralizing titers in serum, but seldom beyond day 11 of clinical illness. It is believed that FMDV is localized in epithelial cells of the oropharynx during persistent infection, so that virus may be found in esophagopharyngeal fluid for a considerable period of time.

Within a week of development of neutralizing antibody, the titer of virus in circulation declines. Ordinarily, serum antibody titers decline progressively and fairly rapidly. The duration of persistence of antibody is correlated with the initial titer. In general, animals are resistant to reinfection with homologous strains by natural exposure for about 2–4 years; susceptibility increases as the antibody titer declines.

The characteristic **lesions** of FMD are only seen in those animals which are examined at the height of disease. Lesions heal or are obscured by secondary bacterial infection. Lesions develop mainly in areas subject to trauma: the *oral mucosa*, especially the *tongue*; the *interdigital cleft*; and the *teats* in lactating animals. In cattle, there is appreciable loss of weight and the buccal cavity may contain much saliva. In the living animal, there is diffuse buccal hyperemia and mild catarrhal stomatitis, but the hyperemia disappears at death. Vesicles form on the inner aspects of the lips and cheeks, the gums, hard palate, dental pad, and especially on the sides and rostral portion of the dorsum of the tongue. Sometimes they form on the muzzle and exterior nares. The primary vesicles are small, but coalesce to produce *bullae* which may be 5–6 cm across; these bullae rupture in 12–14 hours, leaving an intensely red, raw, and moist base to which shreds of epithelium may still adhere (Fig. 1.84A). The eroded to ulcerated area may be replaced by regenerated epithelium in less than 2 weeks. Secondary infection may complicate this course.

Foot lesions occur in the majority of cases. There is inflammatory swelling with blanching of skin of the interdigital space in ruminants, coronet in swine, and heels in all species a day or so before vesicles form. The swellings persist until the vesicles rupture and the resultant erosions heal; healing may be considerably delayed on the feet. Vesicles may also occur in the other sites, but much less frequently.

A *malignant form of the disease*, without vesiculation, does occur in young animals and occasionally in adults. In these, death is common, due to *myocarditis*. Poorly defined pale foci of variable size are seen anywhere within the ventricular muscle. Although historically referred to as "tiger-heart," these gross lesions are no different from those generated in any other syndrome of severe, acute myocardial damage, but necrosis of fibers may be striking. Chronic lesions include myocardial necrosis and scarring, pancreatitis with acinar necrosis and regeneration. Diabetes mellitus occurs in experimental cases, as does hypophysitis, leading to a constellation of endocrinopathies because of a range of expressions of pituitary dysfunction.

Sheep are, in general, less susceptible than cattle, and the infection runs a milder course, though there may be exceptions. Lesions may not develop. When they do, the *dental pad* is the preferred site in the oral cavity. Lingual lesions tend to occur on the caudal dorsal portion as underrunning necrotic erosions rather than vesicles. These are small and easily missed, and they heal within a few days. *Lameness* may be prominent in acute outbreaks. Typical vesicles develop in the interdigital cleft, on the coronet and bulb of the heel. They may occasionally involve the entire coronet and lead to eventual shedding of the hoof. Vesicles also occasionally occur on the teats, vulva, prepuce, and on the pillars of the rumen. The peracute form with myocardial necrosis may occur in lambs.

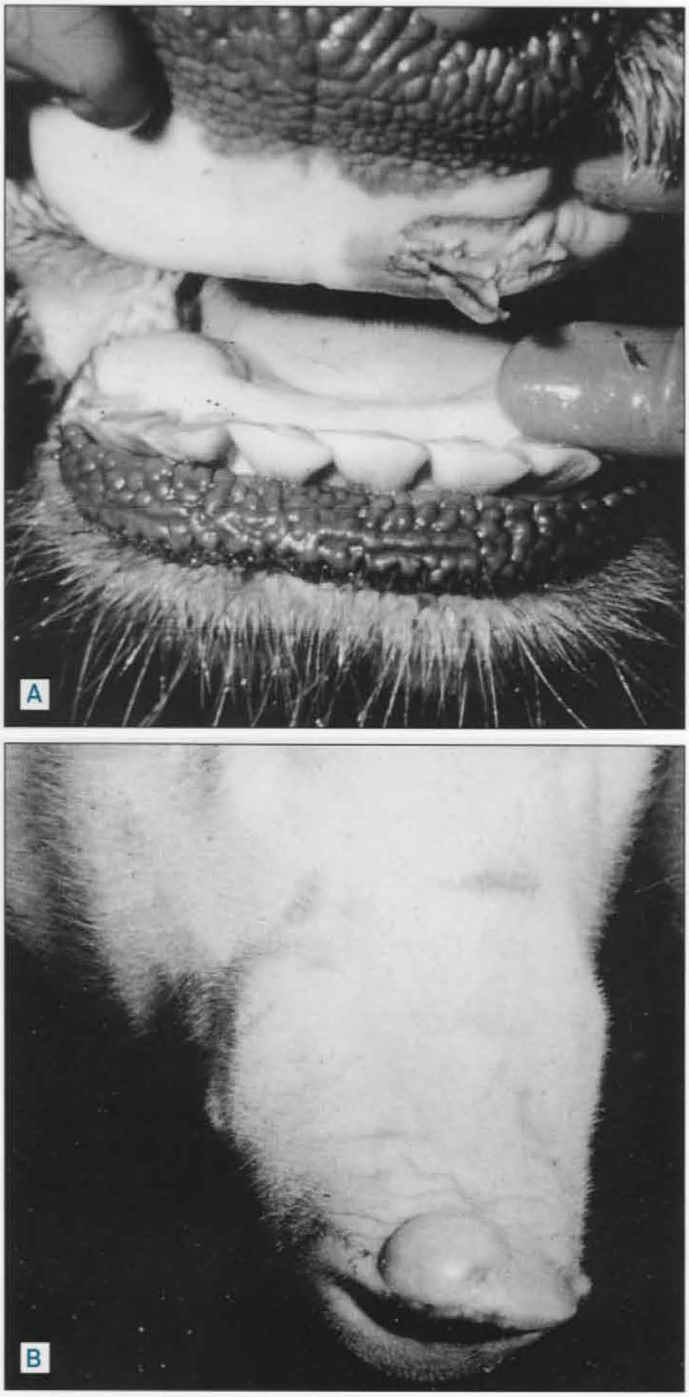

Figure 1.84 Foot-and-mouth disease. A. Ruptured vesicle on the dental pad of a cow. **B.** Vesicle on the snout of a pig.

The disease in **goats** is, in general, similar to that described for sheep. Both species may be inapparent carriers, and many outbreaks worldwide have been due to transport of inapparently infected small ruminants.

In **pigs**, lesions occur in the usual sites, although more commonly on the feet than in the mouth. They may be present on the snout and behind its rim (Fig. 1.84B), and on the teats of lactating sows. Abortion and stillbirth of infected piglets are recorded. The peracute form, with high mortality due to myocarditis, occurs in sucklings, often before vesicle formation is noticed in sows.

FMD must be differentiated from other viral vesicular diseases such as vesicular stomatitis, vesicular exanthema, and swine vesicular disease in susceptible species, and in the latter stages, from diseases producing erosive/ulcerative lesions of the oral cavity. The disease must be considered in the differential diagnosis in cases of sudden death among cloven-footed animals, especially the young. Definitive **diagnosis** requires virus isolation and characterization, demonstration of viral antigen by enzyme-linked immunosortbent assay, or detection of viral genome by polymerase chain reaction or reverse transcriptase-polymerase chain reaction in lesional material. The regulatory status of FMD dictates that this be carried out in accredited laboratories.

Vesicular stomatitis

Vesicular stomatitis (VS) affects horses, cattle, and pigs, and may also affect wildlife species such as white-tailed deer, raccoons, feral swine, and some rodents. In humans, the virus may cause an inapparent infection or a mild influenza-like condition. Experimentally, various rodent species are susceptible and persistence has been demonstrated in hamsters. Also, persistence of viral RNA has been shown in both experimentally and naturally infected cattle, but the reservoir of the virus is unknown. *The disease is important because it causes a loss in production, especially in dairy herds, and it must be differentiated from foot-and-mouth disease in cattle and pigs.* VS is the only vesicular disease naturally occurring in horses. Sheep and goats do not appear to be susceptible to the disease, but a severe, though nonfatal, influenza-like syndrome may occur in infected humans.

VS virus (VSV) belongs to the Rhabdoviridae family, genus *Vesiculovirus* (type species: *VS Indiana virus* (VSIV)). It is an enveloped single-stranded RNA virus, bullet-shaped and about 80 × 120 nm. Apart from being inactivated by pasteurization temperatures, it shares qualities of resistance with the aphthoviruses. There are several serologically and immunologically distinct types of virus based on epitopes of the surface glycoproteins, including New Jersey, Indiana, Piry, Isfahan, and Chandipura. The two most common serotypes of VSV infecting domestic animals in the Americas are New Jersey and Indiana.

VS is enzootic in Central and South America and occurs sporadically elsewhere in the Americas. It has a seasonal occurrence; outbreaks occur in the warmer seasons and usually cease with the onset of cold weather. The seasonal nature of the disease suggests that it is transmitted by *insects*; however, insect transmission is not essential and *contact transmission* has been proven experimentally. VSV has been isolated from both biting and nonbiting insects and black flies have transmitted the virus to pigs. Biting insects most likely become infected from feeding on lesions rather than blood, since viremia is transient, if present. Nonbiting insects act as mechanical carriers of the virus. It is not known how the virus spreads from one geographic area to another. There is some indication that VSVs adapt to specific regions, developing distinct genotypes based on specific vectors or reservoirs in an ecological area. The intact mucosa is resistant to infection, but abrasions in a susceptible site readily result in infection when contaminated with saliva or exudate from a lesion. Environmental factors that increase the chance of causing abrasions to the skin, teats, or oral mucosa may predispose to infection.

Morbidity in lactating dairy cows may be as high as 100%, although only about 60% of the affected animals drool or froth around the mouth. The lesions of VS occur mainly on the *oral mucosa*; occasionally they do occur elsewhere, including on the *feet*, and in swine, foot lesions are common. This is by no means a dependable feature, and outbreaks of the disease in cattle have been described in which the lesions were predominantly on the *teats*.

The incubation period following exposure by abrasion is 24–72 hours and the viremic phase seems to be short-lived, because the virus cannot be cultured from blood. Secondary lesions are rare. In cattle, intramuscular injections will not initiate the disease, a distinguishing feature from foot-and-mouth disease. After experimental infection of swine, infectious viral particles can be recovered from a wide variety of tissues within 6 hours postinfection, including salivary gland, tonsils, snout, skin, and lymph nodes. However, infective virus, viral antigens, and nucleic acids cannot be demonstrated 6 days postinfection.

Specific serum neutralizing antibodies persist for months in swine and years in cattle. There is no evidence that animals with persistent antibodies may act as a source of infection to herd mates. Animals are immune against the homologous but not the heterologous strains of the virus.

The lesions of VS are indistinguishable from those of foot-and-mouth disease (Fig. 1.85A). Initially, in cattle, there is a raised flattened pale-pink to blanched papule a few millimeters in diameter in or near the mouth. These papules rapidly become inflamed and hyperemic. In the course of a day or so, they develop into vesicles 2–3 cm in diameter and by coalescence may involve large areas. The shallow erosions which follow rupture of vesicles heal within 1–2 weeks unless secondary infections occur; in the mouth, the latter are common. Oral and mouth lesions heal rapidly in swine, but coronary band lesions often become secondarily infected to the point where the claw may separate and slough. Serous rhinitis, with the development

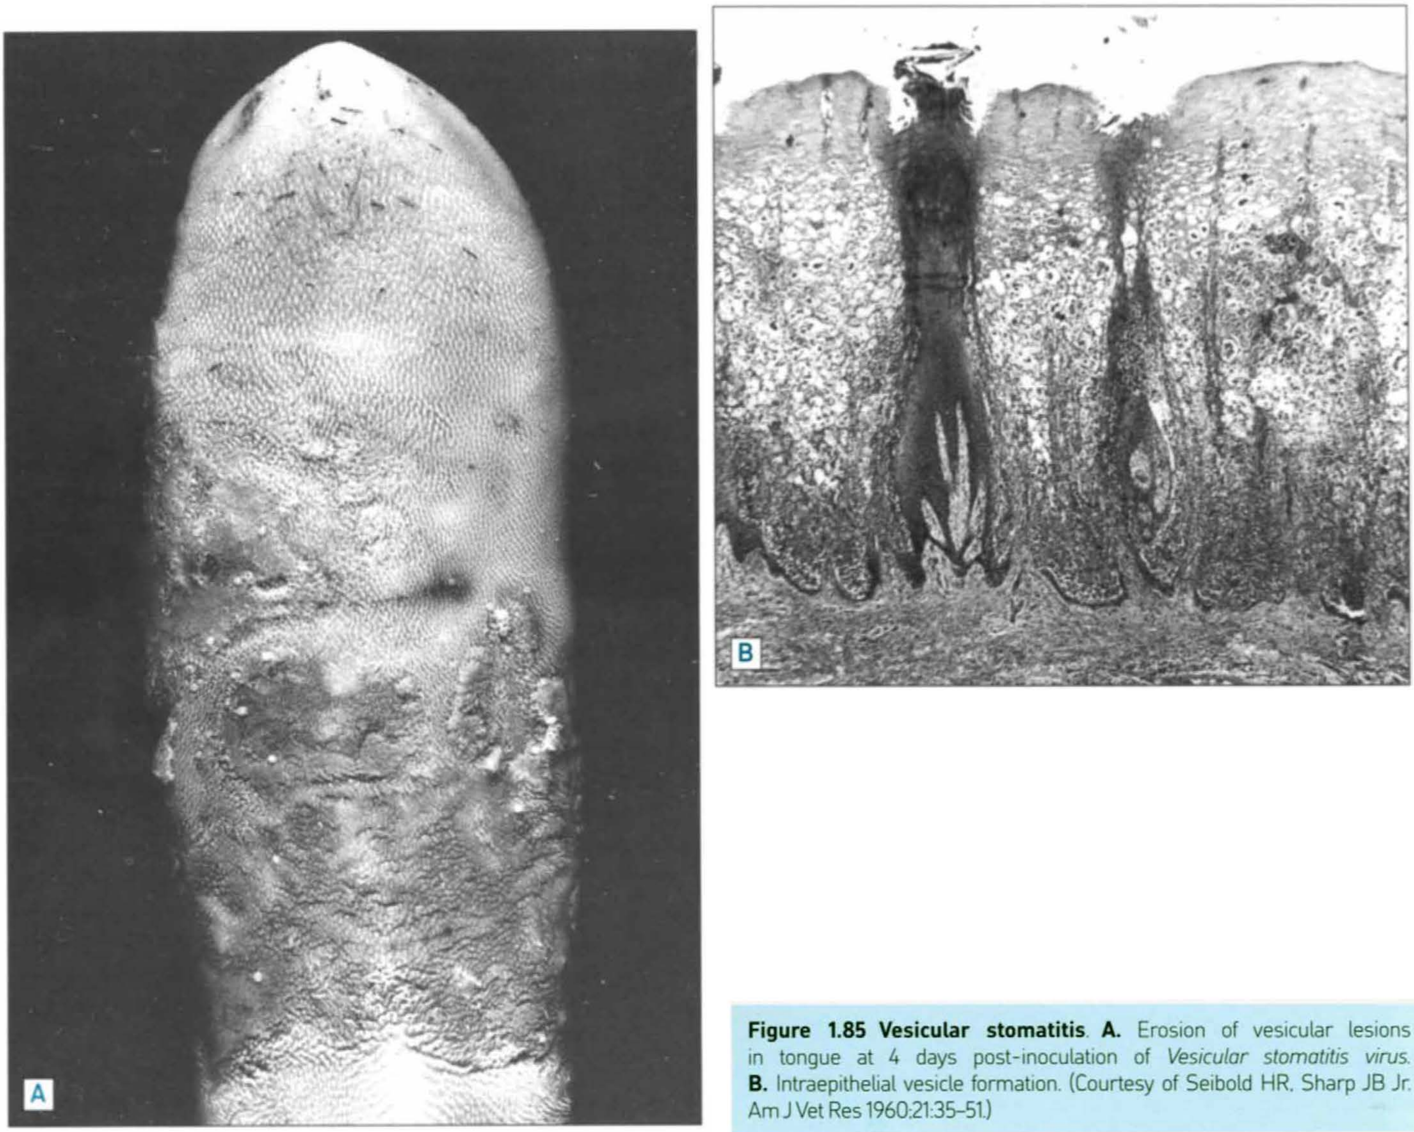

Figure 1.85 Vesicular stomatitis. A. Erosion of vesicular lesions in tongue at 4 days post-inoculation of *Vesicular stomatitis virus*. **B.** Intraepithelial vesicle formation. (Courtesy of Seibold HR, Sharp JB Jr. Am J Vet Res 1960;21:35–51.)

of tags of necrotic mucosa, has been described in experimentally infected swine.

The first microscopic changes are seen in the deeper layers of the stratum spinosum, where the virus replicates. Increasing prominence of the intercellular spaces and stretching of the desmosomes are accompanied by a reduction in volume of the cell cytoplasm (Fig. 1.85B). This dissociation of cells proceeds to distinct intercellular edema (*spongiosis*) followed by further cytoplasmic retraction until the affected epithelial cells float freely in enlarging vacuoles which in turn are loculated by strands of cytoplasmic debris (Fig. 1.86). There is no hydropic degeneration of the epithelial cells and the nuclei until now remain normal. *There are no inclusion bodies.* With the onset of epithelial cell necrosis there is a pleocellular inflammatory reaction in the mucosa and underlying lamina propria. Electron microscopic examination of epithelial cells adjacent to the vesicles confirms the intercellular edema and keratinocyte necrosis seen under the light microscope. The microscopic appearance of the lesions is not diagnostic.

In light of the similarity of VS to foot-and-mouth disease, *laboratory confirmation of VS is essential.* Vesicular fluid and mucosa from the tongue are good sources of the virus. *Diagnosis* is accomplished through virus isolation in tissue culture or embryonated eggs, fluorescent antibody techniques, complement fixation to identify viral antigen, polymerase chain reaction, and inoculation of suckling mice.

Vesicular exanthema of swine

Vesicular exanthema (VE) of swine is an acute, febrile disease of swine that is characterized by formation of vesicles on the snout, mouth, nonhaired skin, and feet. *The lesions are indistinguishable from those of foot-and-mouth disease, vesicular stomatitis, and swine vesicular disease.* VE of swine was first diagnosed in California in the 1930s and eventually spread to most swine-producing states in the USA. An eradication campaign was undertaken and the last reported outbreak of VE was in New Jersey in 1956.

VE of swine virus (VESV) is the type species of the genus *Vesivirus*, family Caliciviridae. It has a single-stranded RNA genome and has only one major polypeptide. It is about 35–40 nm in diameter and characteristic cup-shaped structures (calyces) are evident in electron microscopic preparations. There are 13 immunologically distinct serotypes, which vary in virulence.

In 1973, a virus that is biophysically and morphologically similar to VESV was recovered from sea lions (*Zalophus californianus*) with vesicles on their flippers, off the coast of California near San Miguel island. Several strains of this virus, called *San Miguel sea lion virus* (SMSV), produce milder but otherwise identical lesions to those of vesicular exanthema when inoculated into swine, and SMSV is classified as a serotype of VESV. The host range of SMSV is very broad. One serotype, SMSV-7, has been isolated from opaleye fish (*Girella nigricans*) and it produces lesions identical to VE when inoculated into swine, with horizontal transmission to contact swine. It is now thought that VE of swine arose through the feeding of ocean fish to swine, with some adaptation of the virus allowing for very efficient spread through swine.

Most outbreaks of VE were associated with feeding of raw garbage containing pork waste, indicating that the disease was transmitted by direct contact and fomites. VESV now exists only as viral stocks archived in freezers and should be considered a *disease of historical significance only*. The possibility of a recurrence remains, however, if swine are fed uncooked tissues from ocean-origin fish or marine mammals.

Swine vesicular disease

Swine vesicular disease (SVD) is a highly contagious viral disease of pigs that is characterized by formation of vesicles around the coronary bands and heels of the feet, and, to a lesser extent, on the mouth, lips, tongue, and teats. *Clinically, the disease is indistinguishable from the other vesicular diseases of swine*, including foot-and-mouth disease, vesicular stomatitis, and vesicular exanthema of swine.

The disease was first recognized in Italy in 1966 and it has since been reported from Hong Kong, the UK, continental Europe, and Asia. The economic importance of SVD is related less to the rather limited losses in production and more to the fact that it is difficult to differentiate from other vesicular diseases and hence restricts trade.

Swine vesicular disease virus (SVDV) is a small RNA virus that belongs to the family Picornaviridae, genus *Enterovirus*. It is a porcine variant of Human coxsackievirus B5, which is a serotype of *Human enterovirus B*. SVDV is highly resistant to environmental factors. Unlike foot-and-mouth disease virus, it is not inactivated at the low pH in muscle commonly associated with rigor mortis.

Many outbreaks of SVD appear to originate by feeding raw garbage containing pork products. Transmission within and among affected herds is by direct contact, especially during the early stages of the disease, or by exposure to the virus in the environment, where it is very persistent. The portal of entry is most likely oral or by exposure of excoriated skin. Following contact with infected pigs, vesicles develop within 2 days and consistent virus isolation from tonsil is possible for 1–7 days. Viremia lasts for 2–3 days. SVDV has a strong affinity for the epithelial cells of the coronary band, tongue, snout, lips, lymphoid follicles of the tonsils, myocardial cells, and brain. Virus titers in tissue decrease with the appearance of circulating antibodies, which peak after 2–3 weeks and apparently persist for years. Secretions and excretions have high viral titers for a period of 12–14 days. Feces may contain virus for up to 3 months.

There is some evidence that pigs may become carriers, with stress reactivating viral shedding several months postinfection.

Clinically, *vesicles are most common on the feet*. Oral lesions occur in only about 10% of affected pigs. The foot lesions appear first at the junction between the heel and the coronary band. Initially, there is a 5-mm wide, pale, swollen area that encircles the digit. In later stages a 1-cm wide band of necrotic skin is located along the coronet. Vesicles on the mouth, lips, and tongue occur in clusters and they are small, ~2.0 mm in diameter, white, and opaque. They coalesce and rupture within 36 hours and may be covered by a pseudodiphtheritic membrane due to secondary bacterial infections. Affected pigs usually recover in 2–3 weeks.

The development of vesicles tends to follow a similar course as that reported for foot-and-mouth disease. The virus infects individual epithelial cells in the stratum spinosum, which leads to focal areas of keratinocyte degeneration and vesicle formation. There is an intense leukocytic reaction in the necrotic areas, which is mainly neutrophilic. As with the other vesicular diseases, after 1 week there are indications of epithelial regeneration.

Nervous signs and lesions of *nonsuppurative meningoencephalomyelitis* have been reported in field outbreaks and reproduced experimentally in SVD. Lesions involve most areas in the brain and sometimes spinal cord, and are centered on ganglia and spinal nerve roots. Clinically, the severe lameness tends to overshadow any nervous signs that might be present.

Laboratory diagnosis depends on demonstration of the agent by virus isolation, antigen capture enzyme-linked immunosorbent assay or polymerase chain reaction, in accredited laboratories, on account of its regulatory status.

Bovine viral diarrhea

Bovine viral diarrhea virus (BVDV) is an RNA virus of the *Pestivirus* genus in the family Flaviviridae. It is widespread in cattle populations and it or closely related viruses can infect most even-toed ungulates, including swine. As an RNA virus, BVDV is highly mutable, due to the error-prone nature of the RNA polymerases responsible for replication of viral RNA. As a result, "swarms" of viral mutants form "quasispecies" that circulate within an infected individual and among individuals in a population. While most quasispecies lack a selective advantage, or suffer deleterious point mutations, preventing them from becoming dominant, the ability to generate mutants enables BVDV to adapt to host responses, and to establish chronic or persistent infections in some circumstances. While low virulence would seem to promote prolonged viral shedding, there may be advantages in high virulence that favor the emergence of quasispecies capable of causing severe disease and high virus shedding.

Point mutation and recombination have produced a number of genotypes of *Pestivirus*, including *Classical swine fever virus* and *Border disease virus*. Two genotypes of BVDV occur, **type 1** (BVDV-1) and **type 2** (BVDV-2), each of which has a number of closely related subgenotypes, many of which circulate widely. Viral genotype may be linked to specific manifestations of BVDV infection; noncytopathic (NCP) BVDV-2 has been associated with thrombocytopenia, for instance. However, there is a range of virulence among both type BVDV-1 and BVDV-2 isolates, varying from subclinical infections or mild clinical disease to severe fatal syndromes.

Recombination of RNA from homologous (BVDV) or heterologous (other viral or host) sources, usually involving the region encoding the nonstructural protein NS2–3 of noncytopathic virus, results in a shift in biotype of either genotype of virus, from the more common **NCP biotype**, in which inapparent persistent infection is produced in cultured cells, to a **cytopathic (CP) biotype**, capable of inducing cytoplasmic vacuolation and apoptotic death of cells in tissue culture. Recombination splits NS2–3, resulting in a small NS3 protein, which induces apoptosis, and is a marker for CP BVD viruses. Reversion of CP viruses to an NCP biotype also occurs, less commonly. *Cytopathogenicity in vitro is not directly related to virulence in vivo.*

BVDV gains access to the oropharyngeal mucosa by ingestion or inhalation, and primary replication is in oropharyngeal lymphoid tissues, including tonsils. The outcome of the ensuing viremia is a product of the genotype and virulence of the virus, the immune status of the host, whether or not the animal is pregnant, and, if so, the stage of pregnancy.

Infection of immunocompetent, seronegative, nonpregnant animals usually results in subclinical infection or mild clinical disease. Affected animals develop a slight fever, leukopenia, and specific neutralizing antibodies, the outcome in 70–90% of BVDV infections. In a few situations, animals, mainly over 6 months of age, develop a more obvious clinical syndrome, with a high morbidity and low mortality – classical **bovine viral diarrhea (BVD)**. The infecting agent is usually an NCP BVDV. After an incubation period of 5–7 days, the affected animals develop a fever, leukopenia, and viremia that may persist up to 15 days. The virus is present in leukocytes (buffy coat), especially lymphocytes and monocytes, and in plasma. There is a transient decrease in the number of B and T lymphocytes and a decline in responsiveness to mitogen stimulation. Clinically, the disease is characterized by lethargy, anorexia, mild oculonasal discharge, and occasional mild oral erosions and shallow ulcers. Diarrhea may occur. In dairy herds there is a transient drop in milk production. Affected animals develop neutralizing antibodies that peak in 10–12 weeks, and probably are immune for life.

A syndrome of **severe acute BVD**, characterized by high morbidity and mortality in all age groups of susceptible animals, has been recognized since the early 1990s. Sometimes termed "BVD type 2," since it is caused mainly, though not exclusively, by primary infections with type 2 virus, this syndrome usually has a peracute to acute course, with fever, sudden death, diarrhea, or pneumonia. It should be noted that not all BVDV-2 isolates are highly virulent. In some cases a **thrombocytopenic syndrome**, characterized clinically by epistaxis, hyphema, mucosal hemorrhages, bleeding at injection sites, and bloody diarrhea, is superimposed on the alimentary syndrome caused by type 2 BVDV, or occurs independently. The pathogenesis of BVD type 2 is most frequently linked to increased strain virulence. However, production of inflammatory cytokines, in response to widespread infection of mononuclear phagocytes, has also been postulated as a cause for the severe disease seen clinically. The mechanism of thrombocytopenia is not completely defined, although infected megakaryocytes in the bone marrow undergo necrosis.

Fetal infections may occur in pregnant immunocompetent seronegative acutely infected females, and in persistently infected counterparts. The outcome of fetal infection is primarily dependent on the stage of gestation. The most serious consequences occur if an NCP BVDV crosses the placental barrier during the first 4 months of gestation. It may result in fetal resorption, mummification, abortion, congenital anomalies, or a persistently infected calf. If the calf survives, it remains viremic for life, and it is also immunotolerant to homologous NCP BVD viruses, due to failure of the immature fetal immune system to recognize the infecting viral antigens as "not-self" or foreign.

Persistently infected (PI) calves may be clinically normal, weak, or undersized at birth. They may appear normal, but are often unthrifty, and may have a rough or curly hair coat. The prevalence of these calves in a herd is usually less than 2%, but may be as high as 25–30% in herds where a large number of naive cows, early in pregnancy, have been exposed to NCP BVDV. *Most PI calves succumb to mucosal disease* (see below), usually between the ages of 6 months and 2 years. The offspring of the few animals that reach sexual maturity and become pregnant are also persistently infected, which can result in families of animals persistently infected with BVDV. PI animals are viremic, and lack antibody to the infecting virus, which they shed constantly, acting as the *most important source of infection in the population*.

In PI animals, virus is present in a wide variety of tissues, and antigen can be demonstrated by immunohistochemistry in skin biopsies – in keratinocytes, hair follicle epithelium, hair matrix cells of the hair bulb, and dermal papillae. Use of skin biopsies for diagnosis of persistent infections by immunohistochemistry or enzyme-linked immunosorbent assay has been exploited diagnostically, but it should be recognized that acutely infected animals may have virus in skin biopsies as well. Lesions in PI animals are minimal and subclinical, in spite of the widespread infection of virtually all tissues.

Mucosal disease is a clinicopathologic syndrome occurring in PI animals that subsequently become infected with a closely related CP strain, or probably more commonly, when the virus causing persistent congenital infection spontaneously develops a recombination encoding NS3. The result is an overwhelming infection that destroys cells, and to which the animal is incapable of responding. Characterized by *low morbidity but very high mortality*, mucosal disease most commonly occurs in cattle that are 6 months to 2 years of age. While deaths may occur within a few days of illness, and almost always within 2 weeks, some cases may survive for months. The incubation period after experimental infection with a CP strain in an animal persistently infected with an NCP BVDV is usually 7–14 days, but may be considerably longer.

Basically, there are *two forms of clinically severe BVDV infection*: mucosal disease in persistently infected animals, and the more recently recognized severe acute form of BVD caused by primary infections with very virulent strains of virus. At necropsy, one cannot confidently differentiate spontaneous cases of severe acute BVD due to BVDV-1 or BVDV-2 from each other, or from cases of mucosal disease, other then by the more hemorrhagic character of some cases of severe acute BVD due to type 2 isolates. Tentative differentiation of mucosal disease from severe acute BVD rests on the epidemiologic picture, and antigenic or molecular characterization of the involved viruses is required for definitive diagnosis of the various syndromes.

Fulminant severe acute BVD or mucosal disease closely resembles rinderpest. At the onset the animal is febrile, with serous to mucoid nasal discharge. Discrete oral lesions are preceded by acute stomatitis and pharyngitis, the mucosae being hyperemic and pink and covered by a thin gray film of catarrhal exudate. There is severe diarrhea and tenesmus with feces containing little or no blood or mucus. Affected animals become lethargic, anorexic, and dehydrated; they have ptyalism, polypnea, and tachycardia, and may die quickly.

In more chronic cases, the development of the oral lesions is like that found in acute cases; however, by the time they die there is usually some evidence of healing. The watery diarrhea of the early phase gradually gives way to feces that are passed frequently, are scant in volume, and contain a large proportion of mucus flecked with blood. Late in the clinical course, there is lethargy, emaciation, ruminal stasis, and frequent attempts at defecation accompanied by severe tenesmus. Interdigital dermatitis, coronitis, and laminitis affecting all four feet may be present in chronically affected animals (Fig. 1.87A), resulting in lameness. In these too, the skin is dry and scurfy, especially over the neck, withers, back, perineal and preputial areas, and vulva, while that on the medial aspect of the thighs and forelegs becomes moist and discolored a dirty yellow.

At necropsy, the **gross lesions** vary considerably, especially in acute cases, in which either upper alimentary or intestinal lesions rarely may be absent, and less so in the chronic disease, in which a broader pathologic picture is often present, perhaps partially obscured by healing or evolution of lesions.

Crusts, erosions, and shallow ulcers are present on the muzzle and nares of many affected cattle. There is loss of epithelium from much of the oral cavity. The most conspicuous oral erosions are on the palate, on the tips of the buccal papillae (Fig. 1.87B), and on the gingiva. Many, especially on the papillae, the hard palate, and in the pharynx, are sharp punched-out ulcers, and expose a denuded, intensely hyperemic lamina propria. In more chronic cases, ulcers may have a margin of thickened proliferative epithelium. The tongue is not always affected; when present, lesions may be evident on all surfaces (Fig. 1.88A, B).

Esophageal lesions are usually present, most commonly in the upper third. In some acute cases, the lesions are shallow erosions, rather than ulcers. The erosions are more or less linear but otherwise irregular, have a dirty brown base, and little or no reactive hyperemia, and may be covered by shreds of necrotic epithelium in animals that have not been swallowing (Fig. 1.88C). In more advanced cases, discrete ulcerations occur. In many chronically affected animals, the ulcers are beginning to heal and have yellow-white slightly elevated plaques of proliferative epithelium at the periphery of the mucosal defect.

Lesions are found in the *reticulorumen and omasum*, but usually not in the esophageal groove. The ruminal content in chronically affected animals with prolonged anorexia is usually scant and dry. In most acute cases, the ruminal content is unusually liquid and putrid. The lesions on the wall of the rumen resemble those present elsewhere in the upper alimentary tract and, although they occur anywhere, they

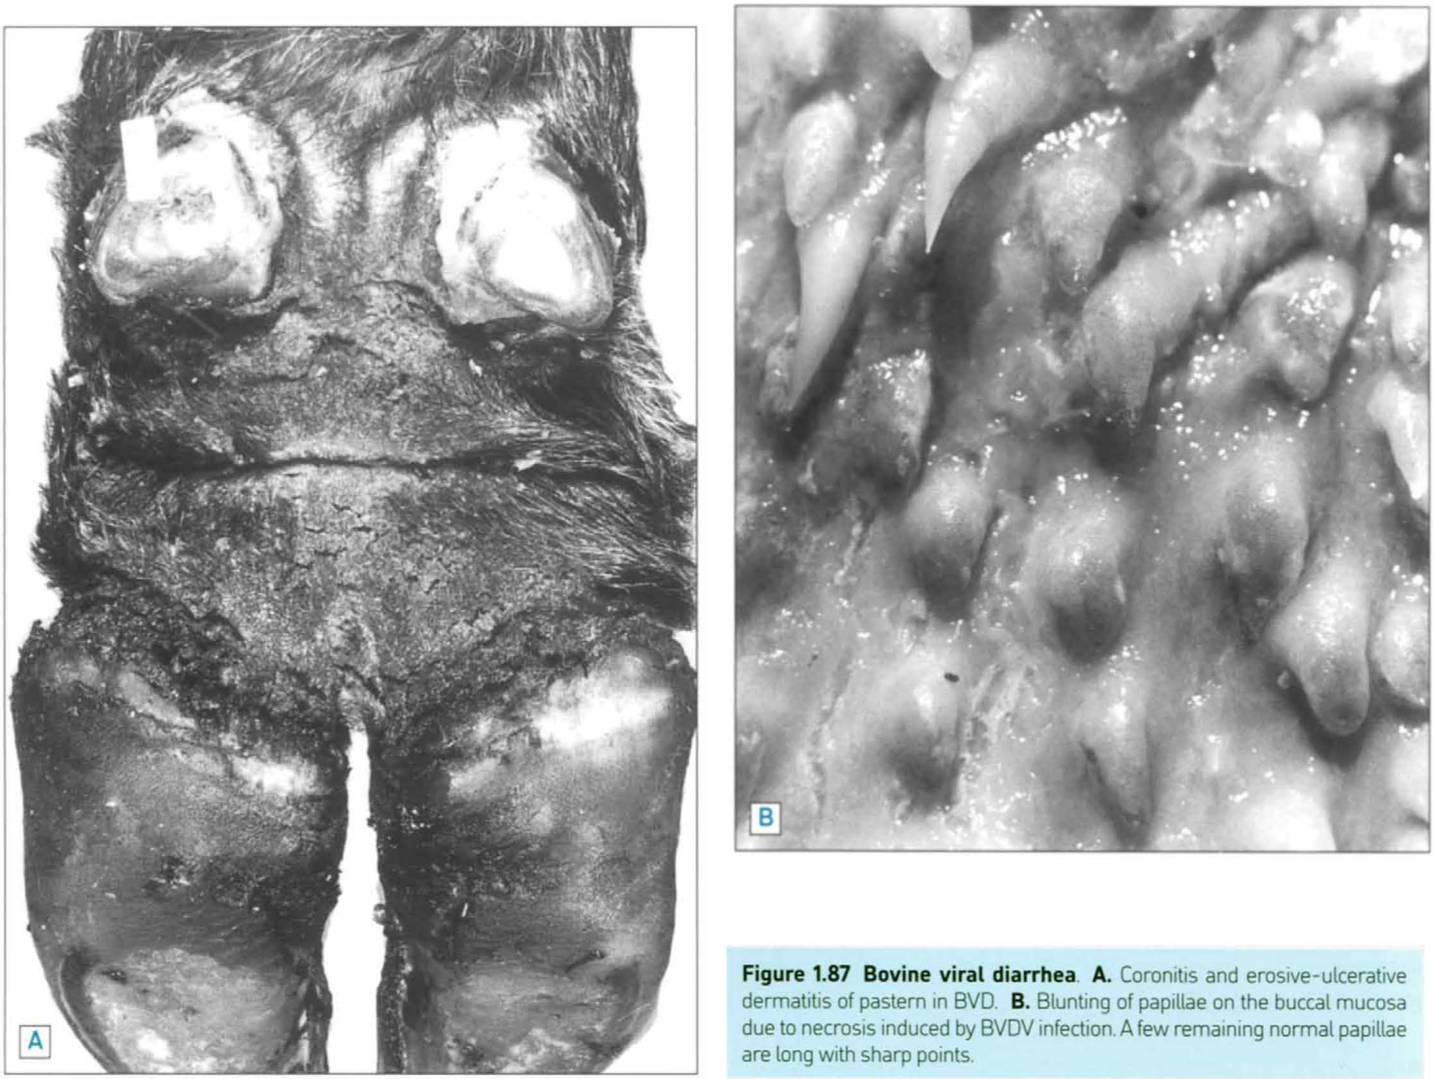

Figure 1.87 Bovine viral diarrhea. A. Coronitis and erosive-ulcerative dermatitis of pastern in BVD. **B.** Blunting of papillae on the buccal mucosa due to necrosis induced by BVDV infection. A few remaining normal papillae are long with sharp points.

are best seen on the pillars and other smooth or nonvillus portions of the mucosa (Fig. 1.89). The omasal lesions are most numerous along the edges of the leaves, sometimes causing a scalloped margin or perforation.

The morphogenesis of the lesions in the squamous mucosa of the upper alimentary tract begins with necrosis of the epithelium (Fig. 1.90). Individual cells and groups of cells deep in the epithelium are eosinophilic and swollen, with pyknotic nuclei. These foci enlarge progressively and form areas of necrosis that extend to, and may involve, the basal layer. In the early stages there is little or no inflammation of the lamina propria, but leukocytes infiltrate the necrotic epithelium. These necrotic foci enlarge progressively and by coalescence, and may form small cleavage vesicles along the proprial–epithelial junction (Fig. 1.91A), leading to erosions or ulcers as necrotic epithelium is abraded away. The ulcerations of the squamous epithelium of the upper alimentary tract are accompanied by inflammation in the lamina propria, especially where this forms papillae (Fig. 1.91B).

Changes are regularly present in the *abomasum*. The sides of the rugae bear ulcers that may be punctate to 1 cm or more in diameter (Fig. 1.92). The histological changes in the glandular epithelium of the abomasum are characterized by epithelial necrosis, mainly in the depths of the glands, and accompanying interstitial inflammation.

The mucosa of the *small intestine* often appears normal over much of its length. However, in some cases the mucosa of the small intestine may have patchy or diffuse congestion. In rare cases, fibrin casts may be in the lumen of the small bowel.

In acute cases, it is usual to find *coagulated blood and fibrin overlying and outlining Peyer's patches*, the covering of which is eroded. This, when present, is a very distinctive lesion that is only paralleled in rinderpest. Severely affected Peyer's patches are often obvious through the serosa as red-black oval areas up to 10–12 cm long on the antimesenteric border of the gut (Fig. 1.93A). Less acutely affected Peyer's patches may be overlain by a diphtheritic membrane, while in milder or more chronic cases the patches may be depressed and covered by tenacious mucus. Mesenteric lymph nodes may or may not be enlarged.

Lesions in the *large bowel* are highly variable. The mucosa may be congested, often in a "tiger-stripe" pattern following the colonic folds, a reflection of tenesmus. In acute cases there may be fibrinohemorrhagic typhlocolitis (Fig. 1.93B). In more chronic cases, fibrinous or fibrinonecrotic lesions and focal or extensive ulceration may be present at any level of the large bowel, but particularly in the cecum and rectum.

The characteristic **microscopic lesion** in the intestinal mucosa is *destruction of the epithelial lining of the crypts of Lieberkühn*. In the

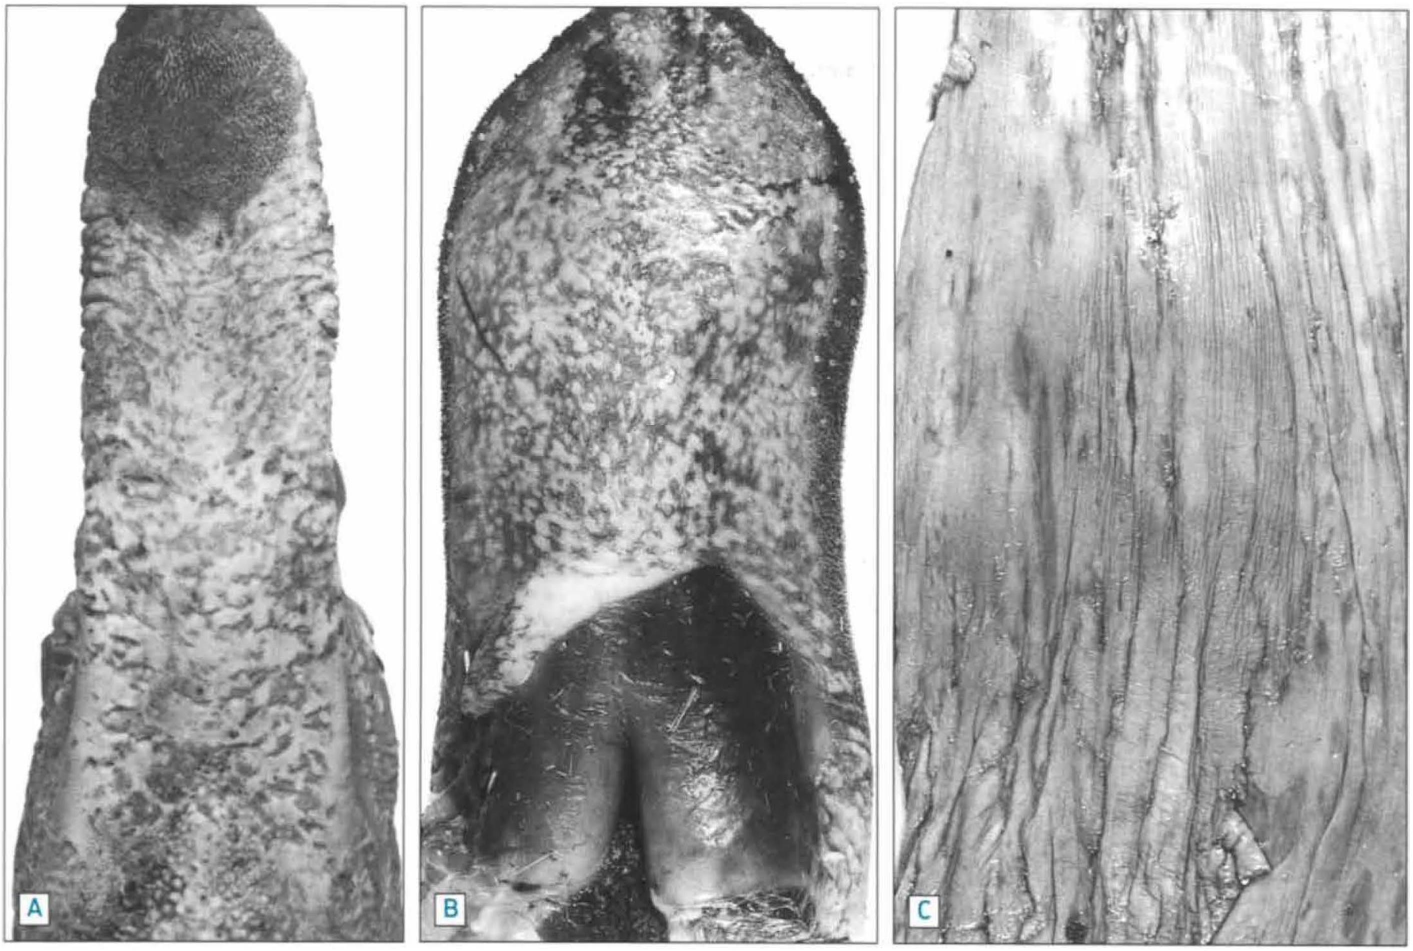

Figure 1.88 Bovine viral diarrhea. A. Dorsal surface of tongue showing multiple confluent ulcers. **B.** Ventral surface of tongue showing multiple confluent ulcers. **C.** Longitudinal erosions and ulcers on the esophagus.

duodenum, only a few crypts are affected, but more crypts are affected more severely in the lower reaches of the small intestine and in the cecum and colon. Affected crypts are dilated and filled with mucus, epithelial debris, and leukocytes. Remaining crypt-lining cells are attenuated in an attempt to cover the basement membrane. Reparative hyperplasia of crypt lining is rarely encountered. Crypt drop-out may be evident microscopically. In the cecum and colon, extensive damage to crypts and attendant collapse of the lamina propria are the probable cause of ulceration seen grossly (Fig. 1.94A). Congestion of mucosal capillaries, and in acute or ulcerated cases, effusion of fibrin and neutrophils from the mucosal surface may be evident.

The microscopic lesions of Peyer's patches are distinctive in BVD, comparable lesions being caused only by rinderpest. In the acute phase of the disease, severe acute inflammation in the mucosa over Peyer's patches accompanies almost complete destruction of the underlying glands, collapse of the lamina propria, and lysis of the follicular lymphoid tissues (Fig. 1.94B). Later in the course of the disease, dilated crypts, lined, at least in part, by cuboidal epithelium and filled with necrotic epithelial cells, mucus, and inflammatory cells appear to *herniate* into the submucosal space previously occupied by involuted lymphoid follicles. Peyer's patches should be sought assiduously at autopsy since their gross and microscopic appearance may provide useful evidence for diagnosis.

Microscopically, the mesenteric and sometimes other lymph nodes show a diminished population of lymphocytes and necrosis of germinal centers. By immunohistochemistry, there is a marked decrease in most lymphocyte subpopulations.

An important microscopic lesion is *hyaline degeneration and fibrinoid necrosis of submucosal and mesenteric arterioles* (Fig. 1.95A). A mild-to-moderate mononuclear inflammatory cell reaction is frequently present in the walls of the vessels and in perivascular areas. The vascular lesions may also be present in a variety of other organs, such as the heart, brain, and adrenal cortices, which may make it difficult to differentiate the disease from malignant catarrhal fever. The vascular lesions in acute mucosal disease are less consistently present and are usually milder, and there is *involution of lymphoid tissue in BVD*, in contrast to the lymphoproliferation characteristic of malignant catarrhal fever.

Coronitis may extend completely around the coronary band, with some separation of the skin–horn junction causing disturbance and overgrowth of the horn (see Fig. 1.87A). Dermatitis may extend from the coronet up the back of the pastern. Milder dermatitis is generalized, with scurfiness, especially from the ears to the withers. In sections of the skin of animals with chronic mucosal disease, there is hyper- and parakeratosis with focal accumulations of necrotic epithelium with intense hyperemia of the adjacent superficial dermis. The epithelial lesions are basically similar to those in the squamous mucosa of the

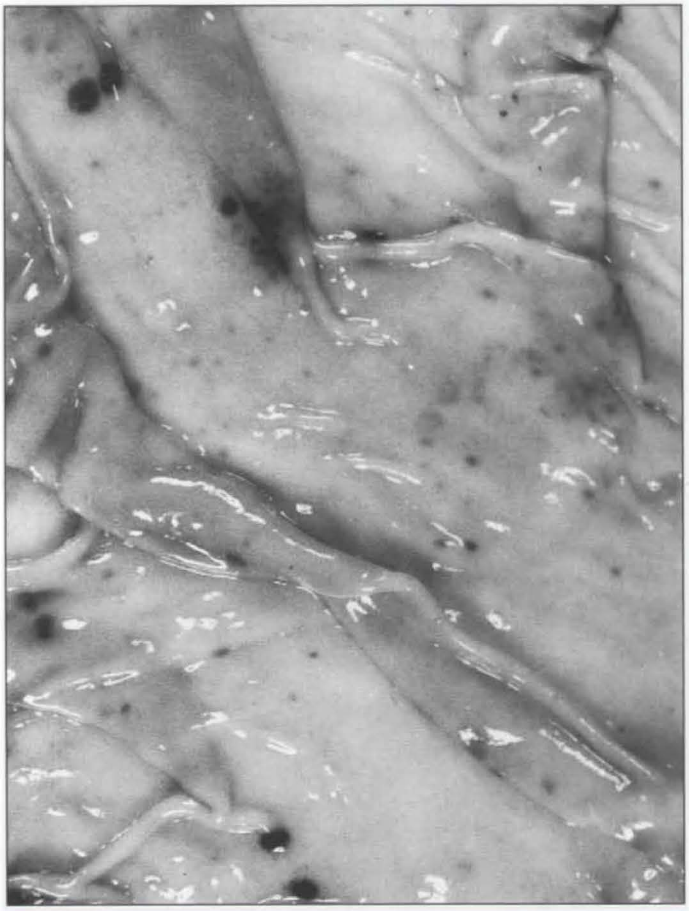

Figure 1.92 Hemorrhage and ulceration in the abomasum in **bovine viral diarrhea**.

upper alimentary tract (Fig. 1.95B). Necrosis often extends deeply to or through the basal layers; it results in minute erosions or ulcerations. There is massive infiltration of macrophages and some lymphocytes in the underlying dermis. These deeper lesions occur in the inner aspects of the legs and the perineum, and there is exudation of serum in these areas. The overlying degenerate epithelium becomes disorderly and eventually is lifted off.

Some animals with chronic disease develop *mycotic infections* secondary to lesions in the forestomachs, abomasum, and Peyer's patches. The lesions are areas of hemorrhagic necrosis involving the mucosa, submucosa, and sometimes deeper layers of the wall. Fungal hyphae are found invading the stroma and causing thrombosis in venules.

Infection of oocytes and cumulus cells in the ovaries has been well-documented, causing speculation concerning ovarian dysfunction and reduced fertility in animals surviving BVDV infection.

After *experimental inoculation with virulent BVDV-2*, animals are febrile by 7 days postinfection. Prominent clinical signs are anorexia, depression, and episodes of profuse watery and blood diarrhea that persist until the animal is moribund at 13–14 days postinfection. Pregnant animals may abort. Leukopenia and thrombocytopenia are often marked. In cases with severe thrombocytopenia, hemorrhage may be evident clinically.

Lesions are found in the digestive and respiratory systems. There is mild tracheitis, bronchitis, and bronchiolitis, which can progress to secondary bacterial pneumonia. Strains may vary in their ability to infect the pulmonary tree and result in disease. Intestinal lesions strongly resemble those seen in mucosal disease, with severe lymphoid depletion and necrosis of epithelial cells. However, with these BVDV-2 infections, there is often also a significant amount of hemorrhage evident externally, as described above, and there may

Mucus and inflammatory exudate are in the cystic glands and on the surface of the mucosa.

be extensive subserosal hemorrhages in the thoracic and abdominal cavities (Fig. 1.96). Similarly, edema may be more noteworthy in this form than in mucosal disease. Severe necrotizing vasculitis, especially arteritis, is noted in multiple organs but is most readily identifiable in lymphoid tissue. Meningoencephalitis associated with neuronal infection by BVDV-2 has been reported.

By immunohistochemistry, there is widespread viral antigen within epithelial cells (including oral and esophageal epithelium), smooth-muscle cells, and mononuclear phagocytes in multiple organs, although lesions often do not correspond to sites of antigen staining.

Bovine viral diarrhea virus and secondary infections

BVDV infection suppresses interferon production and impairs lymphocyte function, monocyte proliferation and chemotaxis, humoral antibody production, neutrophil function, and bacterial clearance. These changes are fairly persistent in chronically infected animals and in animals with mucosal disease. The failure of immunogenic response may be associated with immunotolerance, or destruction of immunocompetent cells, which is reflected in lymphopenia. In addition to a lack of humoral antibody response, there is also depression of cell-mediated immunity, as indicated by a poor response of cultured peripheral lymphocytes to various mitogens. The impairment of neutrophil function in cattle infected with BVDV may explain in part the apparent susceptibility of such cattle to *secondary bacterial infections.*

Fetal infection with *Bovine viral diarrhea virus*

In addition to the early embryonic death and abortions that can be ascribed to BVDV, infections of seronegative immunocompetent

dams, usually between 90 and 120 days of gestation, may result in a wide spectrum of *teratogenic lesions*, including microencephaly, hypomyelinogenesis, cerebellar hypoplasia and dysgenesis, hydranencephaly, hydrocephalus, and defective myelination of the spinal cord. Ocular lesions, such as microphthalmia, cataracts, retinal degeneration, atrophy and dysplasia, and optic neuritis, have all been associated with fetal infections by BVDV (see Vol. 1, Nervous system; Vol. 1, Eye and ear; Vol. 3, Female genital system). Infections of the immunocompetent fetus, usually after 135 days of gestation, result in antibody production that is detectable in precolostral serum samples of the newborn calf.

Fetal infection later in gestation may produce lesions unrelated to teratogenesis. Alimentary tract lesions of the disease may be observed in the fetus. Punctate hemorrhages with ulcers 1–3 mm in diameter may be profuse in the oral cavity, excepting the dorsum of the tongue, and in the esophagus, larynx, trachea, conjunctiva, and abomasum. The fetal lesions of squamous epithelium evolve in somewhat the same manner as those described earlier, with focal hemorrhages in the lamina propria and epithelial necrosis beginning in the basal layer.

Bovine viral diarrhea virus infection in pigs

The prevalence of naturally occurring antibodies to BVDV in swine in different countries varies between 2 and 40%. The antibodies may complicate the diagnosis of classical swine fever, especially in those countries considered to be free of this disease. Cattle, and modified live virus vaccines containing contaminated fetal bovine serum, are considered to be common sources of infection for swine. There are sporadic reports of disease associated with BVDV infection, including stillbirth, and poorly viable piglets, some showing tremors. Some 2–4-week-old pigs in infected herds are anemic, have a rough hair coat, growth retardation, wasting, and diarrhea. Affected pigs fail to develop neutralizing antibodies to the infecting homologous BVDV. Littermates that remain normal develop neutralizing antibodies. The suggestion is that the infections are congenital. Experimental in utero BVDV infection of sows may result in prenatal and perinatal deaths, persistently infected immunotolerant or normal pigs. Many of these conditions resemble the effects of in utero infection with NCP BVDV in cattle.

Border disease

Border disease is a congenital infection of sheep and goats, usually with one of several NCP genotypes of *Border disease virus* (BDV), a pestivirus antigenically related to BVDV and *Classical swine fever virus*, but apparently also with some BVDV-2 strains. The disease was first reported in lambs from border areas between England and Wales. It is characterized by embryonic and fetal death, abortion, mummification, and birth of weak lambs or kids. The affected animals have an abnormal body conformation, long hairy fleece, clonic rhythmic tremors ("*hairy shakers*"), unthriftiness, and poor viability (see Vol. 1, Nervous system; Vol. 1, Skin and appendages; Vol. 3, Female genital system).

A syndrome resembling mucosal disease has been reported in lambs that survived the initial border disease; they were persistently infected with an NCP BVDV. Immunohistochemical examination of tissues from persistently infected sheep reveals viral antigen in smooth-muscle cells of hollow organs and blood vessels, epithelial cells in the gastrointestinal tract, lymphocytes, neurons, and glial cells. When cytopathic BDV is superimposed on persistent infection, affected sheep develop chronic diarrhea, wasting, nasal discharge, and polypnea. Macroscopic lesions are particularly present in the cecum and colon and in a few sheep also the terminal ileum. There is marked thickening of the gut wall due to subserosal and mucosal edema and diffuse polypoid hyperplasia of the mucosa, which is hemorrhagic and focally ulcerated.

The *microscopic lesions* in the gut are similar to those described for mucosal disease in cattle. Lymphoid cell reactions are evident in the choroid plexus, portal triads of the liver, kidney, myocardium, thyroids, lungs, spleen, and lymph nodes. In addition, some lambs have marked hypertrophy and edema of the muscularis of the terminal ileum. The lesions in the terminal ileum resemble "terminal ileitis," and BVDV should be considered as a possible cause of that syndrome.

The pathogenesis of fetal infections, resultant border disease, and related enteric lesions in sheep appear to be similar to the multitude of conditions associated with NCP BVDV prenatal infections in cattle. Seronegative ewes infected before 80 days of gestation may produce persistently infected, immunotolerant, chronically viremic lambs.

Rinderpest

Otherwise known as "cattle plague," rinderpest is an *acute or subacute highly contagious disease of cattle, characterized by erosive or hemorrhagic lesions of all mucous membranes*. The distribution of the disease is progressively shrinking, but it is still enzootic in parts of Africa, the Middle East, and the Orient, to which places it is restricted by limitations on animal movement and the use of highly efficacious vaccine. Pandemics have occurred in the Middle East, sub-Saharan and equatorial Africa, and some of these were apparently related to a relaxation in vaccination programs.

Rinderpest virus (RPV) belongs to the family Paramyxoviridae, genus *Morbillivirus*. It is a highly pleomorphic single-stranded RNA virus with a core diameter of 120–300 nm and a spiked envelope. The virus is highly fragile under ordinary environmental conditions; it is incapable of surviving more than a few hours outside the animal body under normal circumstances.

Probably all cloven-hoofed animals are naturally susceptible to infection, but the expression of infection varies considerably. Goats and sheep do respond, but inconsistently, to experimental inoculations of RPV. Infection in Asiatic pigs may be severe but it tends to be mild in European breeds, which are considered "dead-end" hosts for rinderpest.

Although different strains of RPV vary considerably in their pathogenicity, they are grouped in a single serotype and, when suitably modified, make effective vaccines.

Control of the disease in endemic areas is impeded by difficulties inherent in systems of husbandry and by the coexistence of cattle with large populations of susceptible ungulate wildlife. The infection impacts heavily on wildlife populations in close contact with cattle, and they are important in virus spread. However, wildlife in east Africa are not clearly implicated as reservoirs of the infection. The lability of the virus is such that the *spread of infection* from endemic areas is most likely to be by live animals with mild or subclinical disease.

The disease in cattle may be mild, especially in endemic areas, but will probably be acute or peracute and severe in new foci. The different degrees of severity are in part due to real differences in virulence of strains, and largely due to differences in susceptibility of breeds or races of cattle. Rinderpest may also persist for prolonged periods as a very mild disease in endemically infected cattle and wild ungulate herds and may remain stable for years before the emergence of more pathogenic strains that induce the characteristic disease.

The *nasopharyngeal mucosa* appears to be the main portal of entry in rinderpest. The virus uses glycoproteins expressed on activate lymphocytes and monocytes and on dendritic cells as receptors, and destruction of such cells may be a means by which it causes immunocompromise. It localizes and replicates initially in the palatine tonsils and regional lymph nodes. This is followed after an 8–11-day incubation by a 2–3-day period of viremia that coincides with the fever seen clinically. In circulation, the virus is associated with mononuclear cells. After the viremic stage, the virus replicates in all lymphoid tissues, the bone marrow, and the mucosa of the upper respiratory tract and the gastrointestinal tract. Nasal, oral, and ocular secretions, as well as feces, contain high titers of the virus. In general, excretion of virus ceases by about day 9 of the clinical disease, with the onset of neutralizing antibodies. Recovered animals do not appear to be carriers, although there are reports to the contrary.

Fever and its attendant signs usher in the **clinical syndrome**, with early leukopenia. Fever reaches its peak in about 3 days and falls with the onset of diarrhea, which may be bloody. There is severe abdominal pain, anorexia, ocular and nasal discharge, tachypnea, fetid breath, occasional cough, lethargy, severe dehydration and emaciation, and prostration. Death occurs in 5–8 days. Explosive outbreaks with high morbidity and mortality are more likely to occur in naive populations. Vaccinated or recovered animals usually have lifelong immunity. Secondary bacterial, viral, protozoal, and rickettsial infections are common.

The **gross morbid anatomical changes** in rinderpest are characteristic but not pathognomonic, and are similar to mucosal disease (Fig. 1.97). The lesions in the upper alimentary tract are *necrotizing and erosive-ulcerative*.

RPV has an affinity for the alimentary epithelium. Most severely affected areas in the oral cavity are those contiguous with lymphoid aggregates. Consequently, the caudal part of the oral cavity is affected preferentially. There is some strain variation with respect to presence of oral lesions. In nonfatal cases, there is rapid regeneration of the oral mucosal lesions. Esophageal erosions are usually mild and affect the proximal portion. The forestomachs rarely exhibit any lesions.

The **histologic lesions** of stratified squamous epithelium originate in the stratum spinosum. Entrance into the epithelium may be via infected Langerhans cells that then pass virus along to adjacent cells. Immunohistochemically, irregularly shaped rafts of acanthocytes are infected with virus. These same cells then undergo degeneration and necrosis. Multinucleate syncytia form in the epithelium (Fig. 1.98) and these may have *cytoplasmic and nuclear inclusions*. Abrasion causes the necrotic tissue to lift off and produce shallow erosions or ulcers. This occurs so readily that they are usually the first lesions observed. Their margins are sharp, and the bases are reddened by the underlying congested capillaries. The initial minute erosions enlarge and coalesce to form extensive defects.

The abomasum is often severely reddened, which may just be a reflection of generalized stress for, although immunohistochemically abomasal epithelium is infected with virus, the extent of infection and resulting necrosis is far less than that seen in intestinal mucosa.

Lesions in the intestine are severe and severity correlates with amount of lymphoid tissue in subjacent areas. Consequently, greatest mucosal damage is seen in ileum and the proximal colonic patch. Peyer's patches are almost universally involved. These areas become hemorrhagic and necrotic, and are associated with necrosis of the overlying mucosa, leaving deep ulcers (Fig. 1.99A).

Microscopically and immunohistochemically, there is replication of virus at all levels of intestine, with both crypt and villus epithelium involved. Replication is associated with formation of inclusion bodies, both nuclear and cytoplasmic, degeneration, necrosis, denuding of epithelium, formation of crypt abscesses and, if prolonged enough, villus atrophy. The formation of syncytia within gut epithelium is a rare event, in contrast to the oral cavity lesions, where it is seen with some regularity.

Receptor affinity dictates that *RPV is tropic for lymphoid tissues*. Infection and replication have been documented in both lymphocytes and macrophages. Necrosis of follicular lymphocytes is extreme, and gross inspection, which reveals little abnormality of

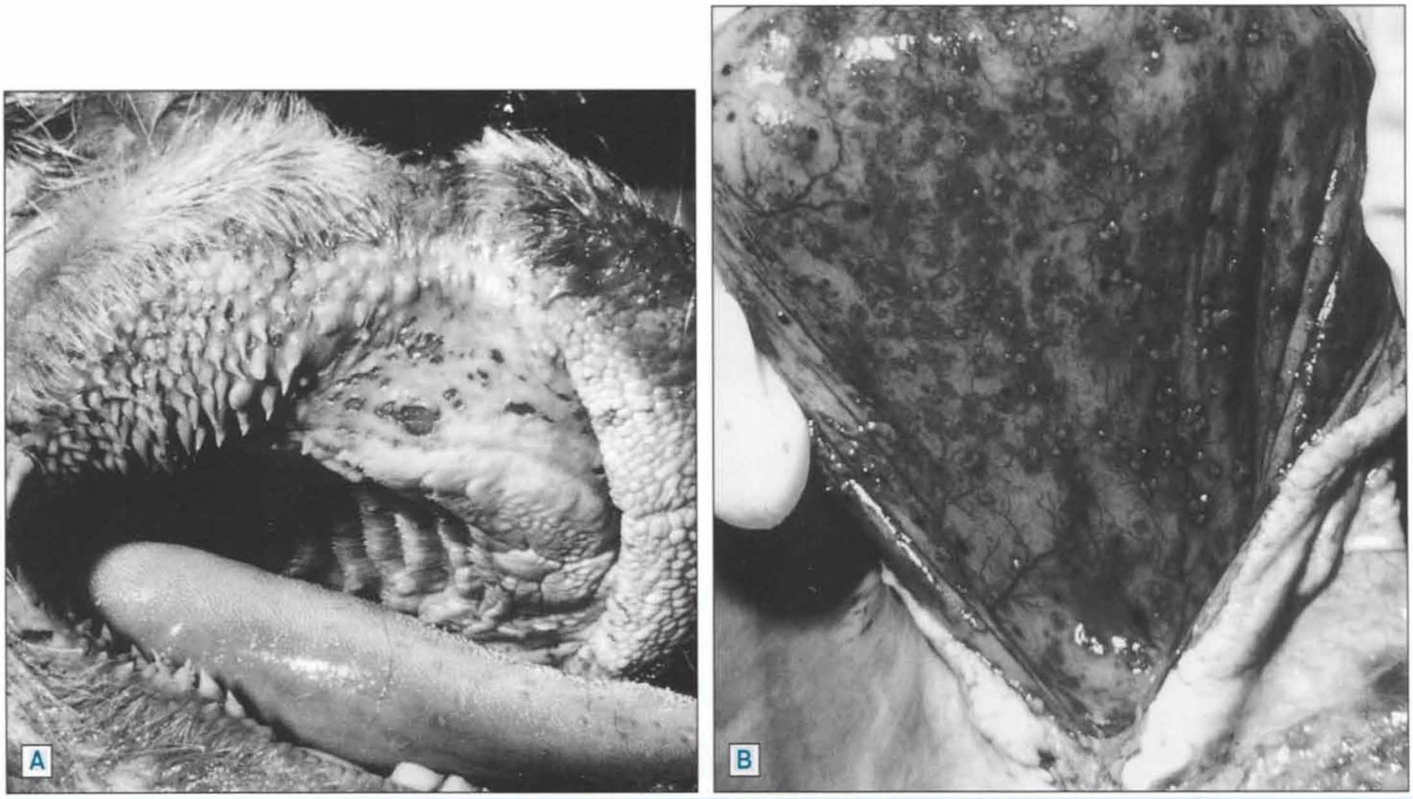

Figure 1.97 Rinderpest in a cow. **A.** Ulcers on the buccal mucosa, and small incipient ulcers on the underside of the tongue. **B.** Multifocal to coalescing fibrinohemorrhagic colitis.

nodes, is misleading (Fig. 1.99B). Multinucleate cells, similar to those in the oral mucosa, occasionally form in the lymph and hemolymph nodes. All or only some follicles may be involved and there is often an increase of other leukocytes in the sinuses. Similar lesions occur in the spleen, tonsils, and, as already noted, in the Peyer's patches.

Acute congestion and edema of the conjunctiva may be followed by purulent conjunctivitis and corneal ulceration. Petechiae are common in the mucosa of the upper respiratory tract, which is usually covered with mucopurulent exudate.

The gross lesions resemble those of severe acute bovine viral diarrhea and mucosal disease, but *rinderpest is distinguished microscopically most readily by the presence of syncytia and inclusion bodies.* Its regulatory status demands laboratory diagnosis in accredited laboratories, by virus isolation, antigen identification in fresh or fixed specimens, or polymerase chain reaction.

Peste des petits ruminants

Peste des petits ruminants is an acute viral disease of sheep and goats that closely resembles rinderpest and is also known as kata, *stomatitis–pneumoenteritis complex*, goat plague, and pseudorinderpest. The disease was first recognized in West Africa, and is now distributed in sub-Saharan Africa, the Arabian Peninsula, Anatolia, and the Indian subcontinent, including Nepal and Bangladesh. *Peste-des-petits-ruminants virus* (PPRV) is in genus *Morbillivirus*, family Paramyxoviridae, closely related to *Rinderpest virus*, with which it shares common antigenic determinants. The virus cross-reacts with RPV in the immunodiffusion and complement fixation tests. It may be differentiated from RPV using monoclonal antibody techniques and cDNA probes.

The clinical signs, pathogenesis, and lesions of the disease in sheep and goats in general are similar to those of rinderpest (Fig. 1.100), except that the disease is more acute in onset, especially in goats, and follows a more rapid course.

Another difference is the marked involvement of the respiratory tract; affected animals have dyspnea, hyperpnea, and cough. There is

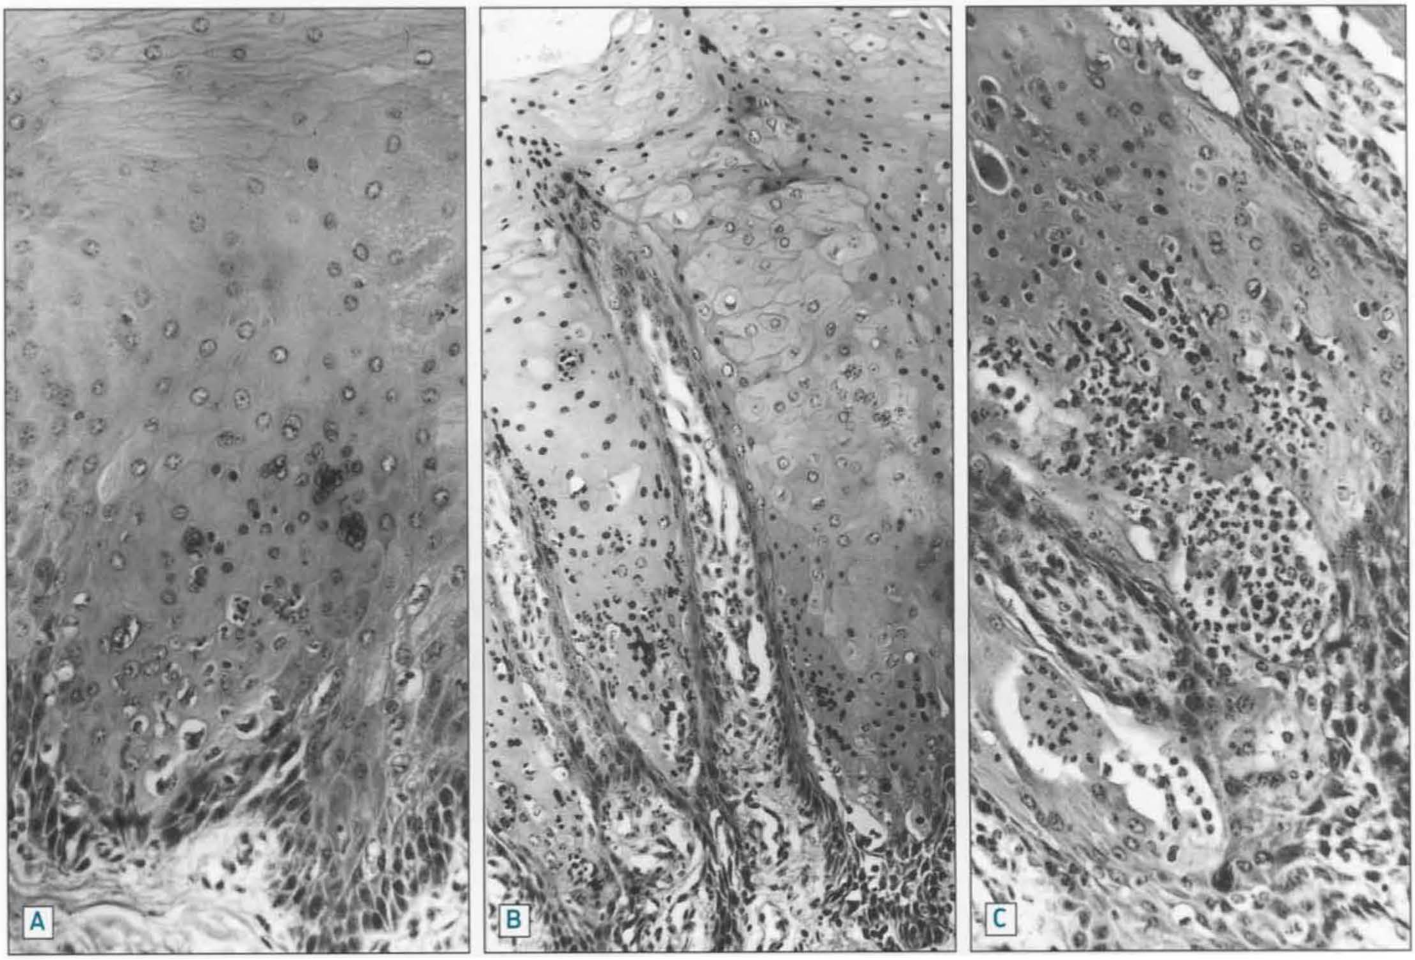

Figure 1.98 Rinderpest lesions in the tongue of an ox. **A.** Early stage of oral lesion showing disorganization of epithelium above the basal layer and formation of syncytial cells. **B, C.** Slightly later stage of (**A**) with beginning separation sparing basal cells.

also a marked serous to mucopurulent nasal and ocular discharge, and erosion/ulceration of the pharyngeal epithelium may be diffuse. The pulmonary lesions of peste des petits ruminants are similar to pneumonia due to *Canine distemper virus* in dogs and *Measles virus* infections in humans. The macroscopic pulmonary lesions include consolidation, atelectasis, and dark-red discoloration of the cranioventral lobes. Some animals have fibrinous pleuritis (see Vol. 2, Respiratory system). Microscopically, there is mild multifocal tracheitis, bronchitis and necrotizing bronchiolitis, and diffuse proliferative *interstitial pneumonia*, with formation of alveolar syncytial cells. Eosinophilic cytoplasmic and nuclear inclusions are present in the epithelial cells of the air passages, type II pneumocytes, and syncytial cells. Viral antigen may be demonstrated in the same cells with appropriate immunohistochemical techniques. The primary viral lesions are often complicated by secondary bacterial infections.

Experimental inoculation of PPRV into cattle and pigs does not produce clinical disease, but these animals will resist subsequent challenge with *Rinderpest virus*. These species are considered to be "dead-end" hosts, since they do not seem to spread the infection to other species. Natural infection or vaccination of sheep and goats with *Rinderpest virus* will protect them against PPRV.

A zoo outbreak of peste des petits ruminants that involved several species of wild ungulates has been reported, and Indian buffalo are also susceptible. The distribution of the virus in free-ranging wild ungulates has not been investigated.

Peste des petits ruminants must be distinguished from rinderpest in the laboratory based on use of monoclonal antibodies to distinguish the agents immunologically in wet or fixed tissue, or by molecular techniques.

Malignant catarrhal fever

Malignant catarrhal fever (MCF) is an infectious disease of domestic cattle, some wild ruminants, and occasionally pigs, also known as malignant head catarrh, and snotsiekte. The disease is characterized by *lymphoproliferation, vasculitis, and erosive-ulcerative mucosal and cutaneous lesions.*

MCF is distributed worldwide. It is generally sporadic, although severe herd outbreaks have been reported in feedlot, dairy and range cattle, in farmed bison and deer, and in zoos. Among the Cervidae, all species except fallow deer are probably susceptible. Other susceptible species of ruminants include banteng, Cape buffalo, and greater kudu. *Mortality in susceptible species approaches 100%,* although there are rare recorded cases of chronic infection and also of recovery from the disease, especially in infected goats, bison, cattle, and pigs. Although the agent is transmissible, the disease is apparently not contagious among cattle or bison by direct contact.

MCF is caused by cross-species infections with members of the MCF virus group of ruminant rhadinoviruses (genus *Rhadinovirus*, subfamily Gammaherpesvirinae), four of which are associated with clinical MCF: (1) ***Alcelaphine herpesvirus 1*** (AlHV-1), carried by wildebeest (*Connochaetes* sp.); (2) ***Ovine herpesvirus 2*** (OHV-2), endemic in domestic sheep; (3) ***Caprine herpesvirus 2*** (CpHV-2), endemic in domestic goats; and (4) a virus of undetermined origin causing *MCF in white-tailed deer* (MCFV-WTD). Related rhadinoviruses, as yet unassociated with MCF, have been detected in a variety of members of the Bovidae. Rhadinoviruses of ruminants are highly cell-associated lymphotropic herpesviruses, difficult or impossible to isolate, which are typically transmitted from adults to offspring within the first 2–3 months of life, probably via free virus shed in nasal secretions. In the natural host, infection is latent or inapparent, with intermittent virus shedding, although disease has been incited in sheep by experimental aerosol inoculation of a large dose of OHV-2.

Formerly, MCF was described as the "African" or *wildebeest-associated* (**WA-MCF**) form if it was presumed to be due to AlHV-1, and "North American" or *sheep-associated* (**SA-MCF**) if it was presumed to be due to exposure to sheep. There is no clinicopathologic difference in the disease induced by the various rhadinoviruses, and these terms have only broad epidemiologic connotations. The blue, brindled, or white-bearded wildebeest (*Connochaetes taurinus*) carries AlHV-1. Wildebeest calves become infected during the first 2–3 months of life, when they are also viremic and shed cell-free AlHV-1 in nasal and ocular secretions. Most wildebeest older than 7 months are serologically positive for AlHV-1. In utero infections have also been reported. Wildebeest are infected for life and transmit AlHV-1 to their calves without showing clinical signs. *Wildebeest calves are considered to be the main source of infection for cattle in East Africa.* They may shed infective cell-free virus, in nasal and ocular secretions, for several days. Transmission to cattle may occur even without intimate contact, suggesting aerosol spread. Viremia apparently ceases with the development of active neutralizing antibodies in animals >6 months old. It may be reactivated during late pregnancy or periods of stress, e.g., transportation. Although AlHV-1 produces MCF in many captive exotic species of ruminants, apparently most species that are exposed in their native habitat do not develop disease. AlHV-1 has been transmitted and adapted to domestic rabbits, hamsters, rats, and guinea pigs, in which it produces MCF-like lesions.

The etiologic agent of SA-MCF has never been isolated from sheep; however, polymerase chain reaction probes have permitted its differentiation. *Most sheep have polymerase chain reaction-detectable specific OHV-2 sequences in cells,* and identical sequences are detectable in spontaneous cases of SA-MCF. Experimental transmission of OHV-2 between sheep has been accomplished using an aerosol of virus-infected nasal secretions, and natural transmission from adults to offspring probably takes that route, producing very high rates of infection in the sheep population, where it can be considered ubiquitous. The other two rhadinoviruses associated with MCF have also been identified and implicated by molecular diagnostic techniques.

Attempts to reproduce MCF in cattle by inoculating sheep tissues and secretions have been unsuccessful, but MCF-like disease can be induced in rabbits, hamsters, and guinea pigs by transfer of lymphocytes or T lymphoblast cell lines derived from MCF-affected cattle and deer. The domestic rabbit is the most commonly used model to study the pathogenesis of both forms of MCF. MCF due to OHV-2 occurs spontaneously and experimentally in pigs, and the relative rarity of the disease in swine may be due to lack of exposure to ruminant rhadinoviruses under most conditions of husbandry.

SA-MCF occurs where bovids and deer come in contact with sheep. There is considerable variation in the susceptibility of various ruminant species to SA-MCF. Domestic cattle (*Bos taurus* and *B. indicus*) appear to require high levels of exposure to induce disease. Bali cattle or banteng (*B. javanicus*), the domestic water buffalo (*Bubalus bubalis*), American bison (*Bison bison*) and most species of deer, with the exception of fallow deer (*Dama dama*), seem to be highly susceptible. MCF is one of the most serious diseases of farmed deer in New Zealand, Australia, and the UK. Multiple case outbreaks have also been reported in captive North American cervids.

The *mucosa of the upper respiratory tract and/or the tonsil* is the most likely natural route of entry for the agents of MCF. Both WA-MCF and SA-MCF can be transmitted to susceptible hosts with large volumes of whole blood or lymphoid tissues administered intravenously, but not by cell-free filtrates, indicating that the agents are cell-associated, probably with lymphocytes. The incubation period of MCF is usually 2–10 weeks, but may, on occasion, be very much longer than this.

Antibodies against the rhadinovirus involved can be detected in animals with MCF, and often in herdmates, implying subclinical infection. Development of antibodies does not prevent a fatal outcome.

The **pathogenesis**, clinical signs, and lesions are similar, whatever the agent inducing MCF. Viremia in WA-MCF usually starts about 7 days before the onset of fever, and persists throughout the course of the disease. MCF is characterized by *marked T-lymphocyte hyperplasia.* A population of large granular lymphocytes appears to be infected and transformed by rhadinoviral infection, and OHV-2 genome has been detected in CD8+ T cells, the predominant cell infiltrating around vessels in the brains studied. These cells are probably cytotoxic T lymphocytes or T-suppressor cells, but the mechanism by which they mediate the lesions of MCF is unclear. Dysfunction of this cell population may result in de-repression of T-lymphocyte replication, permitting lymphoproliferation. Deranged cytotoxic T-cell activity may then create the epithelial and vascular lesions, through a type of graft-versus-host response, attacking epithelium of the respiratory and gastrointestinal systems, as well as medium-sized arteries throughout the body. This is a unifying, but unproven, hypothesis explaining the lymphadenopathy, mucosal epithelial lesions, and vasculitis characteristic of MCF. Vascular lesions may mediate infarction of some affected tissue fields, as well.

There is wide variation in the presenting **clinical syndromes**, which are potentially pansystemic. Quite consistently, affected animals have enlarged lymph nodes, although this may be less the case in bison, and there is usually some degree of ocular and oral disease, and exudative dermatitis. There is edema of the eyelids and palpebral conjunctivae and congestion of the nasal and buccal mucosae.

Photophobia is accompanied by copious lacrimation. There is conjunctivitis and an increasing rim of corneal opacity, starting at the limbus and progressing centripetally. Corneal ulceration occurs in some cases, but in those that die quickly, the infiltration of the filtration angle may be all that is seen, and this is easily overlooked. Hypopyon may be seen. In some cases there are nervous signs, such as hyperesthesia, head pressing, trembling, nystagmus, incoordination, and behavioral changes. Other animals may have gastroenteritis with diarrhea, which may in acute cases be bloody. This is most commonly seen in deer. The disease may take an acute course of about 1–3 days, particularly in animals with hemorrhagic enteritis. Those with less severe gastroenteritis, central nervous signs, or generalized disease may linger for as long as 9–10 days. Mortality in MCF has been considered to approach 100% of clinical cases, but recovery may occur, although chronic ocular lesions and vasculitis persist.

Gross morbid changes may not be present in occasional animals that die of peracute MCF, and in these the diagnosis must rest on the detection of the characteristic histologic changes, and demonstration of the genome of an implicated rhadinovirus in tissue.

The carcass is dehydrated, and may be emaciated if the course has been prolonged. Conjunctivitis may be evident. The muzzle and nares are heavily encrusted and, if wiped, often reveal irregular raw surfaces, although in some cases there may be only a slight serous discharge. Cutaneous lesions, especially in SA-MCF, are common, but often overlooked. Affected areas include the thorax, abdomen, inguinal regions, perineum, udder, and occasionally the head. There may be, acutely, more or less generalized exanthema with sufficient exudation to wet and mat the hair, and to form detachable crusts; in unpigmented skin there is obvious hyperemia. The crusts may become several millimeters thick, and there is patchy loss of hair. Sometimes these cutaneous changes begin locally about the base of the hooves and horns, the loin, and perineum; they may remain localized or become generalized. In severe cases, the horns and hooves may slough. *Caprine herpesvirus-2* has been associated with syndromes in deer that include dermatitis and alopecia, alone, or in combination with gastrointestinal or neurological disease.

The respiratory system may have minor or severe lesions (Fig. 1.101A). When the course is short, the nasal mucosa may only have congestion and slight serous exudation. Later, there is a copious discharge. Lesions are most severe in the rostral third of the nasal cavity, corresponding to the zone of stratified squamous epithelium. In some cases, fibrinous tracheobronchitis may occur (Fig. 1.101B).

The lower alimentary mucosae may have no significant lesions in the peracute disease, although *oral lesions are present in most cases of MCF*. Minor erosions are first observed on the lips adjacent to the mucocutaneous junction. Sometimes apparently normal epithelium on the surface of the tongue peels off in sheets (Fig. 1.102). Later, erosive and ulcerative lesions may involve a large area of oral mucosa, frequently occurring on all surfaces of the tongue, the dental pad, the tips of the buccal papillae, gingivae, both areas of the palate, and the cheeks. In some areas, the cheesy or tattered necrotic epithelium may not be sloughed at the time of inspection. Esophageal erosions or

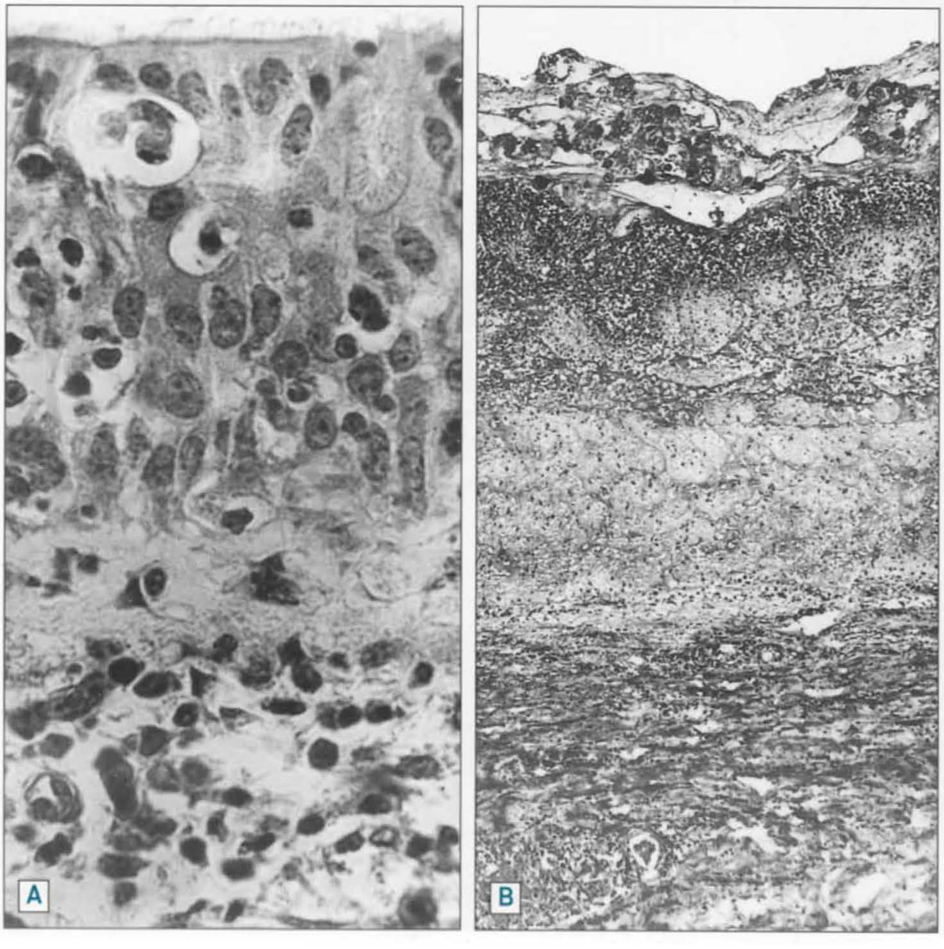

Figure 1.101 Malignant catarrhal fever. **A.** Nasal mucosa, with degeneration of epithelium and infiltration of lymphocytic cells in uncomplicated rhinitis. **B.** Pseudomembranous tracheitis.

ulcers, similar to those that occur in the other diseases causing ulcerative stomatitis, occur in MCF, and, as in rinderpest, are most consistent in the cranial portion. Lesions of the same sort may be present in the forestomachs. Focal ulceration or generalized hyperemia may be evident in the abomasal mucosa. In deer, especially, hemorrhagic or fibrinohemorrhagic typhlocolitis may be a prominent finding.

The *liver* may be slightly enlarged. Close inspection will reveal, in some cases, diffuse mottling with white foci, which are periportal accumulations of mononuclear cells (Fig. 1.103). There may be numerous small hemorrhages and a few erosions of the mucous membrane of the gallbladder.

Characteristic lesions may occur in the *urinary system.* Renal changes are not always present. They are infarcts or 2–4 mm foci of nonsuppurative interstitial nephritis (Fig. 1.104). They may be numerous enough to produce a mottled appearance, and may form slight rounded projections from the capsular surfaces. The pelvic and ureteral mucosa frequently has petechial and ecchymotic hemorrhages. Similar lesions are present on the mucosa of the urinary bladder, or there may be more severe hemorrhage erosion and ulceration of the epithelium, and hemat Superficial lesions may occur in the vagina and vulva of the oral cavity and skin.

Enlargement of lymph nodes is a characteristic le most species, perhaps except bison. All nodes may some may appear grossly normal. Affected nodes ma the normal size, and some, including hemolymph usually too small to recognize, may become qui 1.106). There is edema of the affected nodes and connective tissue. On cross-section it is apparent th size is due to *lymphocytic hyperplasia.* Some of the no or hemorrhagic. The spleen is slightly enlarged, a follicles are prominent.

Most animals may have *meningoencephalitis,* as a tis, perhaps reflected grossly by meningeal edema, the most consistent histologic lesions of the diseas

The **histologic changes** must usually be relied nosis of MCF, and its differentiation from similar access to molecular diagnosis of specific rhadinov increasing. The characteristic histologic changes a phoid tissues and in the adventitia and walls of medi especially arteries in any organ, and these will be

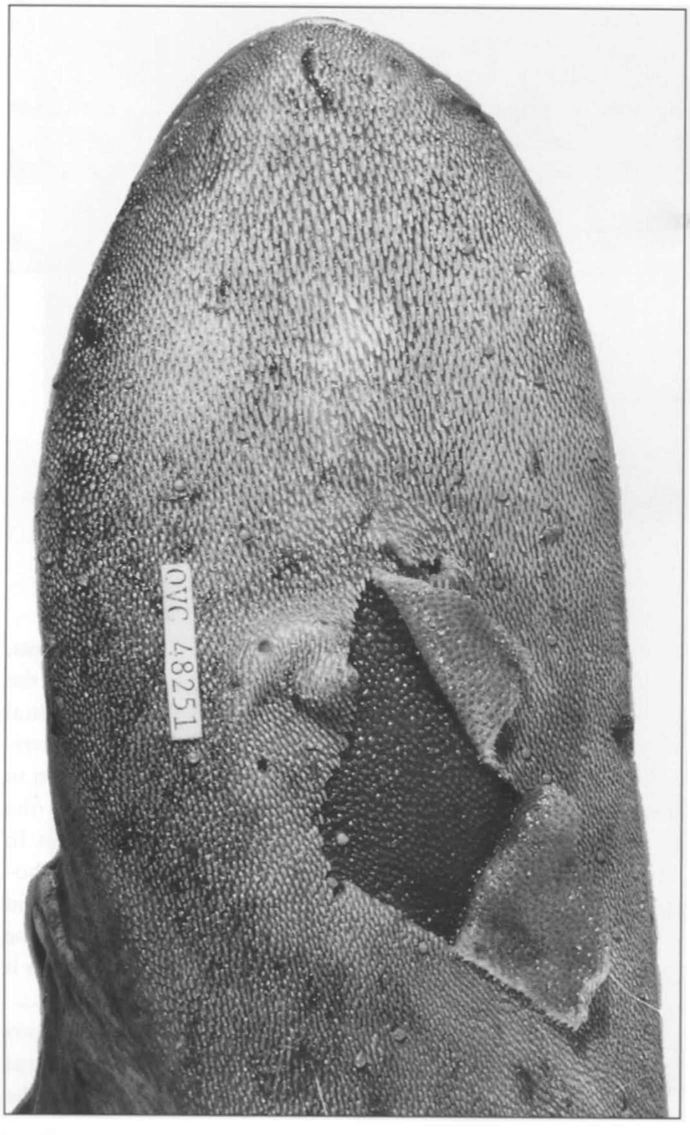

Figure 1.102 Separation of necrotic lingual epithelium from underlying propria in an ox with **malignant catarrhal fever**.

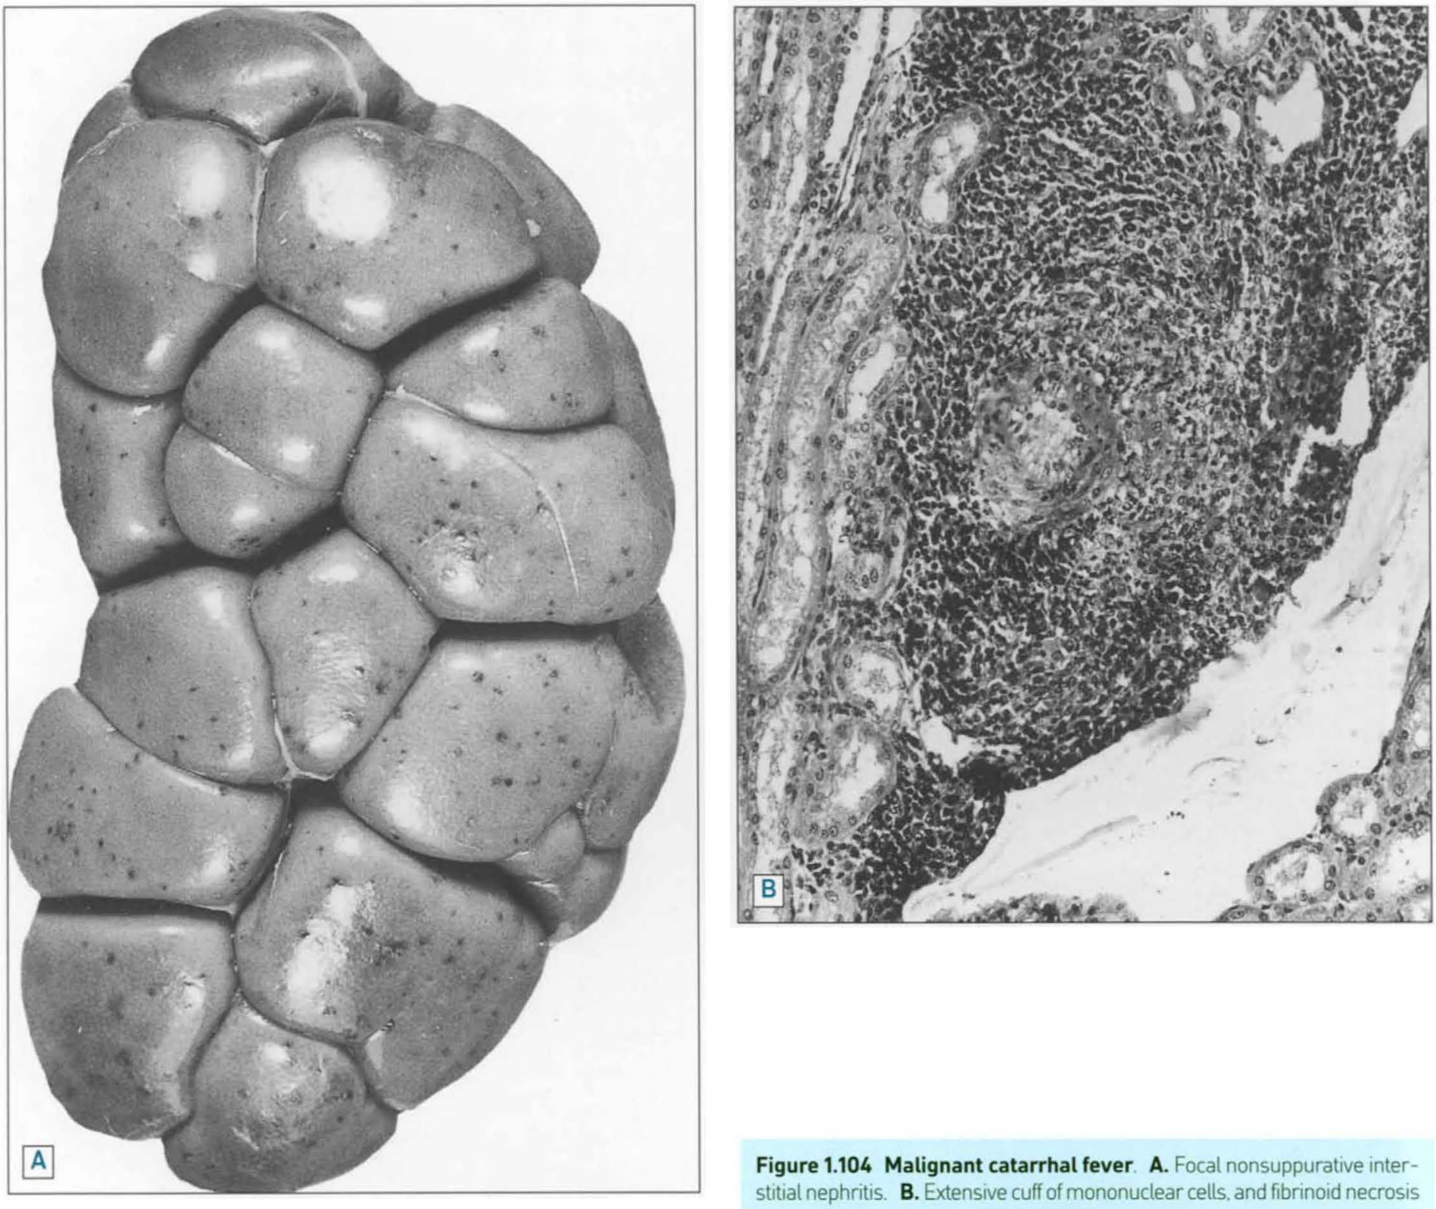

Figure 1.104 Malignant catarrhal fever. **A.** Focal nonsuppurative interstitial nephritis. **B.** Extensive cuff of mononuclear cells, and fibrinoid necrosis in the wall of a small arteriole in the kidney.

other lesions. They are characterized by perivascular accumulation of mainly mononuclear cells, and fibrinoid necrotizing vasculitis (Figs 1.107 and 1.108). These changes may be focal or segmental, and may involve the full thickness of the wall, or be confined more or less to one of the layers. When the intima is involved, there is often endothelial swelling. Thrombi are difficult to demonstrate in damaged vessels. The media may be selectively affected, or perhaps the adventitia alone. Severely affected segments of vessel are replaced by a coagulum of homogeneous, eosinophilic material, in which fragmented nuclear remnants are seen. The perivascular accumulation of cells is particularly characteristic. They are mainly lymphoid cells with large open nuclei and prominent nucleoli; small lymphocytes and plasma cells may be present occasionally. The vascular lesions may be more subtle in other species (especially deer and elk) than in cattle. Cattle that recover from SA-MCF also have distinctive vascular lesions 90 days after clinical onset. Concentric fibrointimal plaques, disrupted inner elastic lamina, focally atrophic tunica media, and vasculitis of variable severity are evident in many organ systems.

In *lymph nodes* there is active proliferation of lymphoblasts, which form extensive homogeneous populations of cells in the T-cell-dependent areas of the interfollicular cortical and paracortical zones. Focal areas of hemorrhage and necrosis associated with arteritis may be seen in all areas of the nodes. The lymphoid reaction in the spleen varies from marked lymphoid cell hyperplasia, in the periarteriolar sheaths, to atrophy and depletion of lymphocytes. In addition, there is marked proliferation and infiltration of lymphocytic and lymphoblastic cells, mainly perivascular in distribution, in a variety of organs. The lymphoreticular proliferation may become so severe in some organs that it is difficult to determine whether it is hyperplastic or neoplastic.

Microscopic arteritis similar to that present in other organs occurs in the nervous system of many cases. Necrotizing arteritis, plasma exudation into the meninges or Virchow–Robin space, and the predominantly adventitial lymphocytic response are, in the brain of cattle, *unique to MCF*, and allow it to be differentiated from other nonsuppurative encephalitides. Degenerative changes in nervous

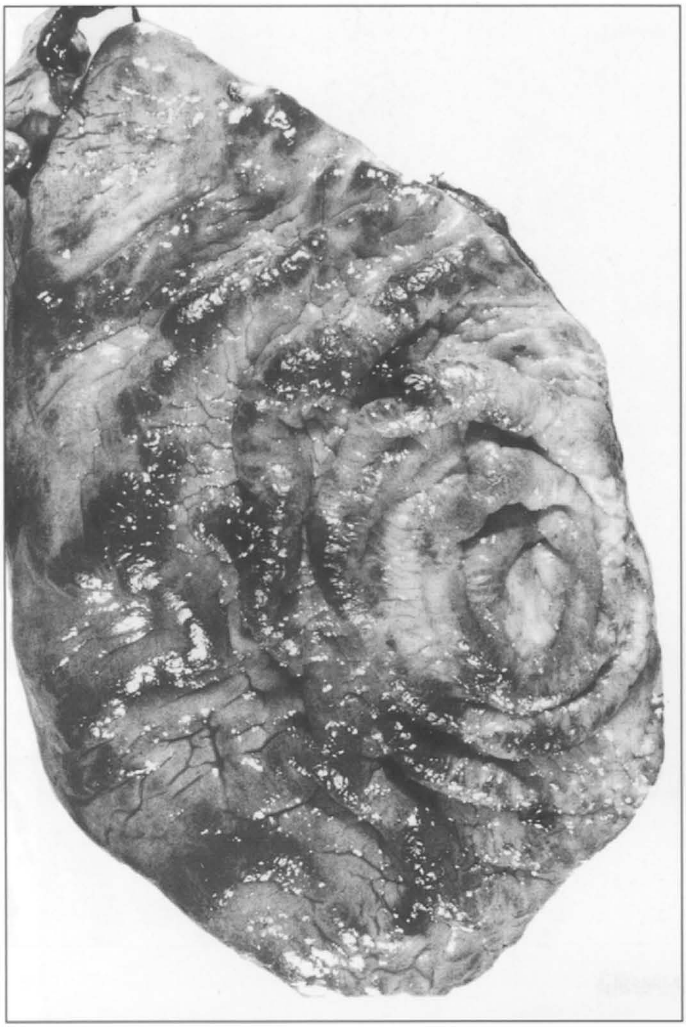

Figure 1.105 Hemorrhages in mucosa of urinary bladder in **malignant catarrhal fever**.

parenchyma can be explained on the basis of the vascular changes.

The lesions in *skin and squamous mucosae* of the alimentary tract consist of a lichenoid infiltrate, as the altered and proliferating lymphoid population moves into the upper dermis and then the epidermis (Fig. 1.109). Often, typical arteritis, involving small and medium-sized vessels, is present in underlying tissue. Groups of epithelial cells become necrotic, with swollen, strongly acidophilic cytoplasm; ultimately the full thickness of epithelium in affected areas undergoes necrosis and ulcerates (Fig. 1.109). Granulomatous mural folliculitis was the prominent microscopic finding in alopecic sika deer infected with CpHV-2.

The mucosa of the abomasum may be infiltrated by lymphocytes, and undergo mucous metaplasia or focal ulceration. The mucosa of the lower alimentary tract, especially the cecum and colon in deer, may similarly be heavily infiltrated by lymphocytes, often with fibrin and blood exuding into the lumen where surface and glandular epithelium has undergone necrosis and collapsed, sometimes over wide areas (Fig. 1.110). Submucosal arterioles in affected areas of abomasum and intestine are affected by the characteristic arteritis.

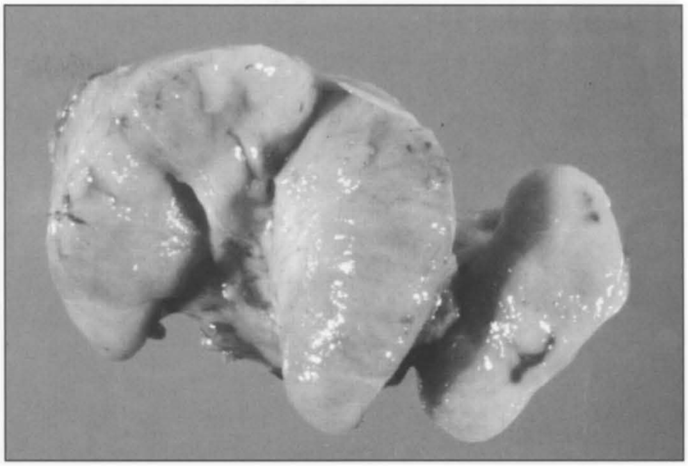

Figure 1.106 Hyperplastic enlarged lymph nodes bulging on cut surface, in cow with **malignant catarrhal fever**.

The *mottling of liver and the focal nephritis* seen grossly are due to the perivascular accumulation of mononuclear cells in the portal triads of the liver (Fig. 1.103) and in the cortices of the kidney. In the liver, these cuffs may be very large and invest the branches of the hepatic artery, which may undergo fibrinoid necrosis. Microscopic lesions are frequently present in the kidneys, even though gross lesions are not; they consist of vasculitis involving the smaller arteries and afferent arterioles. Extensive diffuse lymphocytic infiltrates disrupt the normal renal cortical architecture, and in some cases, infarcts appear to be associated with vasculitis involving arcuate arteries.

Ophthalmitis often occurs, and its presence is a useful differential criterion from other ulcerative diseases of the alimentary tract. Corneal edema, secondary to vasculitis, is responsible initially for the opacity (Fig. 1.111). Later there may be lymphocytic infiltration of various structures within the globe. There is retinal vasculitis and, in some cases, hemorrhagic or inflammatory detachment of the retina in focal areas. Lymphocytic optic neuritis and meningitis may be seen (see Vol. 1, Eye and ear).

Differentiation of acute severe BVD and mucosal disease from MCF is sometimes difficult, but *MCF usually affects one or more organ systems or tissues (liver, kidney, bladder, eye, brain, tracheobronchial tree) not involved in mucosal disease, and typically produces lymphoid hyperplasia in cattle, whereas lymphoid tissue in BVDV infections is expected to be atrophic.* Arteritis may be seen in some cases of BVDV infection, mainly in the submucosa in the lower alimentary tract. Fortunately, arteritis is present in one tissue or another in all cases of MCF, whether peracute, acute, or mild with recovery, though it may be necessary to examine many sections to find it. The best organs to examine for vascular lesions are the brain and leptomeninges, carotid rete, kidney, liver, adrenal capsule and medulla, salivary gland, and any area of skin or alimentary tract showing gross lesions. *A combination of arteritis, lymphoid hyperplasia, and lymphocytic infiltrates into affected epithelia is very characteristic of MCF.*

Bali cattle as well as other species of cattle and buffalo are affected with a disease that closely resembles MCF, and both diseases occur geographically together in Indonesia. **Jembrana disease** is caused by a *lentivirus* distinct from *Bovine immunodeficiency virus*, and has associated mononuclear proliferation and thrombosis in vessels of multiple organs, seemingly similar to MCF. Proliferation of T lymphocytes

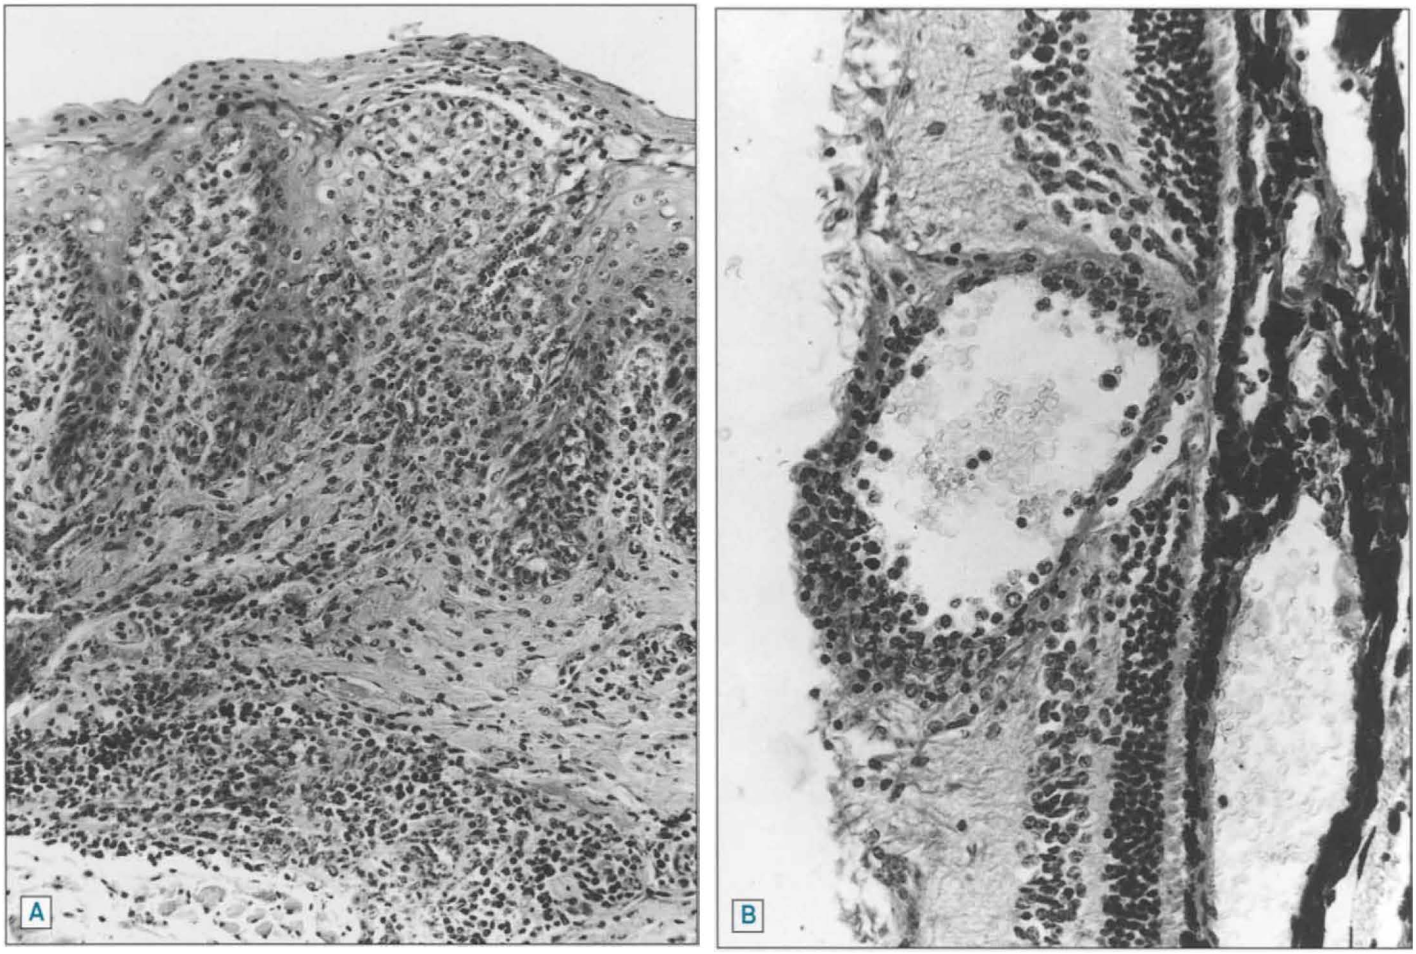

Figure 1.107 Malignant catarrhal fever. **A.** Vasculitis, with infiltration of lamina propria by lymphocytic cells with developing ulcer over papilla in the tongue. **B.** Vasculitis in retina.

and atrophy of follicles in lymph nodes and spleen, with lymphoid infiltrates in multiple organs in Jembrana disease, appear similar to lesions of MCF.

Bluetongue and related diseases

Bluetongue is caused by a reovirus of the genus *Orbivirus,* family Reoviridae. There are at least 24 recognized serotypes of *Bluetongue virus* (BTV), distinguished by serum neutralization tests. Immunity to one serotype does not confer resistance against another, and may cause sensitization, with a more severe syndrome following infection by a second type. Apparently, not all serotypes are pathogenic.

Epizootic hemorrhagic disease of deer is caused by a virus which represents another serogroup of *Orbivirus.* The virus causing *Ibaraki disease,* recognized in cattle in Japan, is a variant of *Epizootic hemorrhage disease virus* (EHDV); seropositive animals have also been found in Taiwan and Indonesia, and an identical virus has been isolated in Australia.

BTV, EHDV, and related viruses are spread by vector-competent *Culicoides* spp., also known as midges or gnats. The virus multiplies by a factor of 10^3–10^4 in the *Culicoides* within a week of the infected blood meal being ingested, and transmission can occur, following infection of the salivary glands, 10–15 days after the initial blood meal. Transovarial transmission of virus in *Culicoides* does not occur.

BTV circulates in a broad belt across the tropics and warm temperate areas, from about latitude 40°N to 35°S, with incursions or recrudescence during the *Culicoides* season, annually, or at irregular longer intervals in cooler temperate areas. The condition is enzootic or seasonally epizootic in most of Africa, the Middle East, the eastern Mediterranean basin, the Indian subcontinent, the Caribbean, and the USA. It appears sporadically in the Okanogan valley of western Canada. Recently it has made persistent incursions into the Iberian peninsula, Corsica and Sardinia, Italy, and the Balkans, perhaps associated with climate change. Seasonality of infection toward the periphery of its distribution probably reflects the unavailability of vectors, since virus may be able to overwinter in latently infected $\gamma\delta$T cells in the skin of sheep, which express virus once vector feeding occurs again.

Sheep, goats, and cattle are the susceptible domestic species, wherever bluetongue occurs. Sheep are the domestic species most highly susceptible to bluetongue, but there is considerable variation in expression of the disease, depending on the breed, age, and immune status of the sheep, the environmental circumstances under which they are held, and the strain of virus. Typically, indigenous breeds seem more resistant to clinical disease than do exotics. Goats, though susceptible to infection, rarely show signs; however, disease has occurred in goats in the Middle East and India. Infection in cattle usually produces only inapparent infection or mild clinical disease. In Africa, a wide variety of nondomestic ungulates and some small mammals may be inapparently infected; mortality has occurred in naturally or experimentally infected topi, Cape buffalo, and kudu. In North America, wildlife species, particularly white-tailed deer, black-tailed or mule

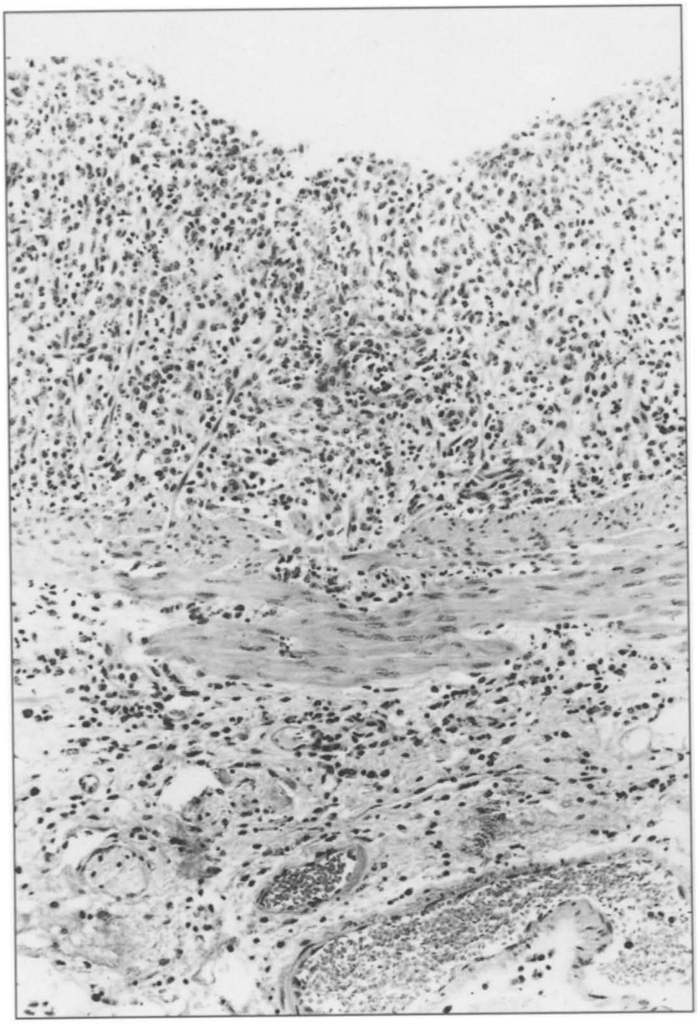

Figure 1.110 Colitis with collapse of glands and edema of submucosa in **malignant catarrhal fever**.

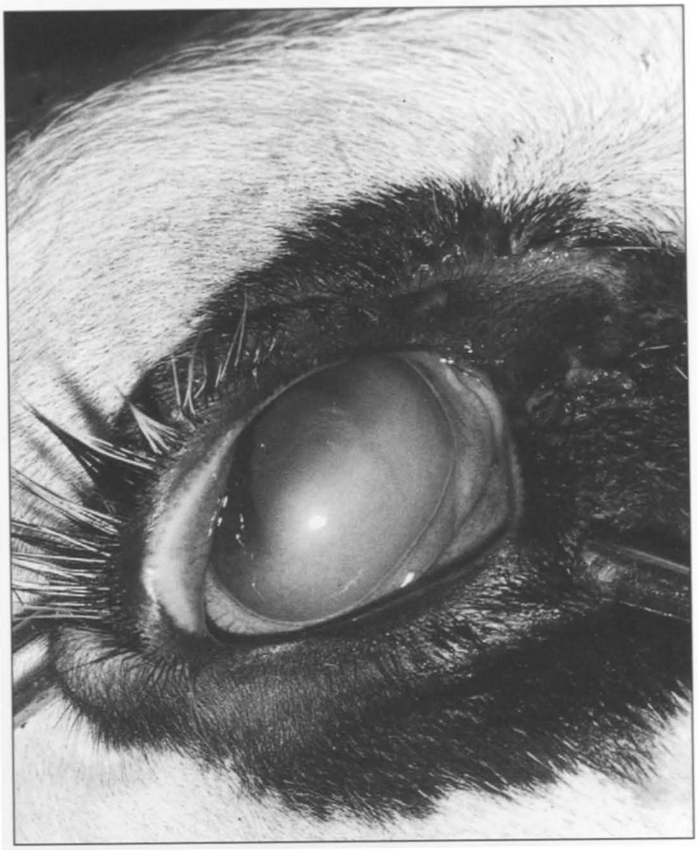

Figure 1.111 Corneal edema in **malignant catarrhal fever**.

deer, elk, bighorn sheep, bison, and pronghorn antelope are also infected. Bluetongue is responsible for significant mortality in all these species except elk, which usually develop mild or inapparent infection, and bison, which are infrequently demonstrated to be serologically positive. Vaccine inadvertently contaminated with BTV and administered to dogs caused significant mortality, but BTV is not normally considered a pathogen in dogs.

Epizootic hemorrhagic disease serogroup virus has been isolated in Nigeria, but the natural vertebrate hosts there are not known. In North America, the white-tailed deer is extremely susceptible, and widespread epizootics have occurred among this species in the USA. A single outbreak has been recognized in Alberta, Canada. The rate of survival is much higher among black-tailed deer and pronghorn antelope, and elk are only very mildly affected. Clinical disease similar to that produced by bluetongue may occur rarely in cattle. Though sheep are not considered to develop disease when infected with BTV, occasional mild clinical signs and lesions resembling bluetongue have been reported in sheep inoculated with some Australian isolates. In Japan, the *Ibaraki virus* strain of EHDV produces a clinical syndrome resembling bluetongue in cattle, but not in sheep.

BTV and EHDV circulate together in North America. Both viruses may be involved simultaneously in outbreaks of hemorrhagic disease in wild ruminants, and both have been isolated from *Culicoides* in a single locality at the same time. The role of cattle as reservoirs of BTV is uncertain. Cattle may act as reservoirs in that the virus will be associated with the erythrocytes for the lifespan of that cell. Detectable viremia in cattle is thought to be less than 9 weeks.

The **pathogenesis** of bluetongue, epizootic hemorrhagic disease, and Ibaraki disease is fundamentally similar in all species in which disease is seen. Primary viral replication following insect bite occurs in regional lymph nodes and spleen. Viremia about 4–6 days after inoculation results in secondary infection of endothelium in arterioles, capillaries, and venules throughout the body, but especially in lung microvascular endothelium. Microscopic lesions, fever, and lymphopenia begin a day or so later, about a week after inoculation. BTV in the blood appears to be closely associated with, or in, both leukocytes and erythrocytes, and it may co-circulate with antibody.

Endothelial damage caused by viral infection initiates local *microvascular thrombosis and permeability*. This is reflected microscopically by the presence of swollen endothelium, and fibrin and platelet thrombi in small vessels, with edema and hemorrhage in surrounding tissue. These lesions in turn mediate the full spectrum of gross findings. These are fundamentally *ischemic necrosis* of many tissues; *edema* due to vascular permeability; and *hemorrhage* resulting from vascular damage compounded, in severe cases, by consumption coagulopathy due to thrombocytopenia and depletion of soluble clotting factors. Differences in the expression and activity of vasoactive and pro- and anticoagulant mediators by infected pulmonary endothelium may explain the greater propensity of sheep to show signs, in comparison with cattle.

Bluetongue in sheep is highly variable; it may cause inapparent infection or an acute fulminant disease. Typically, leukopenia and pyrexia occur, even in mild infections, coincident with viremia. The degree and duration of fever do not correlate with the severity of the syndrome otherwise.

In the early phase there is hyperemia of the oral and nasal mucosa, drooling, and nasal discharge within a day or two of the onset of fever. Hyperemia and edema of the eyelids and conjunctiva may occur, and edema of lips, ears, and the intermandibular area becomes apparent. Hyperemia may extend over the muzzle and the skin of much of the body, including the axillary and inguinal areas. Focal hemorrhage may be present on the lips and gums, and *the tongue may become edematous and congested or cyanotic*, giving the disease its name. Infarcted epithelium thickens and becomes excoriated; erosions and ulcerations develop along the margins of the tongue opposite the molars, and the mucosa of much of the tongue may slough.

Excoriation and ulceration also occur on the buccal mucosa, the hard palate, and dental pad. Affected areas of skin may also become encrusted and excoriated with time, and a break in the wool can result in parts or much of the fleece being tender or cast. The coronet, bulbs, and interdigital areas of the foot may become hyperemic. Coronary swelling and streaky hemorrhages in the periople may be evident as a result of lesions in the underlying sensitive laminae. These hemorrhages may persist in the hoof as brown lines that move down the hoof as it grows. A defect parallel to the coronet may also be evident in the growing hoof in recovered cases.

Internally, in acute cases, there is *subcutaneous and intermuscular edema*, which may be serous or suffused with blood. Superficial lymph nodes are enlarged and juicy. Bruise-like gelatinous hemorrhages and contusions, which may be small and easily overlooked if not numerous, are often present in the subcutis and intermuscular fascial planes. Focal or multifocal pallid areas of streaky myodegeneration may be present throughout the carcass, perhaps partly obscured by petechial or ecchymotic hemorrhage. Resolving muscle lesions may be mineralized or fibrous. Stiffness, reluctance to move, and recumbency seen clinically are due to these muscle lesions.

Necrosis may be present deep in the papillary muscle of the left ventricle, and elsewhere in the myocardium. The lesion which is perhaps most consistent and closest to pathognomonic for bluetongue is *focal hemorrhage*, petechial or up to 1 cm wide × 2–3 cm long, in the tunica media at the *base of the pulmonary artery*. These hemorrhages are visible from both the internal and adventitial surfaces, and may be present in clinically mild cases with few other lesions. Petechial hemorrhage may also be present at the base of the aorta and in subendocardial and subepicardial locations over the heart.

There may also be edema and petechial or ecchymotic hemorrhage in the pharyngeal and laryngeal area. In severe cases the lungs may assume a purple hue, with marked edematous separation of lobules, and froth in the tracheobronchial tree, probably due to pulmonary microvascular damage and heart failure. Animals with pharyngeal or esophageal myodegeneration suffer from dysphagia, or regurgitate, and may succumb to aspiration pneumonia.

Hyperemia, occasionally marked hemorrhage, or in advanced cases, ulceration of the mucosa may occur on rumen papillae, the pillars of the rumen, and the reticular plicae. In convalescent animals, stellate healing ulcers or scars on the wall of the forestomachs may be apparent.

Microscopically, acute lesions are characterized by microvascular thrombosis, and edema and hemorrhage in affected sites recognized at autopsy. In squamous mucosa and skin, capillaries of the proprial and dermal papillae are involved, resulting in vacuolation and necrosis of overlying epithelium. There is a mild, local neutrophilic infiltrate acutely, and a similarly mild mononuclear reaction in the dermis or propria in uncomplicated chronic lesions, which may granulate if widely or deeply ulcerated. Similar microvascular lesions are associated with necrosis and fragmentation of infarcted muscle. Muscle during the reparative phase follows the usual course of regeneration of fibers or fibrous replacement, depending on whether or not the sarcolemma retains its integrity.

In **cattle**, *clinical bluetongue is rarely apparent*; in endemic areas it may never be evident. Mortality is low, and it is often attributed to secondary infection. Clinical disease may be a function of hypersensitivity in previously exposed animals, and disease in experimentally infected animals is poorly defined. Fever, loss of appetite, and leukopenia are usually seen after an incubation period of 6–8 days, and there may be a drop in milk production in dairy cattle. There is reddening of the epithelium of the mucous membranes, and of thin exposed skin, especially notable on the udder and teats. Edema of the lips and conjunctiva may be present. Drooling may become profuse, and as the disease progresses over the next several days, hyperemia and congestion of the mucosae become more intense. Ulcerations of the gingival, lingual, or buccal mucosa occur, most consistently on the dental pad. There may be necrosis of epithelium on the muzzle. Muscle stiffness is a feature of the disease in some animals. Laminitis, characterized by hyperemia and edema of the sensitive laminae at the coronet, may be apparent, and in some cases, hooves on affected feet may eventually slough. Sloughing or cracking of crusts of necrotic epithelium may also occur on affected parts of the skin, but the ulcerative or erosive defects heal readily. Viral antigen and thrombosis are present in small vessels in affected tissues during the acute phase.

The signs and lesions of **Ibaraki disease** are similar to those of bluetongue in cattle, though more severe in some cases. As well as the signs and lesions described in cattle with bluetongue, there may be difficulty in swallowing in 20–30% of clinically affected animals, and the swollen tongue may protrude from the mouth. At necropsy, in addition to the lesions observable externally, there may be congestion, erosion, or ulceration of the mucosa of the abomasum, and less commonly, the esophagus and forestomachs. Ischemic necrosis and hemorrhage of the striated muscle in the tongue, pharynx, larynx, and esophagus cause the difficulty in swallowing seen clinically, and similar changes are seen in other skeletal muscles. Necrotizing aspiration pneumonia is a sequel to dysphagia in some animals.

The *hemorrhagic diseases* in bighorn sheep, pronghorn antelope, and white-tailed and black-tailed or mule deer in North America resemble bluetongue in sheep. White-tailed deer may develop a particularly severe and fulminant hemorrhagic disease, with high mortality. There may be necrosis of velvet antler, and hooves may slough in survivors. Bluetongue in goats, though usually inapparent, can resemble bluetongue in sheep.

Bluetongue in sheep must be differentiated from foot-and-mouth disease, peste des petits ruminants, contagious ecthyma, and photosensitization in particular. In cattle, the condition must be differentiated from foot-and-mouth disease, vesicular stomatitis, bovine viral diarrhea, rinderpest, malignant catarrhal fever, and photosensitivity. In Japan, Ibaraki disease of cattle must in addition be differentiated clinically from ephemeral fever virus.

In addition to the systemic disease described, *abortion*, perhaps unobserved, and birth of progeny with various *congenital defects* may follow BTV infection of pregnant sheep and cattle. In sheep, BTV infection of ewes early in gestation may result in hydranencephaly. Anomalous calves produced by BTV-infected cattle have excessive gingiva, an enlarged tongue, anomalous maxillae, dwarf-like build, and rotations and contractures of the distal extremities. Porencephaly, hydranencephaly, and arthrogryposis are also reported in calves infected in utero with BTV. Antibody may be sought in neonates that have not sucked, and attempts should be made to isolate virus, since some prenatally infected animals may have immune tolerance, and persistent infection. Anomalies of the brain are considered further in Vol. 1, Nervous system.

Parapoxviral infections

Bovine papular stomatitis

Papular stomatitis of cattle occurs worldwide. *It is generally an insignificant infection*, but needs to be differentiated from other more serious diseases affecting the oral cavity and skin. It is caused by *Bovine papular stomatitis virus* (BPSV), a member of the family Poxviridae, genus *Parapoxvirus*, that is closely related to *Pseudocowpox virus* that causes pseudocowpox in cattle and milker's nodules in humans. It is morphologically similar to, and shares antigens with, *Orf virus* of sheep and goats (see Vol. 1, Skin and appendages). However, analysis of the genome indicates that these viruses are distinct.

BPSV is relatively host-specific. As with many of the poxviruses, neutralizing antibody is not readily demonstrated. Infection does not confer significant immunity, and successive crops of lesions and relapses can occur. The disease is more common in calves than in older animals, although the susceptibility of, or recrudescence in, the latter may be increased by intercurrent debility, disease such as bovine viral diarrhea, infectious bovine rhinotracheitis, or other stressors.

The *papular lesions* of this disease occur on the muzzle and in the rostral nares, on the gums, the buccal papillae, the dental pad, the inner aspect of the lips, the hard palate (Fig. 1.112A), the floor of the oral cavity behind the incisors, the ventral and lateral (not dorsal) surfaces of the tongue, and, occasionally, in the esophagus (Fig. 1.112B) and forestomach.

The initial lesions, which are likely to be detected on the muzzle or lips, are erythematous macules, ~2 mm–2 cm in diameter. Shortly, the central portion becomes elevated as a low papule, although the elevation is not easy to see, and by the second day a gray central zone of epithelial hyperplasia has developed on which there is superficial scaliness and necrosis. A central necrotic area may slough to form a shallow craterous defect surrounded by a slightly raised red margin. Lesions may coalesce. The course of individual lesions is about a week.

Histologically, there is focal but intense hyperemia and edema in the papillae of the lamina propria, with accumulation of a few mononuclear leukocytes. The epithelium is thickened, sometimes to twice its normal depth, by hyperplasia and ballooning degeneration in the deeper layers (Fig. 1.112C). The cytoplasm of affected cells is clear, and the nucleus may be shrunken. *Dense eosinophilic inclusion bodies lie in the vacuolated cytoplasm*, especially in cells at the active margin of the lesion. In the central, more advanced part of the lesion, a mainly neutrophilic infiltrate into the superficial propria and epithelium is associated with erosion of the upper layers of necrotic cells. The basal layer survives and may be very flattened in eroded areas. Vesicles do not form.

A *chronic form* has been reported, with necrotic and proliferative stomatitis, represented histologically by extensive parakeratotic hyperkeratosis, pseudoepitheliomatous hyperplasia, and occasional intracytoplasmic inclusion bodies.

Papular stomatitis is probably more common and widespread than reports indicate. Variation in the extent and gross appearance of the lesions is to be expected, depending on the usual host–parasite factors and the nature of superimposed infections. They may predispose to the development of necrotic stomatitis, and must be differentiated from the lesions of bovine viral diarrhea, alimentary infectious bovine rhinotracheitis, and other causes of ulcers and erosions in the upper alimentary tract. The infection can be transmitted to humans to produce small papules that may persist for several weeks on the skin, usually of the fingers or forearms.

Rapid diagnosis is readily accomplished by demonstration of characteristic parapoxvirus particles in negatively stained material from lesions examined under the electron microscope.

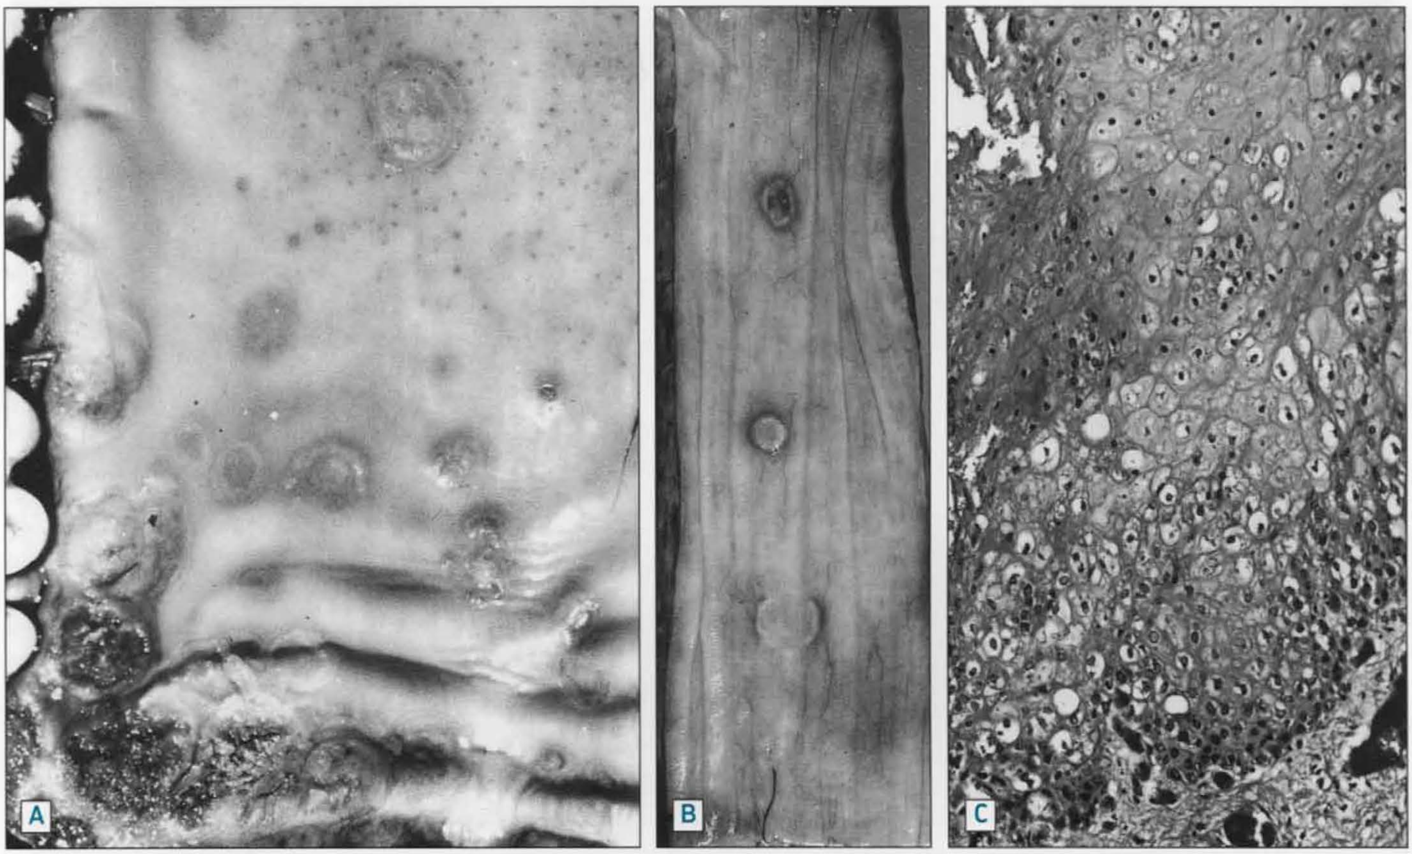

Figure 1.112 Bovine papular stomatitis. A. Lesions at various stages of evolution in palate. **B.** Lesions in esophagus. **C.** Thickened epithelium at the margin of a lesion, with ballooning degeneration of cells in the deeper layers.

Contagious pustular dermatitis

Contagious pustular dermatitis, also called **orf** or **contagious ecthyma**, is a parapoxviral disease of sheep and goats that is characterized mainly by *proliferative scabby lesions on the lips, face, and feet* (see Vol. 1, Skin and appendages). The disease has also been reported in camels and a gazelle. Lesions may extend into the oral cavity, involving the tongue, gingiva, dental pad, and palate. Involvement of the esophagus and forestomachs occurs, but is very unusual. In general the evolution of the lesions is similar to papular stomatitis of cattle, though they are more exudative and usually much more proliferative. Morbidity may be high, and death can occur in suckling animals. In the upper alimentary tract, lesions may consist of focal red, raised areas, which coalesce to form papules followed by pustules. The latter rupture, and on the muzzle and in the mouth they may become covered by a gray to brown scab, although scab formation may not occur in the mucosa of the upper alimentary tract. Diagnosis is by demonstration or isolation of *Orf virus*.

Infectious bovine rhinotracheitis

Bovine herpesvirus 1 (Infectious bovine rhinotracheitis virus, BoHV-1), which is in genus *Varicellovirus*, subfamily Alphaherpesvirinae, has been associated with a wide range of clinicopathologic syndromes in cattle. These include necrotizing rhinotracheitis, conjunctivitis, infectious pustular vulvovaginitis and balanoposthitis, vesicular lesions of the udder, abortions, and latent infection (see appropriate chapters). Clinical significance of BoHV-1 in other species such as bison that have serological evidence of exposure is not known.

A *systemic form* of the disease, which usually involves the alimentary tract, may occur spontaneously in neonatal calves (in which it may be congenital, or acquired shortly after birth) and in feedlot cattle. It has been reproduced experimentally in young calves.

The pathogenesis of systemic infection with BoHV-1 is poorly understood. Colostrum-deprived calves are especially susceptible,

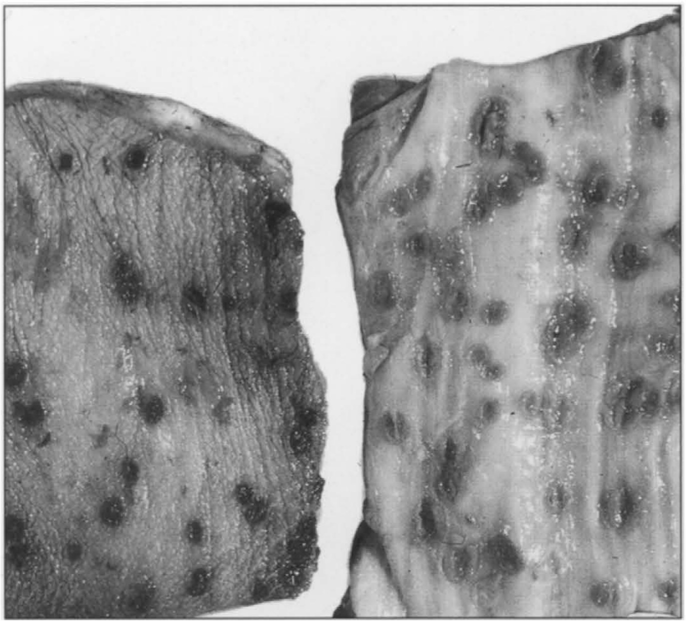

Figure 1.113 Foci of necrosis on mucosa of esophagus and rumen in a neonatal calf in **infectious bovine rhinotracheitis**.

and the disease can be prevented by feeding colostrum from actively immunized dams. The virus probably spreads from the mucosa of the upper respiratory tract to other tissues by circulating leukocytes. Peripheral blood mononuclear leukocytes may exhibit apoptosis in response to BoHV-1, but the significance of this is unknown. Experimental infection of calves with noncytopathic *Bovine viral diarrhea virus* (NCP-BVDV) followed by BoHV-1 inoculation results in dissemination of the latter to a variety of tissues. BVDV impairs cell-mediated immunity, and this may allow BoHV-1 to escape from the respiratory tract and lead to a systemic infection. Dual infections of BVDV and BoHV-1 occur under field conditions, but coinfection of these two viruses is not a prerequisite for the disease to develop.

Clinically affected animals have hyperemic oral and nasal mucosae, and focal areas of necrosis, erosion, and ulceration on the nares, dental pad, gums, buccal mucosa, palate, and the caudal, ventral, and dorsal surfaces of the tongue. Characteristically, the lesions tend to be punctate with a slightly raised margin; the necrotic areas are covered by a gray-white layer of fibrinonecrotic exudate, which leaves a raw red base when removed.

The *lesions* may extend into the esophagus, usually only the upper third, and the forestomachs. In the esophagus, the erosions and ulcers may be irregular, circular, or linear, and often they have a punched-out appearance and a hyperemic border (Fig. 1.113). The ruminal lesions, which are most commonly located in the dorsal and cranioventral sacs, vary considerably. The earliest lesions consist of foci of necrosis and hemorrhage, a few millimeters in diameter. In some cases, the necrosis may involve almost the entire surface of the ruminal mucosa, which becomes covered by a thick, dirty gray layer of exudate, resembling curdled milk, which adheres tightly to the wall (Fig. 1.114A). Similar lesions may be evident in the reticulum. Focal areas of necrosis result in the formation of holes, as large as 1.5 cm in diameter, in the leaves of the omasum. In addition, these calves may have focal areas of necrosis in the abomasal mucosal folds, which may coalesce to form areas of necrosis 2–3 cm in diameter. The intestines are red and dilated, and the serosal surface may be covered by a thin layer of fibrinous exudate.

The enteric lesions may be accompanied by changes in the upper respiratory tract. When present, the respiratory lesions are similar to those described for older cattle, although they are milder and generally limited to the nasal mucosa, larynx, and upper third of the trachea (see The Respiratory System, Volume 2, Chapter 5).

Gray to yellow necrotic foci 2–5 mm diameter may be evident macroscopically on the capsular and cut surfaces of the liver, the adrenal cortices, the spleen, and in Peyer's patches.

Microscopically, the lesions in the squamous mucosa are characterized by *focal areas of necrosis* (Fig. 1.114B), *erosion, and ulceration*. Severe necrosis may involve the entire papilla or mucosa more diffusely. *Nuclear inclusions* may be present in epithelial cells in the periphery of the lesion, although these are an inconsistent finding. They are more likely to be found if tissues are collected in the early stages of the disease and fixed in Bouin's fluid. The abomasal lesions consist of necrosis of glandular epithelial cells. Affected glands are dilated, and filled with necrotic debris. Focal necrotic lesions involving crypts and lamina propria may be present in both the small intestine and large bowel (Fig. 1.115). Abomasal and intestinal lesions may predispose to the development of *secondary mycosis*, which is a common complication.

Foci of coagulative necrosis may occur in the liver, lymph nodes, thymus, Peyer's patches, spleen, and adrenal cortices. Typically, there is little inflammation associated with the necrosis. Herpesviral inclusions are inconsistently seen in cells at the periphery of the necrotic foci.

The lesions in the upper alimentary tract of cattle associated with BoHV-1 infection must be differentiated from those of calf diphtheria, bovine papular stomatitis, and bovine viral diarrhea. The ruminal lesions must be differentiated from those of *Bovine adenovirus* infection and nonspecific rumenitis, described elsewhere in this chapter. The liver lesions may be confused with focal necrosis associated with septicemias, for example, listeriosis or salmonellosis (see Vol. 2, Liver and biliary system).

Caprine herpesvirus

A herpesvirus that shares some antigens with, but on the basis of restriction endonuclease analysis is distinct from, *Bovine herpesvirus 1*, has been isolated from neonatal goat kids in various parts of the world. This virus has been designated *Caprine herpesvirus 1* (CpHV-1),

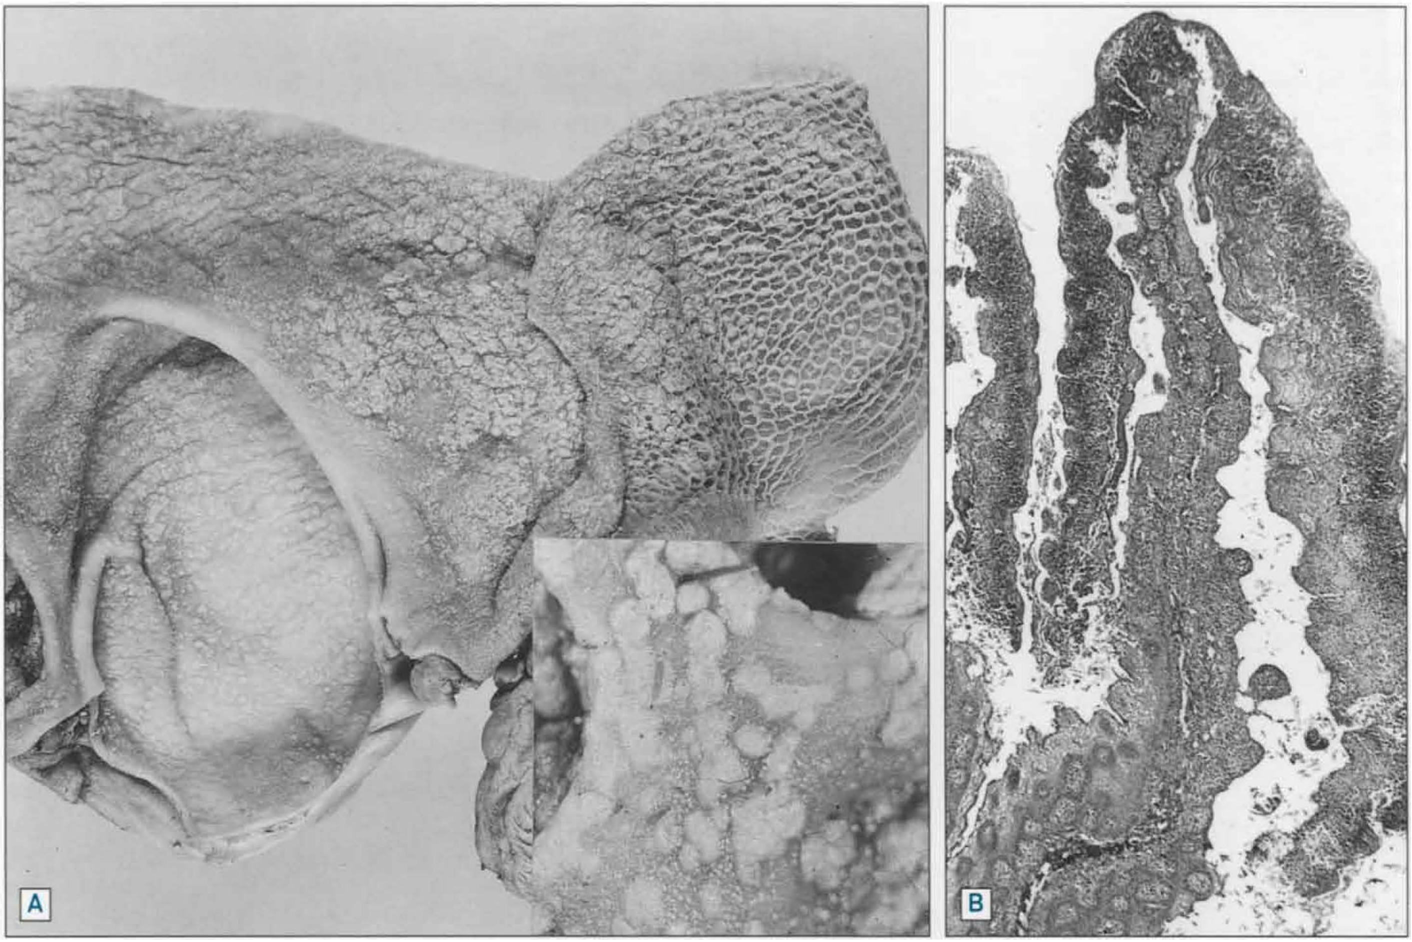

Figure 1.114 Infectious bovine rhinotracheitis in a neonatal calf. **A.** Cheesy necrotic debris in rumen and reticulum. Inset: Detail of rumen lesion. **B.** Necrosis of omasal fold.

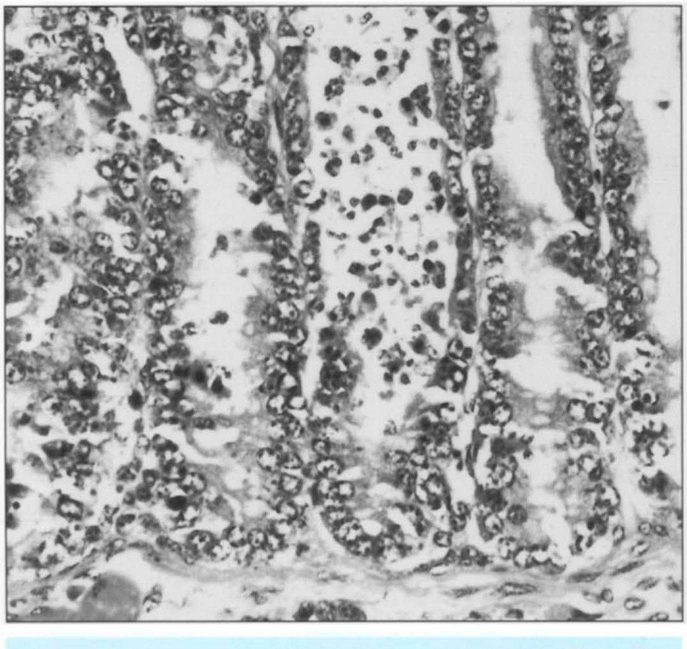

Figure 1.115 Necrosis of epithelium in the crypts of Lieberkühn in the small intestine of a neonatal calf with **infectious bovine rhinotracheitis**.

genus *Varicellovirus*, subfamily Alphaherpesvirinae. Although capable of infecting sheep, cattle, and goats, severe infection is restricted to goats. *CpHV-1 causes severe systemic disease with erosions and ulcerations of the alimentary tract in neonatal goats.* Adult goats may be latent carriers, developing vulvovaginitis or balanoposthitis (see Vol. 3, Female genital system). Infection of pregnant does causes abortion.

The disease in neonatal kids is characterized clinically by fever, conjunctivitis, ocular and nasal discharges, dyspnea, anorexia, abdominal pain, weakness, and death, usually within 1–4 days after onset of clinical signs. Affected kids have leukopenia and hypoproteinemia.

Macroscopic lesions are most obvious throughout the entire alimentary tract. Round or longitudinal erosions, which have a hyperemic border, are evident in the oral mucosa. These are particularly prominent on the gums around the incisor teeth and to a lesser extent in the pharynx and esophagus. Focal red areas of necrosis, which may be slightly elevated above the surrounding mucosa, occur in the rumen. In the abomasum, numerous longitudinal, red erosions are located in the mucosa. The most severe lesions occur in the *cecum and ascending colon*, which are dilated, with a thickened wall, and contain focal to large areas of mucosal necrosis and ulceration, frequently covered by a pseudodiphtheritic membrane. The contents are yellow and mucoid. Hemorrhagic foci may be visible in the bladder mucosa.

Microscopically, the lesions in the upper alimentary tract are typical areas of necrosis and erosion of squamous epithelial cells. The epithelial cells at the periphery of necrotic areas are swollen and vacuolated and these may contain *herpesviral inclusions*. There is marked inflammatory reaction in the underlying lamina propria. The abomasal lesions consist of acute foci of mucosal necrosis. Inclusions are particularly evident in this area. Lesions in the cecum and colon are more extensive and consist of large areas of mucosal ulceration and necrosis, which may involve the entire thickness of the wall. The submucosa is edematous and markedly infiltrated by inflammatory cells. The mesenteric nodes are edematous and germinal centers are depleted of lymphoid cells. Focal areas of necrosis with a mild inflammatory cell reaction may also be present in liver, urinary bladder, and kidney.

Other herpesviruses

Canid herpesvirus 1 causes systemic disease of neonatal puppies characterized by foci of necrosis and hemorrhage in a wide variety of organs, especially the lungs and renal cortices (see section on Viral infections of the pregnant uterus, Vol. 3, Female genital system). Focal areas of necrosis may occur in the intestine as part of the systemic syndrome.

Felid herpesvirus 1 (Feline viral rhinotracheitis virus) causes oral lesions (see section on Inflammation of the oral cavity, above). Viruses antigenically related to *Felid herpesvirus 1* have been isolated from dogs with diarrhea, but descriptions of lesions are not available.

Natural infections with ***Suid herpesvirus 1*** (SuHV-1; Pseudorabies virus, Aujeszky's disease virus) often result in necrotizing tonsillitis. Experimental infection of pigs with SuHV-1 may cause necrotizing enteritis of the distal small intestine. The enteric lesions are characterized by focal areas of necrosis of the cryptal mucosa, muscularis mucosae, and tunica muscularis. Immunohistochemically, antigen is documented in the dome area, the lymphoid follicles of Peyer's patches, and ganglion cells of Meissner's and Auerbach's plexuses.

Necrotizing enterocolitis in adult horses due to ***Equid herpesvirus 1*** has been reported rarely. At necropsy, there are multiple areas of hemorrhage, necrosis, and ulceration, some several centimeters in diameter, of the mucosa in both small and large intestine. Microscopically, these lesions consist of erosions and ulcerations of the mucosa, and necrosis of cryptal epithelial cells in adjacent areas. Cryptal epithelial cells and some proprial mononuclear cells may have acido- and amphophilic nuclear inclusions.

Adenoviral enteritis

The adenoviruses that have been associated with enteric infections in humans, cattle, swine, horses, sheep, and dogs belong to the Adenoviridae, genera *Mastadenovirus* and *Atadenovirus*. Serological surveys show that widely divergent serotypes occur both within and between host species and their distribution is worldwide. All serotypes are morphologically similar; the virus consists of a nonenveloped icosahedral capsid, 70–80 nm in diameter, which has 252 capsomeres. Virus neutralization tests are used to distinguish serotypes. Adenoviral infection of cells causes *intranuclear inclusions*. Adenoviruses are relatively heat-resistant and can survive for several days at room temperature. Most adenoviruses are transmitted by feces, aerosols, or possibly fomites, to susceptible, usually suckling or recently weaned, animals. Infected animals may remain carriers for weeks.

Adenoviruses are highly host-specific. Infections in both humans and animals appear, in general, to be subclinical, and disease seems to occur more commonly in immunologically compromised individuals. Most infections are systemic; certain strains have a tropism for the respiratory tract, and others for the alimentary tract, vascular endothelial cells, or hepatocytes. Their enteric manifestations will be considered here.

Bovine adenoviruses

There are 10 serotypes of *Bovine adenovirus* (BAdV) in the genera *Mastadenovirus* and *Atadenovirus*. Infection has been mainly associated with keratoconjunctivitis and respiratory disease. Many strains have been isolated from normal cattle. Serotypes 3, 4, 7, and 10 have been associated with enteric disease. It appears that after an initial viremic stage, the virus localizes in the *endothelial cells* of vessels in a variety of organs, resulting in thrombosis with subsequent focal areas of ischemic necrosis.

Clinically, enteric infections with BAdV occur sporadically in 1–8-week-old calves and in feedlot animals. Affected animals have fever, and diarrhea that may contain blood, and some animals will die peracutely from dysentery. They are dehydrated and the mucous membranes of the muzzle and mouth are congested. Dry, encrusted exudate may cover the muzzle and there may be serous to mucopurulent ocular and nasal discharges.

Macroscopic lesions may be present in the forestomachs, abomasum, and intestine. Those in the forestomachs are characterized by irregular, raised, red-to-gray necrotic areas, 2–4 mm in diameter on the mucosa of both the dorsal and ventral sacs of the rumen. In some cases, the areas of necrosis coalesce to give rise to diffuse necrotizing rumenitis. Ulcers up to 1.5 cm in diameter may be located on the ruminal pillars and these may be visible through the serosa. Similar lesions may be evident in the omasum. The abomasal mucosal folds are edematous and congested, with focal necrosis and ulceration in the mucosa that, like those in the forestomachs, may be visible on the serosal surface.

The intestinal lesions vary from slight dilation and distension with excessive fluid to severe multifocal or diffuse necrosis, which may be covered by a pseudodiphtheritic membrane. In young calves, the lesions are most severe in the jejunum and ileum, especially over the Peyer's patches. In feedlot cattle, the lesions may be most prominent in the colon. The mucosa is dark red (Fig. 1.116) and there is marked edema of the mesocolon. The mesenteric lymph nodes are enlarged and edematous.

Microscopically, *large basophilic to amphophilic inclusions* completely or partially fill the nuclei of endothelium in the vessels of the lamina propria and submucosa of affected areas of the rumen, abomasum, and intestine. The endothelial cells are swollen and necrotic, and some veins and lymphatics contain thrombi. Foci of ischemic necrosis are evident in the overlying mucosa, and in more advanced lesions, the necrosis extends across the muscularis mucosae (Fig. 1.117A). Fibrinocellular exudate often covers the mucosal surface. Intestinal crypts are dilated, lined by flat epithelial cells, and usually contain necrotic debris (Fig. 1.117B). There is usually marked submucosal edema, congestion, and fibrinous exudation. Foci of necrosis are evident in the lymphoid follicles of the Peyer's patches, which are also depleted of lymphocytes.

Typical inclusions may also be found in endothelial cells of vessels and sinusoids of the adrenal glands, mesenteric lymph nodes, liver, spleen, glomeruli, and interstitial capillaries in the kidney, and in the mucosa of the urinary bladder.

Confirmation of enteric BAdV infection depends on the demonstration of the virus in tissue, through electron microscopy, in situ hybridization, or isolation of the virus in tissue cell cultures. The latter is often difficult because different serotypes and strains of

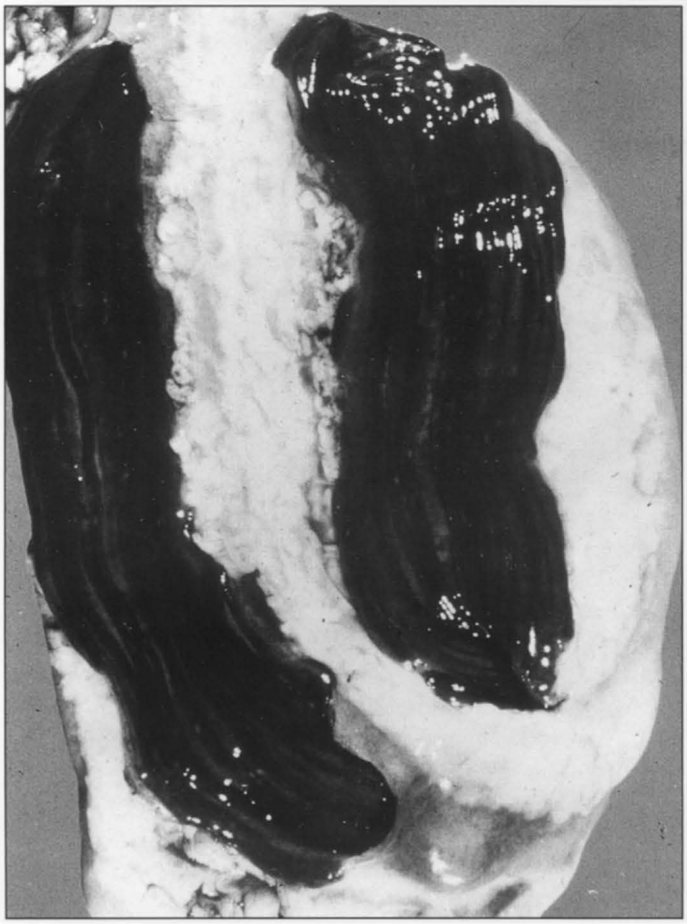

Figure 1.116 Congested and hemorrhagic colon caused by ***Bovine adenovirus*** infection.

the virus require specific tissue cell cultures and several blind passages may be required before cytopathic changes are evident.

Porcine adenovirus

There are six serotypes of *Porcine adenovirus* (PAdV) which, according to serological surveys, are all common. Serotype 4 appears to be the most widely distributed strain of the virus in Europe and North America. Asymptomatic infections are most common in swine and PAdV may be isolated from feces of normal pigs; PAdVs are actually of more interest as viral vaccine vectors than as pathogens.

The importance of adenoviruses as a cause of enteric disease in the field remains controversial. When disease occurs, the macroscopic lesions in the intestine consist of excessive yellow watery to pasty contents and moderate enlargement of the mesenteric lymph nodes, which cannot be differentiated from other causes of diarrhea in neonatal pigs.

In contrast to the situation in calves, in which inclusions are located in the nuclei of endothelial cells, *inclusions in pigs are in enterocytes* in the distal jejunum and ileum, where primary viral replication likely occurs. The infected nuclei are enlarged, round, and displaced to the apical portion of the cell. The villi may be short and blunt. There may be a moderate mononuclear cell reaction in the lamina propria. Inclusions are also found in the squamous epithelial cells of the tonsils.

Ultrastructurally, infected nuclei of enterocytes are round and swollen and contain numerous typical adenoviral particles (Fig. 1.118). Affected enterocytes are cuboidal and the apical portion protrudes slightly into the lumen. The cell membrane and microvilli are irregular and the terminal web is absent. The rough endoplasmic reticulum shows local distension with formation of large multivesicular bodies. Eventually, there is complete loss of microvilli, and the cell membrane ruptures with the release of cell contents and virus particles into the gut lumen.

The significance of adenoviral inclusions in enterocytes must be interpreted with caution. A survey in Canada revealed that 4.4% of 5-day to 24-week-old pigs had adenoviral inclusions in enterocytes, mainly in the ileum. More than 50% of the pigs had diarrhea; however, other enteropathogens were found in most of these animals.

Equine adenovirus

Two serotypes of *Equine adenovirus* (EAdV) have been identified in horses. EAdV-1 has a worldwide distribution. Subclinical infections are common. Clinical disease occurs mainly as an upper respiratory infection in foals less than 3 months of age. The infection is particularly important in Arabian foals with combined immunodeficiency (CID), in which intestinal involvement is common. EAdV is capable of replication in the intestinal epithelium and produces duodenal villus atrophy after experimental infection.

Another adenovirus, proposed to be a prototype of EAdV-2, has been isolated in Australia from foals with diarrhea. *Rotavirus* was also identified in the feces of these foals. A serological survey showed that 77% of adult horses in the area had neutralizing antibodies to this particular serotype.

An unidentified alimentary tract adenoviral infection has been reported in an Arabian foal that did not have lesions of CID. The foal had diarrhea and progressive weight loss over a 2-month period. The macroscopic lesions consisted of ulcers in the distal esophagus and nonglandular mucosa of the stomach. The intestine contained soft to semifluid ingesta. Histologically, there was necrosis and ulceration of the esophageal and gastric squamous mucosa. Typical adenoviral inclusions were found at all levels of the small intestine. These were most commonly located in the villus epithelial cells, less often in the crypts, and only occasionally in the submucosal glands. There was focal-to-diffuse villus atrophy through the small intestine.

Adenoviruses in other species

More than seven serotypes of *Ovine adenovirus* (OAdV) have been isolated from **sheep**. Serotypes 1, 2, and 3 have been recovered from feces of normal sheep, and lambs with enteritis and pneumoenteritis. Experimental inoculation of specific-pathogen-free lambs with OAdV-4 did not cause disease but the virus was re-isolated from feces and nasal secretions for several days postinfection. However, occasionally, there are reports of enteritis associated with abundant adenoviral inclusions in lambs and kids. In the former, inclusions were found predominantly in the lamina propria whereas in the latter they were mostly epithelial.

Goat adenovirus (GAdV) serotypes 1 and 2 can cause enteritis and diarrhea in **goat** kids; GAdV-1 is a serotype of *Ovine adenovirus D,* which also includes serotype 7 and isolate 287.

Two distinct but serologically related adenoviruses have been isolated from **dogs**. *Canine adenovirus 1* (CAdV-1) infection is usually subclinical, but it may cause infectious hepatitis, and diarrhea may be present in these cases. The virus has a particular tropism for hepatocytes and endothelial cells. The serosal hemorrhages in the gastrointestinal tract and possibly the diarrhea may be related to vascular damage in the serosa and mucosa respectively (see Vol. 2, Liver and biliary system). CAdV-2 is usually associated with upper respiratory infections in dogs (see Vol. 2, Respiratory system). Viruses serologically similar to CAdV-2 have been isolated from feces of diarrheic dogs. DNA fingerprinting of two of these isolates indicated that they are distinct from CAdV-2. It may be that the fecal isolates are due to swallowing of virus originating from upper respiratory tract infections.

Enteric coronaviral infections

Coronaviruses cause disease affecting a number of organ systems in a variety of species. Among domestic mammals they mainly cause enteric infections, although coronaviruses are implicated in pneumonia in swine and cattle, and in feline infectious peritonitis.

Genus *Coronavirus* is found with the genus *Torovirus* in the family Coronaviridae. Coronaviruses have a single-stranded RNA genome. They are pleomorphic or roughly spherical and vary in size from about 70 to 200 nm in diameter, averaging ~100–130 nm. They have a phospholipid-bearing envelope, probably derived in part from host cell membrane. They gain their name from the characteristic "corona" of petal- or droplet-shaped radial surface projections ("peplomers") visible under the electron microscope in negatively stained preparations.

The coronaviruses infecting each species of host appear to be distinctive; some species are infected by more than one type of coronavirus. There are antigenic relationships among viruses from various hosts, and experimental cross-infection will occur between some host species, usually without pathologic consequences. The species *Transmissible gastroenteritis virus*, *Feline coronavirus* (with two biological types: Feline infectious peritonitis virus, and Feline enteric coronavirus), and *Canine coronavirus* are in antigenic group 1. *Bovine coronavirus* is in Group 2, antigenically related to *Porcine hemagglutinating encephalomyelitis virus*, *Mouse hepatitis virus*, and *Rat coronavirus*, among others. Persistent infections can occur.

Viral replication in the intestinal epithelium by coronaviruses is similar in all the species studied. Coronavirus infects and replicates in the apical cytoplasm of absorptive enterocytes on the tips and sides of intestinal villi. Virions are probably taken up by the apical border of the cell, by fusion with the plasmalemma. Replication and maturation appear to involve budding of virions from the cytosol through the membrane and into the lumen of vacuoles or cisternae in the smooth endoplasmic reticulum, where they accumulate. Virions are found in tubules of the Golgi apparatus. They may exit via that route from infected cells, by exocytosis at the apical cell membrane, or on the lateral cell surface, since viral particles are often seen lined up between microvilli or in the basolateral intercellular space between infected cells. Virus may also be released by lysis of infected cells. Coronaviruses will also infect some mesenchymal cells in villi and probably mesenteric lymph node.

Changes in the infected cell occur by about 12–24 hours after infection. Mitochondria in virus-infected cells swell, cisternae of smooth and rough endoplasmic reticulum dilate, the cytoplasm of infected cells loses its electron density, and cells lose their columnar profile. The terminal web is fragmented; microvilli swell and become irregular, perhaps in association with blebbing of the apical membrane. Damaged epithelium may lyse in situ, releasing virus retained in cytoplasmic vacuoles, or it may exfoliate into the lumen. Profuse diarrhea usually begins about the time that early cytologic changes are becoming apparent, but before there is extensive epithelial exfoliation.

Exfoliation of damaged epithelium may be massive over a relatively short period of time, leading to the development of *villus atrophy*, the severity of which largely reflects the degree of initial viral damage. Villi may appear fused along their sides or tips, and during the exfoliative phase some villi with denuded tips may be present. The enterocytes present on villi shortly after the initial exfoliative episode are mainly poorly differentiated low columnar, cuboidal, or squamous cells, with stubby irregular microvilli. Within 2–3 days, villi begin to regenerate and the epithelium becomes progressively more columnar, though still lacking a well-developed brush border and its complement of enzymes. Defective fat absorption is reflected in the accumulation of lipid droplets in the cytoplasm of enterocytes on villi. This is particularly marked over the period of about 2–5 days after experimental inoculation.

With progressive epithelial regeneration from the crypts, the *villus fusion*, which may be the result of adhesion of temporarily denuded lamina propria of adjacent villi, regresses. Separation begins along the basal margins of the adhesions and progresses toward the tips of the villi. There may be focal acute inflammation in the lamina propria of temporarily denuded villi, and a mild mononuclear infiltrate in the stroma of collapsed villi. Though several cycles of viral replication may occur, poorly differentiated enterocytes appear relatively refractory to infection, and the virus titer falls, presumably as local immune mechanisms also come into play. Hyperplasia of epithelium in crypts usually results in eventual resolution of the villus atrophy, restoring normal function.

The diarrhea that occurs is a result of electrolyte and nutrient malabsorption, with some contribution by secretion by crypt cells, and probably by poorly differentiated surface epithelium in the reparative phase. Mechanisms of diarrhea in villus atrophy are discussed in the section on the Pathophysiology of enteric disease. Remission of signs occurs within about 4–6 days as regeneration of villi occurs, providing the animal survives the dehydration, electrolyte depletion, and acidosis brought about by diarrhea.

Swine coronaviruses

Three coronaviruses cause gastrointestinal signs in swine. *Porcine hemagglutinating encephalomyelitis virus*, in group 2 species of genus *Coronavirus*, causes vomiting and wasting disease in suckling piglets; this is a condition mainly mediated by infection of the central and peripheral nervous system (see Vol. 1, Nervous system). *Transmissible gastroenteritis virus* (TGEV) and *Porcine epidemic diarrhea virus* (coronavirus 777), both in group 1 species of genus *Coronavirus*, cause syndromes of acute diarrheal disease in all age groups, and chronic diarrhea and runting in weaned pigs. In some areas, coronaviruses, especially TGEV, are the major cause of diarrhea in neonatal swine.

Transmissible gastroenteritis (TGE) may affect swine of any age, causing vomiting, severe diarrhea, and, in piglets, high mortality. The disease is recognized throughout most of the world.

The epizootiology of TGE depends on the overall immune status of the herd and of the various age groups within the herd. Introduction of TGEV into a naive herd results in rapid spread of disease with high morbidity affecting all age groups. Sows and older pigs will show transient inappetence, possibly diarrhea and perhaps vomiting. Signs may be more severe in sows exposed to high virus challenge from infected baby pigs. Agalactia may occur in recently farrowed sows, perhaps related to TGEV infection of the mammary gland. *Suckling piglets develop severe diarrhea*, and mortality may approach 100% in piglets under 10–14 days old. Older pigs usually develop less severe signs and have lower mortality. In herds with enzootic infection, high piglet mortality may occur in the offspring of recently introduced naive sows, and diarrhea with lower mortality may occur in piglets over about 2–3 weeks of age as milk intake and concomitant lactogenic immunity wane. Infected pigs in the late suckling or weanling age group may runt. TGE is more prevalent in the winter, perhaps because the virus is not resistant to summer environmental conditions of warmth and sunlight. Baby pigs that are chilled also seem less able to survive the effects of infection.

The severity of disease in baby pigs is partly related to their inability to withstand dehydration, due to their small size, and to their susceptibility to hypoglycemia. Probably as significant is the differentiation, and low rate of turnover, of small intestinal epithelium in the neonate. The surface epithelium is mature and has an extensive vesicular network in the apical cytoplasm associated with uptake of macromolecules and colostrum during the first day or two after birth. Crypts are short and relatively inactive. The population of epithelium susceptible to infection on each villus is therefore large, and the capacity to regenerate new enterocytes is small. By about 3 weeks of age, epithelium is actively proliferative. Virus production by infected enterocytes in older pigs seems less efficient, and replacement of cells lost to infection is more rapid, contributing to the relative resistance seen in swine over about 3 weeks of age.

Piglets with TGE have the nonspecific gross appearance at necropsy of undifferentiated neonatal diarrhea. The stomach may contain a milk curd or bile-stained fluid. The small bowel is flaccid and contains yellow frothy fluid with flecks of mucus; chyle is not usually evident in mesenteric lymphatics since there is fat malabsorption.

The microscopic lesions are those of villus atrophy due to exfoliation of surface enterocytes (Fig. 1.119), the severity of which is a function of the age of the pig and the stage of the disease. In young piglets, the lesions are most severe about the time of the onset of diarrhea. In later phases or in older pigs there may be subtotal to moderate atrophy, and the mucosa may be lined by cuboidal to low columnar epithelium, with irregular nuclear polarity and an indistinct brush border. Severe atrophy is readily recognized at necropsy of neonatal piglets, by examination of the mucosa under a dissecting microscope. Lesions are most common in the middle and lower small intestine, and villi in the duodenum are usually tall and cylindrical. Lesions may be patchy, and several areas of lower small intestine must be examined before atrophy is considered not to be present. In animals beyond the neonatal age group, atrophy may not be so severe and readily recognized under the dissecting microscope, and the contrast with the normally shorter villi in the duodenum of older pigs is not as marked. Histologic assessment of the gut is essential.

Porcine respiratory coronavirus (PRCoV) is genetically and antigenically extremely close to enteric TGEV. It cross-reacts serologically,

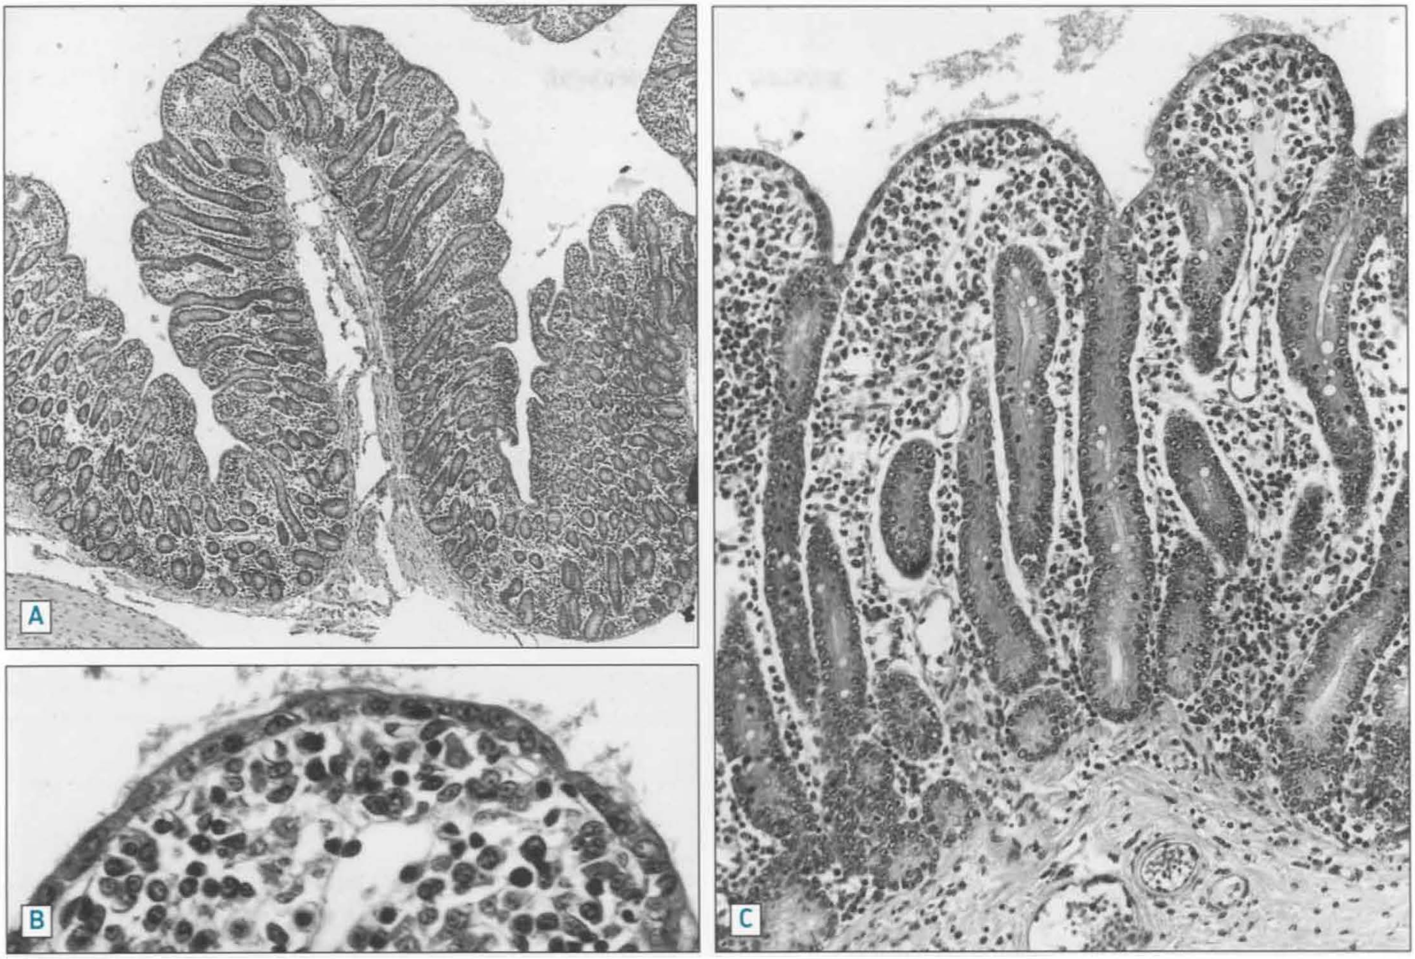

Figure 1.119 Transmissible gastroenteritis in a pig. **A.** Atrophy of villi in small intestine. **B.** Severely attenuated enterocytes on surface of an atrophic villus. **C.** Atrophy of villi, with compensatory hypertrophy of crypts of Lieberkühn. Surface epithelium is cuboidal or flattened.

and vaccinated sows successfully induce passive immunity against enteric infections. PRCoV is spread by inhalation, and infects lining cells of the upper respiratory tract. Mild bronchointerstitial pneumonia results from experimental infection, and the agent has been associated with outbreaks of respiratory disease.

Porcine epidemic diarrhea virus (PEDV), antigenically distinct from TGEV, is reported from England, continental Europe, China, and Taiwan. It causes disease that is essentially similar to TGE in epidemiology, pathogenesis, and lesions, but is milder. In addition to infection of epithelium low on villi and occasionally in small-bowel crypts, PEDV may also cause mild exfoliative lesions in colonic crypts. It is differentiated from TGEV by its distinct viral antigenicity and genome.

Bovine coronavirus

In **neonatal calves,** *Bovine coronavirus* (BCoV) infection is a common cause of diarrhea, either alone or in combination with other agents, particularly *Rotavirus* and *Cryptosporidium*. The disease may be severe in combination with BVDV infection. BCoV is capable of infecting absorptive epithelium in the full length of the small intestine, and in the large bowel. Viral antigen is also found in macrophages in the lamina propria of villi and in mesenteric lymph nodes. In field infections, microscopic lesions are found most consistently in the lower small intestine and colon. Calves with BCoV infection usually develop mild depression, but continue to drink milk despite developing profuse diarrhea. With progressive dehydration, acidosis, and hyperkalemia, the animals become weak and lethargic; death ensues as a result of hypovolemia, hypoglycemia, and potassium cardiotoxicosis. Diarrhea in survivors resolves in 5–6 days.

At autopsy, affected animals have the nonspecific lesions of undifferentiated neonatal calf diarrhea. Rarely, mild fibrinonecrotic typhlocolitis is recognized at necropsy in calves with coronaviral infection. Mesenteric lymph nodes may be somewhat enlarged and wet.

The microscopic lesions of coronaviral infection in calves vary with the severity and duration of the infection; *villus atrophy in combination with mild colitis is typical* (Fig. 1.120). In the calf *small intestine*, villus atrophy is rarely as severe as that seen in neonatal swine with TGE. Rather, villi are moderately shortened, or have subtotal atrophy with stumpy, club-shaped, or pointed tips, and villus fusion may be common. In the early phase of the clinical disease, villi are often pointed and covered by cuboidal to squamous epithelium. Exfoliation of epithelium and microerosion may be evident. Later, the epithelium is cuboidal to low columnar, basophilic, with irregular nuclear polarity and an indistinct brush border. Cryptal epithelium is hyperplastic. The lamina propria may contain a moderate infiltrate of mainly mononuclear inflammatory cells, some of which may have pyknotic or karyorrhectic nuclei. In the early stages of infection, necrosis of cells in mesenteric lymph nodes is associated with viral replication. Peyer's patches in animals examined after 4–5 days of clinical illness often appear involuted, and are dominated by histiocytic cells. Whether this is the result of viral activity or the effect of endogenous glucocorticoids is unclear.

In the *colon* during the early phase of infection, surface epithelium may be exfoliating, flattened, and squamous or eroded in patchy areas; some colonic glands lined by flattened epithelium will contain exfoliated cells and necrotic debris. A moderate mixed inflammatory

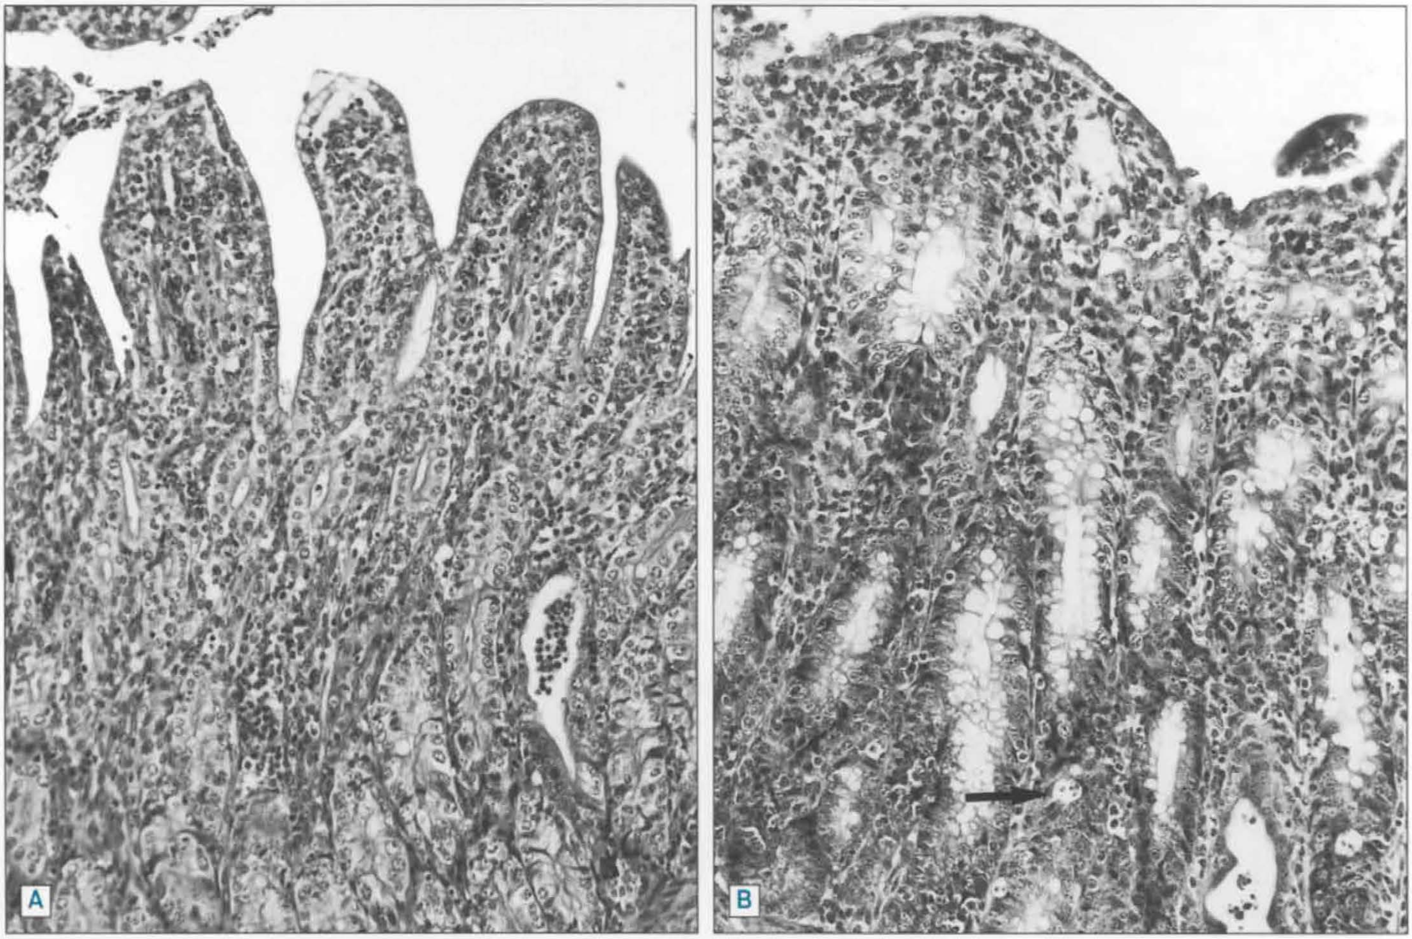

Figure 1.120 ***Bovine coronavirus* infection**. **A.** Blunt, fused villi with cuboidal surface epithelium in small intestine. **B.** Attenuation of surface epithelium and necrosis of gland epithelium (arrow), in colon. (Courtesy of M Morin.)

reaction is present in the lamina propria, and neutrophils may be in damaged glands or effusing into the lumen through superficial microerosions. Later in infection, some dilated debris-filled colonic glands will remain, but other glands will be lined by hyperplastic epithelium, and the surface epithelium will be restored to a cuboidal or low columnar cell type. Goblet cells are usually relatively uncommon. Colonic lesions may be recognizable in tissues from animals submitted dead, though postmortem change has obscured changes in the small intestine.

Live calves in the early stages of clinical disease are the best subjects for confirmation of an etiologic diagnosis. In calves becoming ill under 4–5 days of age, enterotoxigenic *Escherichia coli* is the main alternative diagnosis. *Rotavirus*, *Cryptosporidium*, and combined infections must be considered in calves 5–15 days of age. Infectious bovine rhinotracheitis, salmonellosis, and bovine viral diarrhea must also be considered. Both salmonellosis and bovine viral diarrhea may be associated with depletion of Peyer's patches and colitis that can be confused with that of coronaviral infection; neither is common in the strictly neonatal age group (under 7–14 days of age).

Respiratory tract infection also occurs in calves and feeders infected with BCoV. The virus replicates in the epithelium of the nasal turbinates and tracheobronchial tree, and *respiratory infection may precede, be concurrent with, or follow enteric infection.* Mild nasal discharge, cough, and increased respiratory rate are associated. Respiratory infections may play a role in maintaining the virus within a herd, and significant, but poorly characterized, pneumonia has been reported in some experimentally infected calves. In addition, coronaviral infection may predispose to subsequent respiratory bacterial infections or contribute to more severe respiratory disease as part of the shipping fever syndrome. Virus may be identified in tissue or nasal secretions by immunofluorescence or immunohistochemistry.

Winter dysentery is a syndrome in adult cattle that has been associated with BCoV in a number of areas around the world. Animals develop blood-tinged diarrhea, nasolacrimal discharge or cough, anorexia, and drop in milk production. Mortality is rare, but may occur. The colon of affected animals has linear congestion and hemorrhage along the crests of mucosal folds. Coronaviruses are commonly demonstrated in the feces of cattle with winter dysentery; seroconversions occur, and seroprevalence increases in affected herds; and coronavirus antigen is found in the colonic glands of affected animals, in which there is necrosis and exfoliation of epithelial cells. Certain management practices, notably housing animals in stanchions and use of equipment that handles both manure and feed, have been associated with the development of winter dysentery.

Canine coronavirus

Canine coronavirus (CCV) is widely prevalent in the dog population. Although dogs of all ages appear to be susceptible to infection by CCV, the condition is probably most important as an *uncommon, transient, generally nonfatal, diarrhea in puppies*. Fatal infections have been reported in pups previously infected with parvovirus.

Viral replication occurs in the enterocytes of the small intestine, and in experimental infections in neonatal puppies, the lesion resembles the *villus atrophy* associated with coronaviral infection in other species. Diarrhea begins as early as 1 day after inoculation and in most animals by 4 days. Onset of signs coincides with the development of moderate villus atrophy and fusion. Enterocytes on villi become cuboidal, contain lipid vacuoles, and have an indistinct brush border. Lesions are most consistent and severe in the ileum. Resolution of villus atrophy within 7–10 days is associated with remission of signs.

Colonic infection by CCV was not demonstrated by immunofluorescence in experimental animals, though mild colonic lesions were described, including loss of sulfomucins from goblet cells and some epithelial shedding. However, in a report of lesions due to spontaneous CCV infection, colonic infection and lesions were demonstrated. There was watery content in the lumen of the small and large intestine, and in the cecum and colon fibrin mixed with some blood was evident. Mesenteric lymph nodes were enlarged and edematous. Villus atrophy in the jejunum was inconsistent, but there was necrotic debris in many glands in the cecum and colon. Virus-infected cells were exfoliating into the lumen.

Feline and other enteric coronaviruses

Our understanding of the enteric implications of coronaviral infections of **cats** is still incomplete. It appears that *Feline enteric coronavirus* (FECV) can establish persistent infection in the intestine which, in rare cases, may be clinically apparent. Infection is very common. Diarrhea, when it occurs, is usually mild or moderate, perhaps with some blood, and kittens are most susceptible. Viral antigen is in cells on the tips of villi, and mild villus atrophy has been illustrated. Feline infectious peritonitis (see section on Peritonitis in cats, below), of far greater clinical significance, is due to viruses that arise by mutation from endemic FECV.

Coronaviruses have been recovered from the feces of **sheep** with transient diarrhea, and they have been associated with severe villus atrophy in several spontaneous outbreaks of diarrhea. No experimental confirmation of the pathogenicity of coronavirus in sheep is available.

Coronaviral infection may also be associated with diarrhea in **foals**, but again, experimental confirmation of pathogenicity is lacking.

Rotaviral infections

Members of the genus *Rotavirus*, in the family Reoviridae, infect the gastrointestinal tract of most mammals and birds. Rotaviruses are classified according to antigenic properties with group, subgroup, and serotype categories. Segment 6 of the *Rotavirus* genome codes for the VP6 intermediate capsid protein, which is used to classify the virus into seven serogroups, A–G. *Group A rotaviruses (RV-A) are the most common* and infect all species of domestic animals, as well as humans, laboratory animals, and wildlife. RV-A can be subdivided into G and P serotypes based on VP7 and VP4 external capsid proteins respectively; there are 14 G serotypes and 20 P serotypes. The serotypes isolated most commonly from piglets with diarrhea are P[7],G5, P[6],G4, P[7],G3, and P[7],G11. Individual rotavirus serotypes have a surprisingly wide range of host susceptibility. Nongroup A rotaviruses infect pigs and ruminants, among domestic animals.

The ability to infect cells, and the serotype specificity of rotaviruses, are conferred by elements of the outer capsid layer. The viruses are probably generally host-specific, with little significant zoonotic potential. However, if epidemiologic circumstances are favorable, cross-species transmission may occur.

Rotaviruses infect the absorptive enterocytes and occasionally goblet cells on the tips and sides of the distal half or two-thirds of villi in the small intestine. Rotaviruses infect cells on the apical half (ruminants) or the entire villus (pigs), mainly in the jejunum and ileum. Virus production and the pathogenesis of infection are similar in all species studied. Rotaviruses adhere to cell receptors (e.g., integrins, sialic acid), and inner capsid components are internalized into the cell. Granular "viroplasm" containing incomplete virions is seen in the apical cytoplasm of infected cells, and virions acquire their complete capsid after budding into dilated cisternae of endoplasmic reticulum, where they accumulate. Elongate tubular structures are found in the nuclei and rough endoplasmic reticulum of some infected cells.

Virus-infected cells are most prevalent 18–24 hours after experimental infection, and they tend to diminish in number rapidly, so that by 3–4 days after infection few cells containing viral antigen are present. Infected enterocytes lose cytoplasmic electron density, and mitochondria swell, as does the cell generally. Swollen rarified cells and syncytia may occur in the enterocytes at the villus tips, but cells are fragile and will shed readily, particularly if autolysis intervenes. Syncytial cell formation has been recognized in porcine, bovine, and laboratory animal infections with rotavirus. Microvilli become irregular and somewhat stunted, and there may be some blebbing of membranes. Infected cells exfoliate into the intestinal lumen, and virus is released by lysis of damaged epithelium prior to or after exfoliation.

The *pathogenesis of diarrhea* with *Rotavirus* involves three mechanisms. First, malabsorption occurs secondary to destruction of enterocytes. Second, a vasoactive agent is released from infected epithelial cells and causes villus ischemia and activation of the enteric nervous system. Third, rotaviruses are capable of producing a nonstructural protein, NSP4, which acts as a *secretory enterotoxin*. This is the first viral pathogen known to produce a toxin.

Exfoliation of infected epithelium over a relatively short period of time results in villus atrophy. The mucosal surface is covered by cuboidal, poorly differentiated epithelium that has an ill-defined microvillus border and that may contain lipid droplets in the cytoplasm. Diarrhea is probably mediated by electrolyte and nutrient malabsorption, perhaps exacerbated by the effect of cryptal secretion. It begins about the time of early viral cytopathology 20–24 hours after infection, and may persist for a variable period, from a few hours to a week or more. Regeneration of the mucosa by epithelium emerging from crypts, and differentiating on reformed villi, is associated with remission of signs in animals surviving the effects of diarrhea.

Rotaviruses are widespread, if not ubiquitous, among populations of most species, and they are relatively resistant to the external environment. Protection against infection in neonates is apparently largely conferred by the presence of *lactogenic immunity*. Many individuals in a population probably undergo inapparent infection. Disease is seen in the various species when viral contamination of the environment is heavy, perhaps as a result of intensive husbandry practices, and lactogenic immunity is waning or absent. Though rotaviral infection is usually associated with younger age groups, and viral receptors on cells diminish with age in some species, naive older animals may become infected, sometimes with the development of diarrhea.

Cattle rotaviral infection

Rotaviral infection is mainly implicated in *diarrhea of neonatal beef and dairy calves*, both suckled and artificially reared, though there are reports of its association with diarrhea in adult cattle. Diarrhea may be produced in calves by rotaviral infection alone, but the condition is usually considered to be relatively mild or transient in comparison with that induced by enterotoxigenic *Escherichia coli* or *Bovine coronavirus*. Combinations of agents, including *Rotavirus*, are frequently involved in outbreaks of diarrhea in neonatal calves. *Rotavirus* may be implicated in animals developing signs at any time over the period up to about 2–3 weeks of age, and it is more commonly encountered in animals over 4–5 days of age. Rotaviral diarrhea is most severe in calves that have slower enterocyte regeneration times.

The gross lesions of rotaviral infection are the nonspecific findings of undifferentiated neonatal diarrhea in calves, described previously. *Microscopic lesions in the small intestine cannot be differentiated from those of coronaviral infection.* They may vary somewhat depending on the severity of the initial viral damage and the stage of evolution of the sequelae. Blunt club-shaped villi, mild or moderate villus atrophy, and perhaps villus fusion may be present (Fig. 1.121). Villi are covered by low columnar, cuboidal, or flattened surface epithelium with a poorly defined brush border. There is usually a moderate proprial infiltrate of mononuclear cells and eosinophils or neutrophils, and hypertrophic crypts may be evident. The distribution of lesions may vary between animals and perhaps with time after infection within an individual animal, since the onset of maximal viral damage may not occur synchronously throughout the full length of the intestine. Lesions and viral antigen should always be sought in the distal small intestine, and preferably at several sites along its length. *Rotavirus* does not cause gross or microscopic lesions in the colon, in contrast to coronavirus.

Swine rotaviral infection

Rotavirus infection is widespread and enzootic in most swine herds, and subclinical infection of piglets is common. It assumes particular importance as a cause of diarrhea in pigs with reduced lactogenic immunity, either as a result of early weaning or following normal weaning. High environmental levels of virus may result in disease in piglets suckling the sow, but in these circumstances the signs are usually relatively mild. *Rotavirus* may be a cause of "3-week," "white," or postweaning scours in piglets from 2 to 8 weeks of age.

The signs may resemble those of transmissible gastroenteritis (TGE), although *Rotavirus* infection is considered to be less severe. Vomition is less commonly encountered than with TGE, but depression, diarrhea, and dehydration are usual. The character of the

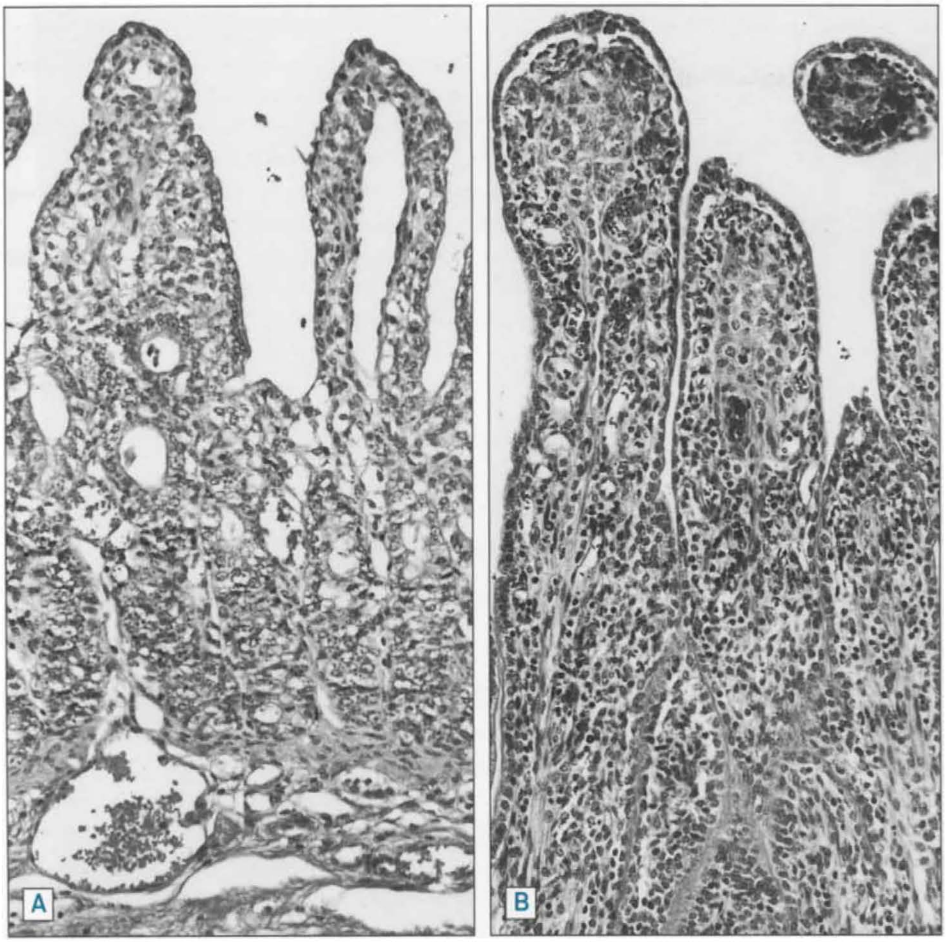

Figure 1.121 Bovine ***Rotavirus*** infection. **A.** Stumpy villi with severely attenuated surface epithelium. **B.** Club-shaped villi with cuboidal or flattened epithelium. (Courtesy of M Morin.)

feces varies with the diet. Steatorrhea occurs in white scours of suckling piglets. *Rotavirus* infection in swine may be associated with other causes of diarrhea, including *E. coli*, coccidiosis, adenoviral infection, and *Strongyloides*.

The gross and microscopic lesions and pathogenesis of rotavirus infection in pigs resemble those of TGE (Fig. 1.122). As in TGE, severity of lesions seems inversely related to age.

Rotaviral infection in other species

Neonatal lambs have proved a useful model for the demonstration of the importance of lactogenic immunity in preventing disease due to *Rotavirus*. *Rotavirus* may cause diarrhea in neonatal lambs alone or in combination with enterotoxigenic *E. coli* and *Cryptosporidium*. The pathogenesis and lesions of *Rotavirus* infection in lambs are like those caused in other species, with the exception that viral infection of the colon may occur.

In **foals** under 3–4 months of age, diarrhea may be associated with *Rotavirus* infection, though mortality is rare. Outbreaks have been reported in many areas of the world. The natural and experimental disease resembles that seen in other species, with significant viral infection limited to enterocytes in the small intestine, where villus atrophy occurs.

In young **puppies**, especially those under 1–2 weeks of age, diarrhea, occasionally fatal, may be caused by *Rotavirus* infection. In experimentally infected pups, green fluid content filled the lower small bowel and colon, and moderate villus atrophy was induced by exfoliation of epithelium from the distal half of villi.

Rotavirus has also been associated with diarrhea in **kittens**, although rotavirus can also be isolated from asymptomatically infected kittens.

Rotavirus infection should be sought in cases of diarrhea in young animals of any species and it should be particularly suspected in animals with villus atrophy in the small intestine. Rotavirus is part of the syndrome of undifferentiated neonatal diarrhea in any species.

Parvoviral enteritis

The Parvoviridae are small nonenveloped viral particles about 18–26 nm in diameter, with icosahedral symmetry and a short single-stranded DNA genome. They replicate, and produce inclusion bodies, in the nucleus of infected cells. Members of the genus *Parvovirus* infect many species of laboratory and domestic animals. Among syndromes associated with parvovirus infection are: disease in cats, dogs, and mink (distinct from *Aleutian mink disease virus*) dominated clinically by enteritis; diarrhea in neonatal calves; and reproductive wastage in swine.

Feline panleukopenia virus (FPV), *Mink enteritis virus* (MEV) and *Canine parvovirus 2* (CPV-2), the agent causing parvoviral enteritis in dogs, are considered host range variants or strains of the feline parvovirus subgroup within the genus *Parvovirus*. These viruses are biologically distinct, varying in their hemagglutination characteristics, in vitro host cell ranges, infectivity, and virulence in experimentally inoculated hosts. There are subtle antigenic differences among them, detected by monoclonal antibodies; these, and differences in host specificity, are conferred by variations in only very small segments of the viral genome. Based on the nucleotide sequence in the gene for capsid proteins VP1/VP2, FPV and MEV are very closely related to each other, and somewhat less related to CPV-2. Two new antigenic types have evolved from CPV-2 – CPV-2a and CPV-2b – and are able to replicate in cats. Another variant, CPV-2c, has been isolated from leopard cats. The host ranges of FPV and CPV are determined by receptor binding, particularly to the transferrin receptor TfR. *Canine parvovirus 2* is distinct from *Canine minute virus* (CMV, or *Canine parvovirus 1*) that also has enteric lesions associated with infection.

Though autonomous parvoviruses may infect cells at any phase of the cell cycle, replication is dependent on cellular mechanisms only functional during nucleoprotein synthesis prior to mitosis. Hence, *the effects of parvoviral infection are greatest in tissues with a high mitotic rate*. These may include a variety of tissues during organogenesis in the fetus and neonate. In older animals, the proliferative elements of the enteric epithelium, hematopoietic and lymphoid tissue are particularly susceptible. At the time of virus assembly, *large basophilic or amphophilic Feulgen-positive nuclear inclusions* may be found in infected cells, especially in Bouin's fixed tissues. Parvovirus is demonstrated in these inclusions by electron microscopy. The chromatin in inclusion-bearing nuclei is usually clumped at the nuclear membrane. Inclusions are most prevalent late in the incubation period, prior to extensive exfoliation or lysis of infected cells. Hence, they are not commonly encountered in animals submitted for autopsy after a period of clinical illness culminating in death. Large nucleoli, seen in proliferative cells encountered in the intestine of parvovirus-infected animals, should not be confused with intranuclear viral inclusions.

The *pathogenesis* of FPV and of CPV-2 infection is sufficiently similar for them to be considered together here, followed by separate discussions of the specific diseases. Oronasal exposure results in uptake of virus by epithelium over tonsils and Peyer's patches. Infection of draining lymphoid tissue is indicated by isolation of virus from mesenteric lymph nodes 1–2 days after experimental inoculation. Release of virus into lymph, and dissemination of infected lymphoblasts from these sites, may result in infection of other central and peripheral lymphoid tissues, including thymus, spleen, lymph nodes, and Peyer's patches, 3–4 days after infection. Lymphocytolysis in these tissues releases virus, reinforcing cell-free viremia. Viremia is terminated when neutralizing antibody appears in circulation about 5–7 days after infection. Moderate pyrexia occurs at about this time.

Infection of the gastrointestinal epithelium is a secondary event, following dissemination of virus by circulating lymphocytes and cell-free viremia. Peyer's patches are consistently infected at all levels of the intestine, and epithelium in crypts of Lieberkühn over or adjacent to Peyer's patches usually becomes infected a day or so later. Infection of gastrointestinal epithelium at other sites in the gut is less consistent, but is usually more severe in the lower small intestine. It may be the result of virus free in circulation, or carried by infected lymphocytes homing to the mucosa. Maximal infection of cryptal epithelium occurs during the period about 5–9 days after infection.

The occurrence and severity of enteric signs are determined by the degree and extent of damage to epithelium in intestinal crypts. This seems to be a function of two main factors. The first is the availability of virus, which is influenced by the rate of proliferation of lymphocytes, and therefore their susceptibility to virus replication and lysis. The second factor influencing the degree of epithelial damage is the rate of proliferation in the progenitor compartment in crypts of Lieberkühn. If many cells are entering mitosis, large numbers will support virus replication and subsequently lyse. Destruction of cells in the crypts of Lieberkühn, if severe enough, ultimately results in focal or widespread villus atrophy and perhaps mucosal erosion or ulceration. The recognition, evolution, and sequelae of radiomimetic insult to the intestine, such as that caused by parvovirus, are described elsewhere (see section on Epithelial renewal in health and disease, above).

Regeneration of cryptal epithelium and partial or complete restoration of mucosal architecture will occur, if undamaged stem cells persist in most affected crypts, and the animal survives the acute phase of clinical illness. In some survivors, focal villus atrophy is associated with persistent dilated crypts containing cellular debris, and with local "drop-out" of crypts completely destroyed by infection. In rare animals recovered from acute disease, chronic malabsorption and protein-losing enteropathy are associated with persistent areas of ulceration caused by more extensive loss of crypts and collapse of the mucosa.

The low rate of replication of intestinal epithelium in germfree cats explains failure to produce significant intestinal lesions and clinical panleukopenia in experimentally infected animals. In spontaneous cases, the lower prevalence of parvoviral lesions in the colon and stomach, in comparison with the small intestine, reflects the relatively lower rate of epithelial proliferation in those tissues. The consistency of epithelial lesions in the mucosa over Peyer's patches probably results from high local concentrations of virus derived from infected lymphocytes in the dome and follicle. This may be coupled with local stimulation of epithelial turnover by cytokines released by T lymphocytes in the vicinity. Variations in the rate of epithelial proliferation related to age, starvation, and refeeding, or concomitant parasitic, bacterial, or viral infections, may also influence the susceptibility of crypt epithelium to infection, and therefore affect the extent and severity of intestinal lesions and signs.

Diarrhea in parvoviral infections is mainly the result of reduced functional absorptive surface in the small intestine. Effusion of tissue fluids and blood from a mucosa at least focally denuded of epithelium probably also contributes to diarrhea. Dehydration and electrolyte depletion are the result of reduced fluid intake, enteric malabsorption, effusion of tissue fluid, and, in some animals, vomition. Hypoproteinemia is common, and anemia may occur due to enteric blood loss; both are exacerbated by rehydration. Anemia reflects hemorrhage into the gut.

Proliferating cells in the *bone marrow* are also infected during viremia. Lysis of many infected cells is reflected in hypocellularity of the marrow caused by depletion of myeloid and erythroid elements, particularly the former. Megakaryocytes may also be lost, but seem the least sensitive cell population in the marrow. The number of neutrophils in circulation drops quickly in severely affected animals. This is due to failure of recruitment from the damaged marrow, and peripheral consumption, especially in the intestine. Transient neutropenia, of about 2–3 days' duration, occurs consistently in cats, and less commonly in dogs. In surviving animals, regeneration of depleted myeloid elements from remaining stem cells restores the circulating population of granulocytes within a few days. Neutrophilia with left shift may occur during recovery.

Lymphopenia, relative or absolute, results from *viral lymphocytolysis* in all infected lymphoid tissue. Relative lymphopenia is more consistently observed in dogs than neutropenia. When lymphopenia and neutropenia occur together, *the combined leukopenia may be profound in both dogs and cats*. In dogs surviving the lymphopenic phase, circulating lymphocytes return to normal numbers within 2–5 days, as regenerative hyperplasia occurs in lymphoid tissue throughout the body. Lymphocyte numbers increase rapidly, sometimes producing lymphocytosis in recovering dogs. However, there may be transient immunosuppression in gnotobiotic pups subclinically infected with CPV-2. Transient depression of T-cell response to mitogens occurs in cats a week after experimental infection with FPV. But immunosuppression by these agents appears to be of little clinical significance.

Most infected cats and dogs do not develop clinical disease. When it occurs, signs usually begin during the late viremic phase, about 5–7 days after infection. Severe enteric damage is the major cause of mortality. Shedding of infective virus in feces begins about 3–5 days after infection, when Peyer's patches and cryptal epithelium first become infected. Virus shedding persists until coproantibody appears to neutralize virus entering the gut, about 6–9 days after infection. Virus-infected cells may still be detected in crypts and Peyer's patches at this time, and virus complexed with antibody may be found in feces or intestinal content by direct electron microscopy. However, attempts to demonstrate virus in tissues or feces after several days of clinical disease, or at death, are often thwarted by the fact that virus is neutralized by antibody present in tissue fluids. Persistent or sporadic shedding of virus by recovered animals may be the result of virus replication in cells entering mitosis days or weeks after they were infected during the viremic phase.

Infection of the fetus during late prenatal life by FPV causes *anomalies of the central nervous system*, mainly hypoplasia of the cerebellum; anomalies of the central nervous system have not been reported in puppies with CVP-2, although there is mounting evidence from polymerase chain reaction studies that central nervous system lesions in puppies can be induced by fetal CVP-2 infections. Infection of proliferating cardiac myocytes in young puppies with CPV-2 results in nonsuppurative myocarditis and sequelae of acute or chronic heart failure (see Vol. 3, Cardiovascular system), but this is rarely seen in populations with a high prevalence of maternal immunity. A tentative association has been made between infection of kittens with FPV and myocarditis, as well as subsequent cardiomyopathy.

Feline panleukopenia

Feline panleukopenia virus (FPV) infects all members of the Felidae, as well as mink, raccoons, and some other members of the Procyonidae. FPV is ubiquitous in environments frequented by cats, and infection is common, though generally subclinical. The disease panleukopenia (infectious feline enteritis, feline distemper) usually occurs in young animals exposed after decay of passively acquired maternal antibody, but it may occur in naive cats of any age. Clinical signs of several days' duration, including pyrexia, depression, inappetence, vomition, diarrhea, dehydration, and perhaps anemia may be evident in the history. However, many cases, particularly poorly observed animals or those prone to wander, may be presented as "sudden death." The pathogenesis of panleukopenia has been considered above. Lesions of the central nervous system in kittens are considered in Vol. 1, Nervous system.

At **necropsy**, external evidence of diarrhea may be present, the eyes may be sunken, and the skin is usually inelastic, with a tacky subcutis reflecting dehydration. Rehydrated animals may have edema, hydrothorax, and ascites due to hypoproteinemia. There is pallor of mucous membranes and internal tissues in anemic animals. Gross lesions of internal organs most consistently involve the thymus and the intestine. The thymus is markedly involuted and reduced in mass in young kittens. Enteric lesions may be subtle and easily overlooked. Hence *it is mandatory that intestine be examined microscopically despite the apparent absence of gross change.*

The intestinal serosa may appear dry and nonreflective, with an opaque ground-glass appearance. Uncommonly in cats, there may be petechiae or more extensive hemorrhage in the subserosa, muscularis, or submucosa of the intestinal wall. The small bowel may be segmentally dilated and can acquire a hose-like turgidity in places, perhaps due to submucosal edema. However, turgidity is difficult to assess in the intestine of the cat. The content is usually foul-smelling, scant, and watery, and yellow-gray at all levels of the intestine. The mucosa may be glistening gray or pink, with petechiae, perhaps covered by fine strands of fibrin (Fig. 1.123). Patchy diphtheritic lesions may be present, especially over Peyer's patches in the ileum. Flecks of fibrin and sometimes casts may be in the content in the lumen. Formed feces are not evident in the colon. Lymph nodes may be prominent at the root of the mesentery. Gross lesions elsewhere in the carcass are usually restricted to pulmonary congestion and edema in some animals, and pale gelatinous marrow in normally active hemopoietic sites.

Microscopic lesions are consistently found in the intestinal tract in fatal cases, and are usual in lymphoid organs and in bone marrow. The *intestinal lesions* vary with the severity and duration of the disease. Lesions may be patchy, and several levels of gut should be examined, preferably including ileum and, if possible, Peyer's patch. During the late incubation period and early phase of clinical disease, crypt-lining epithelium is infected. Intranuclear inclusions may be found, and damaged epithelium containing inclusions exfoliates into the lumen of crypts. Crypts are dilated and lined by cuboidal or more severely attenuated cells. The lamina propria between crypts contains numerous neutrophils and eosinophils at this time, and some emigrate into the lumen of crypts, where they join the epithelial debris.

Subsequently, severely damaged crypts may be lined by extremely flattened cells, and by scattered large bizarre cells with swollen nuclei and prominent nucleoli (Fig. 1.124A). Enterocytes covering villi are not affected. But as they progress off the villus, they are replaced by a few cuboidal, squamous, or bizarre epithelial cells, so that villi in affected areas undergo progressive collapse. If cryptal damage is severe and widespread, the mucosa becomes thin and eroded or ulcerated, with effusion of tissue fluids, fibrin, and erythrocytes. Inflammatory cells are usually sparse in the gut of such animals, and superficial masses of bacteria may be present, occasionally accompanied by locally invasive fungal hyphae. In less severely affected animals with disease of longer duration, corresponding to about 8–10 days after infection, scattered focal drop-out of crypts, or focal mucosal collapse and erosion or ulceration, may be evident. In these animals, remaining crypts recovering from milder viral damage show regenerative epithelial hyperplasia (Fig. 1.124B). Mucosal lesions are often most marked in the vicinity of Peyer's patches.

Lesions in the *colon* generally resemble those found in the small bowel, though they are often less severe or more patchy in distribution. Colonic lesions are present in about half of fatal cases of panleukopenia. Gastric lesions resulting from damage to mitotic epithelium are relatively uncommon in cats. They are recognized by flattening of basophilic cells lining the narrowed isthmus of gastric fundic glands, with some reduction in number of parietal cells in the upper portion of the neck of glands.

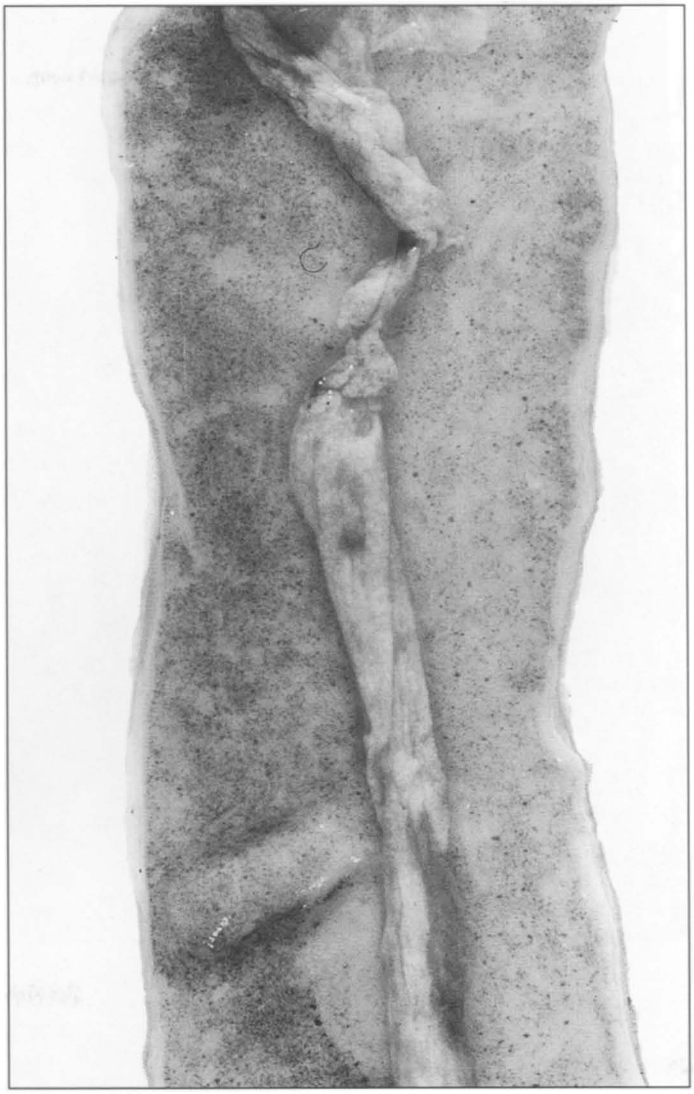

Figure 1.123 Petechiae and fibrin cast on mucosa of small intestine in **feline panleukopenia**.

Lesions of *lymphoid organs* during the early phase of the disease consist of lymphocytolysis in follicles and paracortical tissue in lymph nodes, in the thymic cortex and splenic white pulp, and in gut-associated lymphoid tissue. Lymphoid necrosis has been associated with induced apoptosis of virus-infected lymphocytes. Lymphocytes are markedly depleted in affected tissue and large histiocytes are prominent, often containing the fragmented remnants of nuclear debris. Follicular hyalinosis, the presence of amorphous eosinophilic material in the center of depleted follicles, may be seen. Erythrophagocytosis by sinus histiocytes may occur in lymph nodes, especially those draining the gut. Severely depleted Peyer's patches may be difficult to recognize microscopically. Later in the course of clinical disease, corresponding to the period beyond about 7–8 days after infection, prominent regenerative lymphoid hyperplasia may be found.

In severely affected animals at the nadir of the leukopenia, virtually all proliferating elements in the *bone marrow* may be depleted.

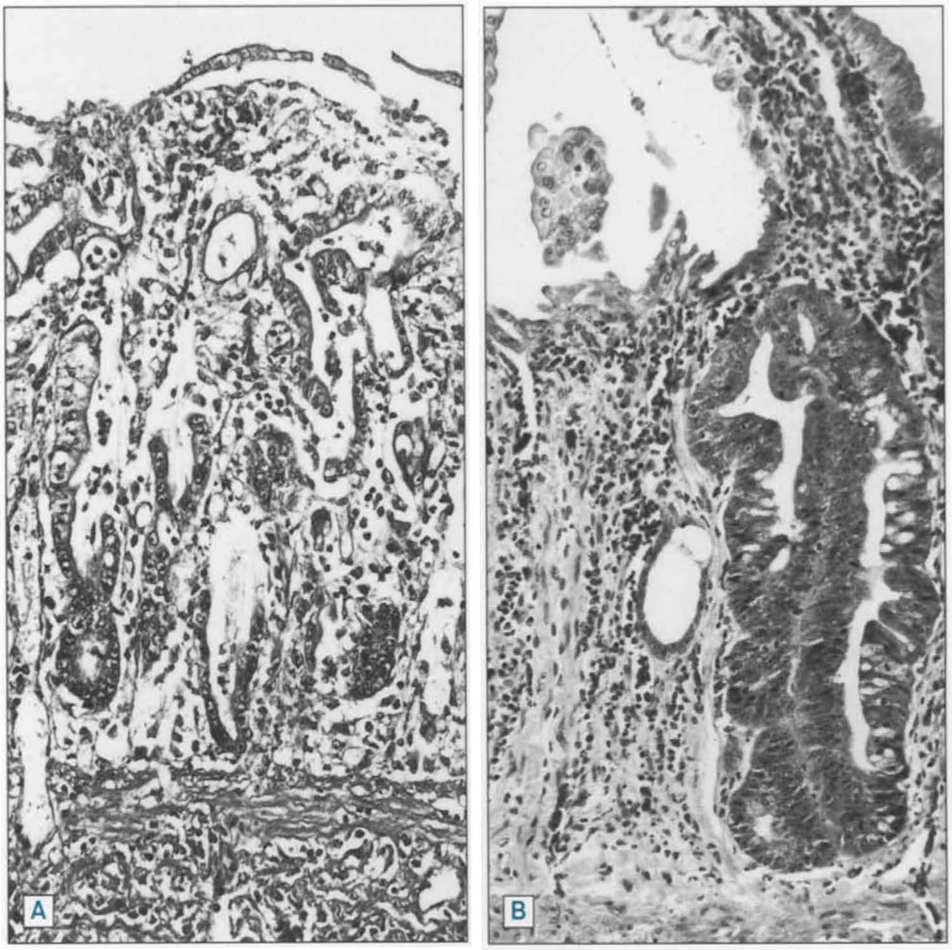

Figure 1.124 **A.** Severe atrophy of villi associated with damage to crypts of Lieberkühn, caused by ***Feline panleukopenia virus*** infection, in a cat. Attenuation of surface epithelium and depletion of proprial inflammatory infiltrate. **B.** Loss of crypts and collapse of proprial stroma; gland is lined by hyperplastic epithelium in a regenerating state in ***Mink enteritis virus*** infection 12 days after inoculation.

The extremely hypocellular, moderately congested marrow is only populated by scattered stem cells. Milder lesions mainly affect the neutrophil series, generally sparing megakaryocytes and the committed erythroid elements. During the later phases of the disease, marked hyperplasia of stem cells, and eventually of amplifier populations in the various cell lines, is evident.

In the *liver*, dissociation and rounding up of hepatocytes, and perhaps some periacinar atrophy and congestion, may be evident. This is probably associated with dehydration and anemia. Pancreatic acinar atrophy is also common, reflecting inappetence. The lung may be congested and edematous. In leukopenic animals, few white cells are seen in circulation in any organ.

A **diagnosis** of feline panleukopenia may be made on the basis of the characteristic microscopic intestinal lesions, in association with evidence of involution or regenerative hyperplasia of lymphoid and hematopoietic tissues. *Inclusion bodies* may be sought in these tissues, but are usually present in significant numbers only during the late incubation and early clinical period. Application of immunohistochemical techniques may identify viral antigen in tissue as late as 8–10 days after infection. Cryptal necrosis is also reported in the intestines of some cats with *Feline leukemia virus* infection, which must be differentiated.

Canine parvovirus 2 infection

Canine parvovirus 2 (CPV-2) resulted from mutation of a closely related virus, likely an FPV-like virus from wild carnivores, such as foxes. It appeared spontaneously and virtually simultaneously in populations of dogs on several continents in 1978, and rapidly spread worldwide. Retrospective serologic studies suggest that it was circulating unnoticed in western Europe by 1976. In addition to domestic dogs, several species of wild canids, including coyotes, gray wolves, and raccoon dogs, are susceptible to infection.

Enteric disease due to this virus was epizootic for several years in naive populations of dogs, affecting animals of all ages. As the prevalence of antibody due to natural infection and vaccination increased, the problem subsided to one of an enzootic disease. It now affects those animals with reduced levels of passively acquired maternal immunity, or scattered naive individuals.

During the epizootic period, nonsuppurative viral myocarditis due to CPV-2 was prevalent in the offspring of naive bitches unable to protect pups with maternal antibody during the first 15 days of life, when replicating myocardial cells are susceptible to parvoviral

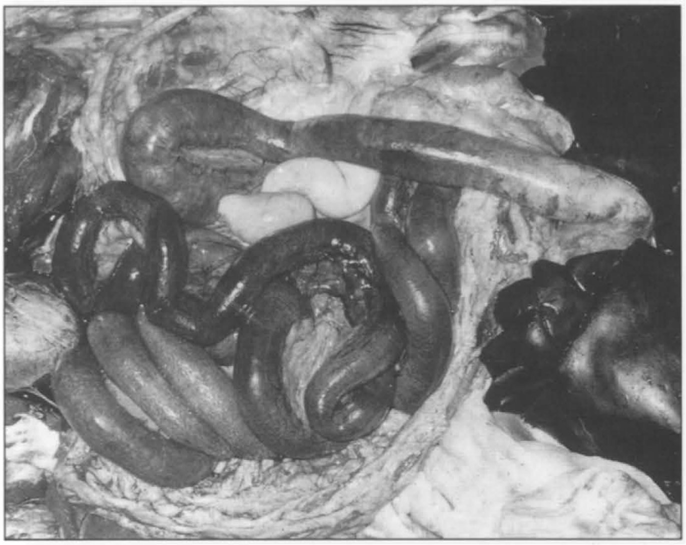

Figure 1.125 Segmental subserosal hemorrhage and mild fibrinous exudation on intestinal serosa in ***Canine parvovirus 2*** infection.

damage. Myocardial disease in pups due to CPV-2 is now fairly uncommon, as most bitches have antibody. Enteric and myocardial disease rarely occur together in the same individual or cohort of animals. Occasional cases of generalized parvoviral infection have been reported in susceptible neonates. Necrosis and inclusion bodies are found in organs such as kidney, liver, lung, heart, gut, and vascular endothelium. They are presumably related to mitotic activity during organogenesis.

Dogs with typical disease due to CPV-2 become anorectic and lethargic and may vomit and develop diarrhea, perhaps in association with transient moderate pyrexia. Relative or absolute lymphopenia or leukopenia of 1–2 days' duration may occur. Diarrhea may be mucoid or liquid, sometimes bloody, and is malodorous. After a period of 2–3 days, dogs either succumb to the effects of dehydration, hypoproteinemia, and anemia, or begin to recover.

Gross findings at autopsy of fatal cases are those of dehydration, accompanied by enteric lesions characteristic of the disease. There is often segmental or widespread subserosal intestinal hemorrhage, which may extend into the muscularis and submucosa. The serosa frequently appears granular due to superficial fibrinous effusion (Fig. 1.125). Peyer's patches may be evident from the serosal and mucosal aspects as deep red oval areas several centimeters long. The intestinal contents may be mucoid or fluid; sometimes they look like tomato soup, due to hemorrhage. The mucosa is usually deeply congested and glistening, or covered by patchy fibrinous exudate. Severe mucosal lesions may be widespread or segmental, and their distribution is irregular; thus tissues from several levels of the small intestine should be selected for microscopic examination. Gross changes in the colon are similar, but less common. The stomach may have a congested mucosa and contain scant bloody or bile-stained fluid. Mesenteric lymph nodes may be enlarged, congested, and wet, or be reduced in size. Thymic atrophy is consistently present in young animals, and the organ may be so reduced in size as to be difficult to find. The lungs often appear congested, and have a rubbery texture.

The **microscopic lesions** in stomach, small intestine (Fig. 1.126), colon, lymphoid tissue, and bone marrow due to CPV-2 infection do not differ significantly from those described above in cats with panleukopenia. Gastric lesions are perhaps more frequently encountered in dogs with parvoviral infection. Small intestinal lesions are invariably severe in fatal cases. The colon is involved in a minority of animals. Pulmonary lesions such as alveolar septal thickening by mononuclear cells, congestion, and effusion of edema fluid and fibrin into the lumina of alveoli may be related to terminal gram-negative sepsis and endotoxemia, which is common in fatal cases. Periacinar atrophy and congestion in the liver are attributable to anemia, hypovolemia, and shock, and prominent Kupffer cells probably reflect endotoxemia. Some studies have shown that viral inclusions may occur in tongue epithelium cells as well. Although these inclusions are nuclear, they often appear to be in the cytoplasm (pseudocytoplasmic). A case of erythema multiforme as a result of CPV-2 infection of keratinocytes has been described in a dog with concurrent parvoviral enteritis; viral inclusions were present in oral and skin epithelial cells.

The **diagnosis** of parvoviral enteritis in dogs follows the principles described for that of panleukopenia in cats. The disease must be differentiated from *Canine coronavirus* infection, which is very rarely fatal, and from canine intestinal hemorrhage syndrome, shock gut, intoxication with heavy metals or warfarin, infectious canine hepatitis, and other causes of hemorrhagic diathesis. Involution of gut-associated lymphoid tissue and cryptal necrosis caused by parvovirus must be differentiated from similar lesions occasionally seen in canine distemper.

Canine minute virus

Canine minute virus (CMV, Minute virus of canines, *Canine parvovirus 1*) is most closely related to *Bovine parvovirus*, and is distinct from members of the feline panleukopenia parvovirus subgroup. Serologic prevalence in the USA is approximately 50% in adult dogs. The virus is capable of transplacental transmission to the fetus, and exposure of pregnant bitches was associated with fetal resorption, or birth of dead or weak pups. CMV causes enteric or respiratory symptoms in puppies less than 3 weeks of age. Large intranuclear viral inclusion bodies are evident in enterocytes. Interstitial pneumonia and myocarditis are variably present in naturally infected puppies, with death occurring sporadically.

Bovine parvovirus infection

The antigenically distinct *Bovine parvovirus* (BPV) has been recognized for many years and occurs widely in cattle populations on all continents. A single serotype is known. It has been isolated from the feces of normal and recently diarrheic calves as well as from conjunctiva, and from aborted fetuses. *The status of BPV as an enteric pathogen is unclear.* Virus shedding is not always associated with diarrhea, and it may be part of a mixed infection in diarrheic animals. Serological prevalence of antibodies to BPV is high, with 83% of cattle and 100% of herds being positive over 2 years of testing in one study. It is rarely diagnosed as a cause of death, and unless sought specifically by culture, direct electron microscopy, or molecular probe, would be missed as a cause of clinical diarrhea. Its significance may be greatest in neonatal calves and animals exposed while passive maternal antibody levels are waning, or in animals in the postweaning period.

The pathogenesis of infection with BPV resembles that in carnivores. Initial viral replication following oral inoculation is in tonsils and gut, with spread to systemic lymphoid tissues, resulting in transient lymphopenia. Viral antigen has been identified in the nuclei of epithelium in intestinal crypts and in cells in thymus, lymph nodes, adrenal glands, and heart muscle. Transient lymphocytolysis in infected tissues, and exfoliation of epithelium in crypts of the small and large intestine, with moderate villus atrophy, depletion of colonic goblets, and mixed inflammatory cell infiltration of the mucosa, have been seen experimentally. Intranuclear inclusions are present at the time when lesions are prevalent. Gross lesions other than abnormally fluid content in the gut are subtle, or absent. Intravenous inoculation of BPV into young calves causes severe watery diarrhea and prostration. Milder diarrhea occurs in calves infected orally. The severity of the disease may be potentiated by concurrent infection with other enteric pathogens, or other factors that may increase intestinal epithelial proliferation.

Bacterial diseases of the alimentary tract

Virulence of bacterial pathogens

Evolutionary processes for bacterial survival, persistence, and proliferation are controlled by virulence genes and are subject to complex mechanisms of regulation of expression. Similarly, evolutionary processes for resisting the effects of bacteria on the host are determined by genetic factors and equally complex regulatory processes in the host. *Bacterial virulence can be resolved into five components*: (1) attachment; (2) colonization or entry into the host; (3) evasion of host defense; (4) multiplication and/or spread within the host, and damage to the host, by direct virulence attributes, or by stimulation of an immunoinflammatory response; and (5) transmission to other susceptible animals. The interplay between host and pathogen has been extensively studied for a number of important enteric bacterial pathogens, including *Salmonella* and *Escherichia coli*. Genes encoding a range of virulence characteristics in pathogenic bacteria, including adhesion factors, toxins, proteolytic enzymes, and other agents that promote tissue invasion, are often clustered in discrete regions of the genome known as *pathogenicity islands*. These appear to be sites of relative instability, and are thought to facilitate the horizontal transfer of virulence factors between bacteria, and their continued evolution. Similarities in the regulatory mechanisms for pathogenicity islands of important enteric pathogens, including *Salmonella*, *Shigella*, *Vibrio*, *Yersinia* and *E. coli*, are providing new insights into the reasons why strains of many genera of bacteria vary greatly in their host range and ability to cause disease.

Escherichia coli

Escherichia coli has several virulence attributes that result in disease in animals. Principally, these promote **colonization or adhesion** to the mucosa; they cause **metabolic dysfunction or death of enterocytes**; they affect the **local or systemic vasculature**; or they promote **invasion and septicemia**. Disease syndromes caused by *E. coli* in domestic animals can be related to the combinations of virulence attributes expressed. Many terms and acronyms have been applied to the mechanisms of action of *E. coli*, with some becoming obsolete and others applying mainly to *E. coli* infections of laboratory animals and humans, rather than to domestic animals.

"**Enterotoxigenic**" *E. coli* (ETEC) cause secretory small-bowel diarrhea stimulated by enterotoxins produced by *E. coli* colonizing the mucosa of the small intestine. This condition is an important, common cause of diarrhea in neonatal animals of many species, and in postweaning pigs.

"**Enteropathogenic**" *E. coli* (EPEC) in humans may colonize the mucosa of the intestine by a mechanism involving adhesion-effacement ("**enteroadherent**" *E. coli* – EAEC, or "**attaching-effacing**" *E. coli* – AEEC). Some do not produce recognized toxins, but are associated with villus atrophy; they are an uncommon cause of disease in domestic animals.

Other strains of *E. coli*, many, but not all, of which are attaching-effacing, in addition secrete *cytotoxins* (Shiga toxins = verotoxins) that have an effect locally or systemically. Depending on the manifestation of this effect, such *E. coli* have been categorized as "**Shiga toxin-producing**" (STEC) = "**verotoxin-producing**" (VTEC), or "**enterohemorrhagic**" (EHEC). EHEC are a serious cause of foodborne illness in humans and have been incriminated as a cause of hemorrhagic enterocolitis in calves under a month of age.

Shigatoxigenic infections in swine, which are not attaching-effacing, are associated with some outbreaks of postweaning *E. coli* enteritis and also cause edema disease of weaned pigs, which is a systemic toxemia.

"**Enteroinvasive**" *E. coli* (EIEC) can be internalized by surface enterocytes and subsequently disseminate through the body to become septicemic. While EIEC are poorly documented in domestic animals, **septicemic colibacillosis** is a common manifestation of *E. coli* infection caused by strains adapted to avoid specific or innate systemic defense mechanisms, often in compromised hosts. The intestine is not necessarily the portal of entry and there may not be alimentary disease. The signs of *E. coli* septicemia are mainly referable to bacteremia, endotoxemia, and the effect of bacterial localization in a variety of tissue spaces throughout the body.

Enterotoxigenic colibacillosis

Enterotoxigenic colibacillosis caused by enterotoxigenic *E. coli* (ETEC) is one of the major forms of diarrhea in neonatal pigs, calves, and lambs, as well as in humans.

Two major attributes confer virulence upon these strains of *E. coli*. These are the ability to colonize the intestine, and the capacity to produce toxins that stimulate secretion of electrolyte and water by the intestinal mucosa. *Colonization and enterotoxin production must occur together for disease to ensue*. The diarrhea produced by ETEC is accompanied by relatively minor microscopic evidence of inflammation, and by little or no architectural change in the mucosa. As a result, overt enteritis is usually not evident at autopsy, and the disease is part of the syndrome of undifferentiated diarrhea of neonatal animals.

Intestinal colonization results from the adhesion of *E. coli* to the surface of enterocytes on villi in the small intestine, and proliferation there (Fig. 1.127A). By adhering to the mucosa, bacteria are able to resist the normal peristaltic clearance mechanisms. Large numbers of organisms, of the order of over 10^7 per gram of mucosa, or 20–30 per enterocyte, cover the surface of villi. The ability to attach to enterocytes is conferred upon ETEC by pili, and may be enhanced by the presence of a capsule.

Fimbriae, or **pili** (also known as **colonization factor antigens – CFA**, with specific names in transition to a system of "F" numbers) are rod-like or filamentous projections from the cell wall of *E. coli* that attach to specific glycoconjugate receptors on the surface of enterocytes (Fig. 1.127B). They are distinct from type 1 fimbriae, which do not promote colonization of the gut. Fimbriae are polymers of protein (pilin) subunits, which are coded by plasmid (F4 (K88), F5 (K99), F18; some F6 (987P)) or chromosomal (F6 (987P), F17, F41) DNA. They are antigenically distinct, permitting recognition by specific antibody.

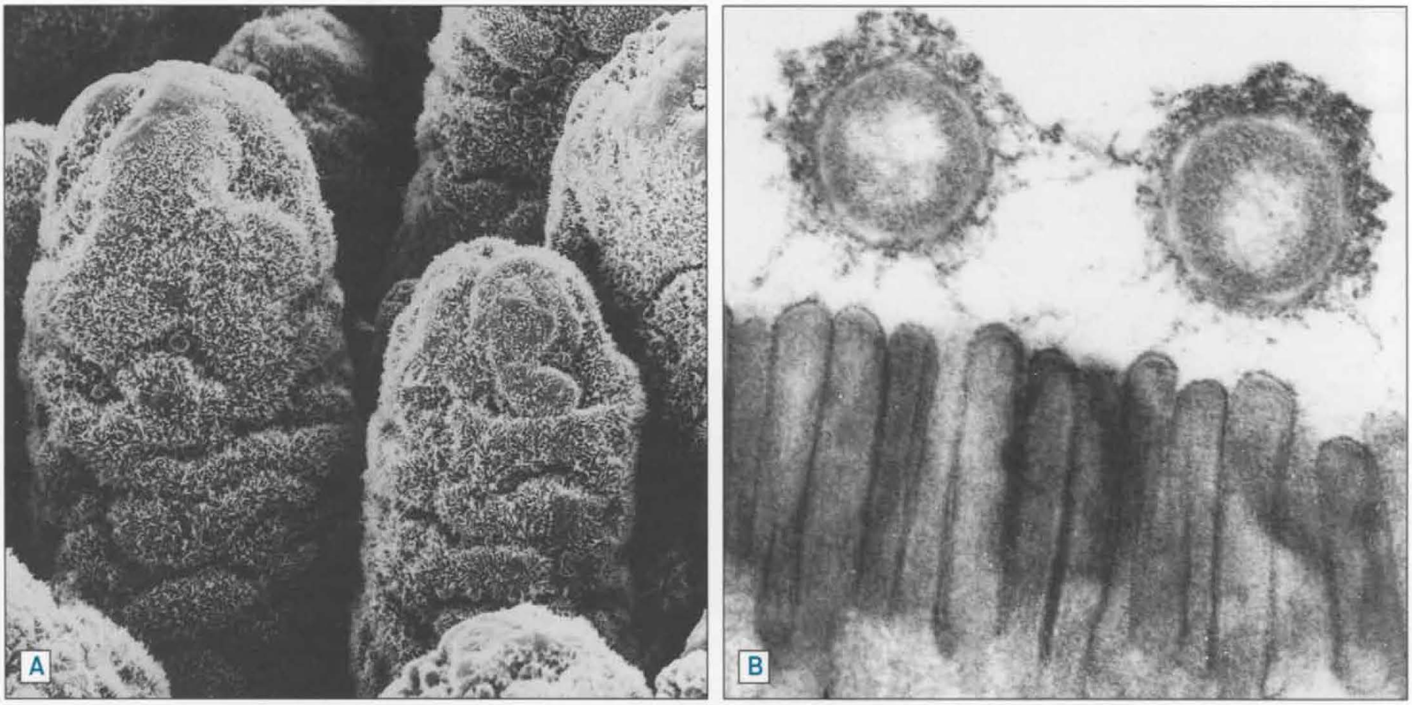
Fimbrial adhesins include **F5** (K99) and **F41** in strains affecting calves, lambs, and pigs; **F42, F165, F17, F18** in calves and pigs; and **F4** (K88), **F6** (987P), **F18** in pigs. Combinations of adhesins may be expressed by the same strain of ETEC; typically, F41 is expressed by strains also expressing F5, and seems to be of minor importance. Bacteria possessing F4 colonize the entire small bowel, whereas those with F5, F6, and F41 mainly adhere in the jejunum and ileum.

Susceptibility to bacterial fimbrial adhesins, especially F5 and F6, appears to be somewhat age-related; the ability of fimbria-bearing *E. coli* to colonize the small intestine is greatest in animals only a few days old. F5 receptors on enterocytes decline in availability with age, while receptors for F6 are shed into the lumen in older pigs, facilitating clearance of bacteria from the mucosa, and interfering with colonization. F18 receptors are not found in neonatal pigs, but are produced with increasing age to weaning. Stimulation of maternal immunity to fimbrial antigens causes secretion of lactogenic antibody, which combines with adhesins in the gut lumen, preventing colonization of the gut of suckling animals.

A nonfimbrial plasmid-encoded *adhesin involved in diffuse adherence* (**AIDA**) of *E. coli* to enterocytes in humans also occurs in strains from pigs associated with edema disease and postweaning diarrhea, often in combination with F18.

Enterotoxigenic strains of *E. coli* produce two classes of plasmid-encoded proteins – heat-labile toxin (LT) and heat-stable toxin (ST) – which act locally in the intestine to alter secretion and absorption of electrolyte and water by enterocytes.

Heat-labile toxin is a large immunogenic plasmid-encoded molecule, with two subgroups (LTI and LTII) and comprised of a small A subunit with two fragments (A1 and A2), which links A1 to a large pentamer of five B subunits. LTI is antigenically similar to cholera toxin, while LTII toxins have B subunits that differ from LTI. The B subunits bind to ganglioside receptors on the enterocyte surface; the toxin complex then dissociates, and the A1 subunit is internalized into the cell. It operates via an adenylate cyclase pathway to cause chloride secretion by enterocytes, sodium, and water following osmotically from the mucosa. Co-transport of sodium chloride by enterocytes, and associated water uptake, is probably also shut down at the same time. LT may also promote mucosal secretion by stimulation of local prostaglandin production, the enteric nervous system, and cytokine activation. LT has a latent period prior to the development of secretion, but the effects on the cell are irreversible.



Heat-stable toxin is classified as STa and STb based on biological properties, and is plasmid-encoded. STa causes an increase in cyclic guanosine monophosphate, which inhibits Na/Cl co-transport and therefore water absorption by surface enterocytes, while in crypt epithelium it promotes Cl^- and water secretion. STb, mainly produced by ETEC associated with pigs, may cause secretion by stimulation of prostaglandin E_2 and 5-hydroxytryptamine production. In pigs, STb can cause exfoliation of surface enterocytes, resulting in mild atrophy of villi.

Enterotoxigenic colibacillosis is among the commonest causes of diarrhea in **neonatal pigs**, from a few hours to about a week of age. Commonly, serogroups O8, O45, O138, O141, O147, O149, and O157, expressing F4, are involved in enterotoxigenic colibacillosis in piglets, though the prevalence of F4-bearing strains may be declining due to vaccination of sows. Less commonly, F5, F6, and F41 pilus adhesins are involved. STb is the most common toxin produced by porcine ETEC; when LT is found, it is in association with STb, which may be encoded on the same plasmid. STa also occurs in strains of ETEC in swine, alone, or in combination with other enterotoxins.

At necropsy, enterotoxigenic colibacillosis cannot be readily separated from the other common causes of undifferentiated neonatal diarrhea without laboratory assistance. Generally there is dehydration, usually with evidence of diarrhea, or a history of its occurrence in the herd. Other than the presence of characteristic fluid content in the flaccid small and large bowel, usually with clotted milk still in the stomach, the internal findings are unremarkable.

In contrast to the viruses and *Isospora*, *ETEC usually does not cause significant villus atrophy* (Fig. 1.128A). Small clumps, or a continuous layer, of bacteria may be found on the surface of enterocytes on villi in mucosal tissue sections, most consistently in ileum (Fig. 1.128B). Some neutrophils may be present in the proprial core of villi, and transmigrating the epithelium into the lumen.

The involvement of ETEC expressing F4 in postweaning diarrhea of pigs over 3 weeks of age, and distinct from postweaning colibacillosis caused by VTEC, discussed below, may be related to colonization of intestine in weaned pigs in which *Rotavirus* infection, changes in diet, or villus atrophy associated with hypersensitivity to dietary protein constituents, provide adhesin-bearing *E. coli* with a competitive advantage. It causes diarrhea for up to a week or so, with ill-thrift, but is uncommonly fatal, though a syndrome probably caused by endotoxic shock, similar to that associated with shigatoxigenic stains associated with postweaning colibacillosis, described below, may occur.

In **calves**, many cases of undifferentiated neonatal diarrhea are accounted for by enterotoxigenic colibacillosis, usually involving strains of serogroups O8, O9, O20, O64, O101 with fimbrial adhesins F5 and F41, and producing STa. Infection is typically restricted to the first 2–3 days of life, probably due to the loss of receptors for F5 in older calves.

ETEC must be differentiated from the other major causes of undifferentiated diarrhea in neonatal calves – *Bovine coronavirus* (BCoV), *Coronavirus*, *Rotavirus*, and *Cryptosporidium*, which typically dominate in calves older than a few days of age. However, ETEC is not uncommonly found in combination with BCoV or *Rotavirus* infection.

The gross findings in calves with enterotoxigenic colibacillosis are the nonspecific appearance of diarrhea and dehydration. The infection is differentiated in tissue sections from the other infectious causes of this syndrome by the *absence of severe villus atrophy* (Fig. 1.129) and by the presence of *bacteria on the surfaces of villi* in the distal small intestine. As in piglets, application of a variety of presumptive or specific tests for the presence of ETEC in the intestine confirms the diagnosis (Fig. 1.130).

Enterotoxigenic colibacillosis is a significant problem in **lambs** in some areas. The serotypes involved, pathogenesis, and diagnosis of the condition are similar to those in calves. Synergism with *Rotavirus* infection may occur.

There are several reports of ETEC isolated from **foals** with diarrhea. The organisms have pili, probably F41, and secrete LT or STa. However, their capacity to produce disease in foals is unproven. Diarrhea has not ensued in foals inoculated with F4-bearing *E. coli*,

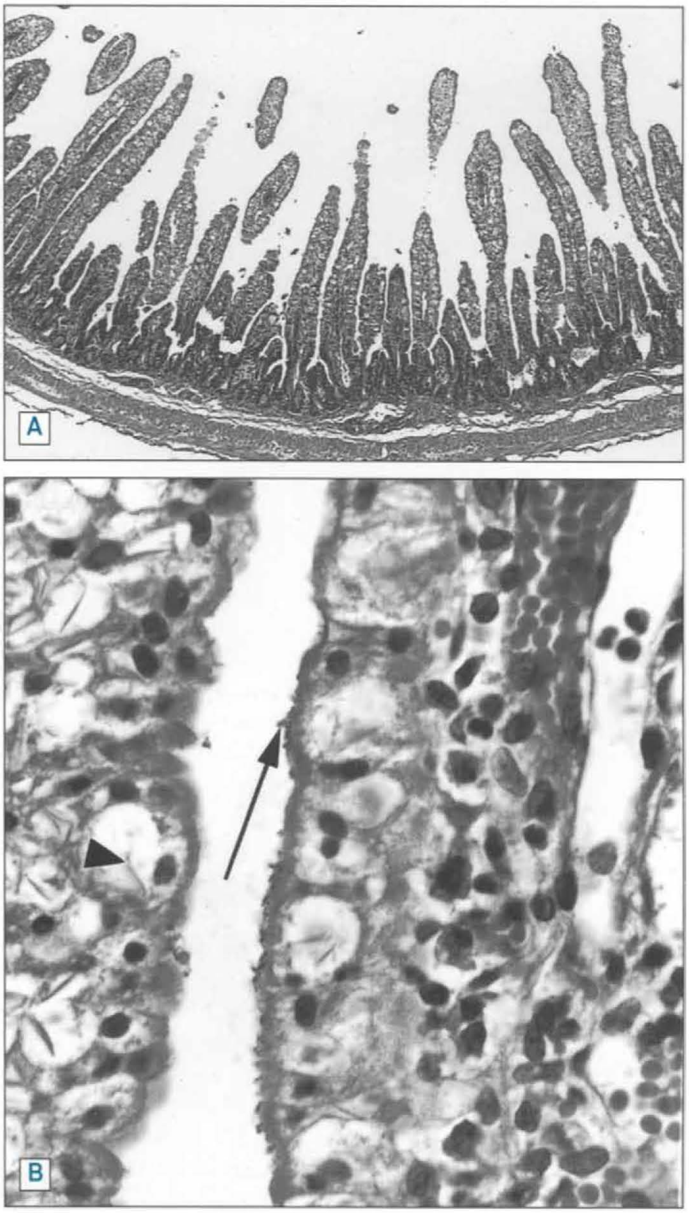


Figure 1.128 Enterotoxic colibacillosis in a piglet. **A.** Villi are tall and crypts are short, as is expected in a 2-3-day-old animal. **B.** Bacteria are present on surface of enterocytes (arrow). Cytoplasmic vacuoles containing eosinophilic spicules (arrowhead) are normal in the ileal mucosa of young piglets.

despite the presence of F4 receptors on enterocytes, and it seems that ETEC has little significance in this species.

Strains of *E. coli* have been associated with diarrhea in neonates of **other species** of animals, especially young dogs, where they mainly produce STa. Generally the enterotoxigenicity and other attributes of virulence have not been well described in strains from other species.

Enteropathogenic colibacillosis

Enteropathogenic *E. coli* (EPEC) are those that cause direct damage to the mucosa, through a *characteristic mechanism of attachment to, and effacement of, epithelium.* These **attaching-effacing *E. coli*** (AEEC) are more common in humans than in animals, where they are most important in pigs, dogs, and rabbits, though they have also been isolated from cats. Control of attaching-effacing activity resides in the **locus for enterocyte effacement** (LEE), a chromosomal pathogenicity island. EPEC have a complicated and sequential relationship with host cells. Long polar fimbriae may mediate initial bacterial interaction with the enterocyte. Secretion of bacterial proteins ensues, including **intimin**, which is an adhesin. A second protein, the **translocated intimin receptor**, is transported via a type III secretion system into the enterocyte cytoplasm, emerging on the cell membrane as the intimin receptor. In response to translocated EPEC proteins, the cell's cytoskeleton is reorganized, resulting in formation of cupped *pedestal-like structures* beneath the attached bacteria, and the subsequent loss of microvilli (Figs 1.119, 1.120, 1.131, and 1.132). Paracellular permeability increases as tight junctions between enterocytes loosen, and neutrophils migrate between cells into the lumen.

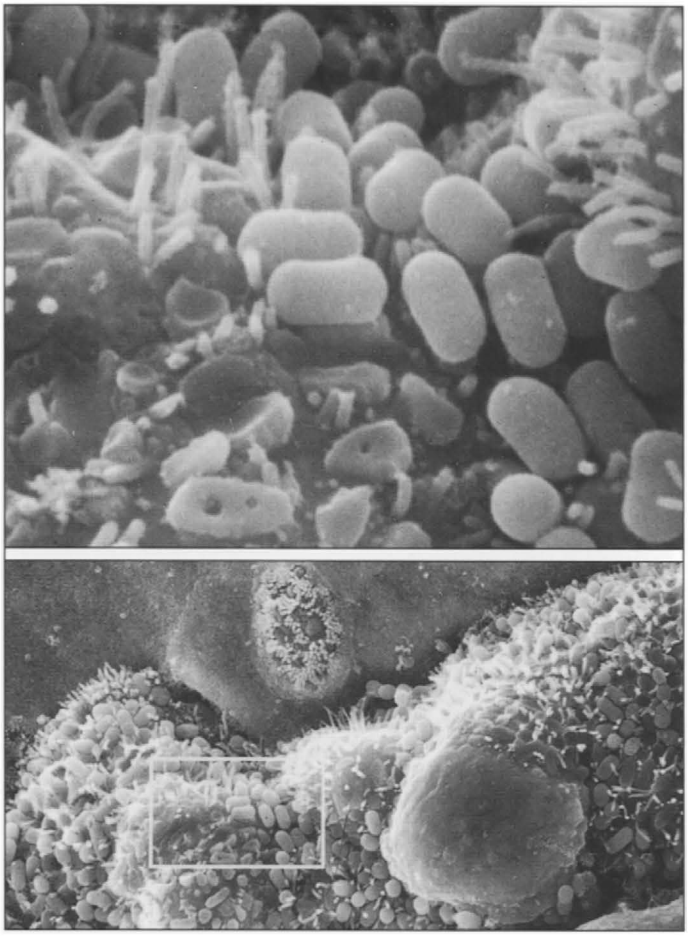

Figure 1.131 Scanning electron micrograph of the colon of a calf with **enterohemorrhagic *Escherichia coli* infection**. Lower: note irregularity of microvilli on cells infected by attaching-effacing *E. coli*, in comparison with microvilli on uninfected cells in background. Outline indicates field illustrated in upper photo. Adherent bacteria are on pedestals projecting from the surface of enterocytes. Occasional bacteria have been lost artifactually, exposing underlying "mushroom-like" pedestals. (Courtesy of M Schoonderwoerd, R Clarke.)

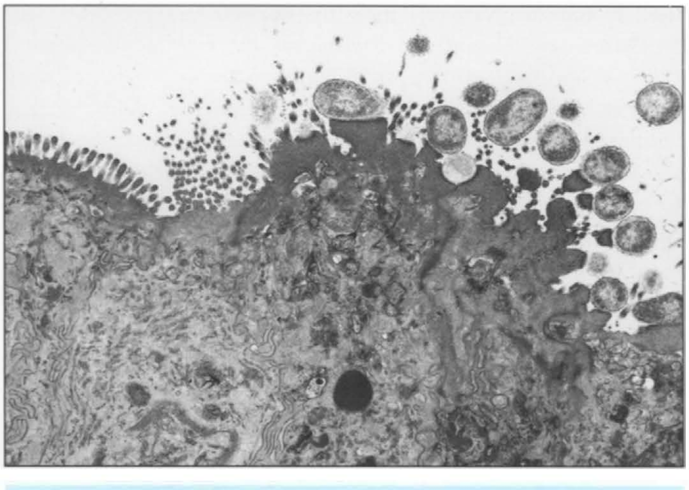

Figure 1.132 Transmission electron micrograph of enterocytes in the colon of a calf infected with enterohemorrhagic *E. coli*. **Enterocyte attaching-effacing *E. coli*** are on pedestals projecting from surface of infected cells. Microvilli are irregular and effaced on infected cells. Normal cell (left). (Reprinted with permission from Schoonderwoerd M, et al. Can J Vet Res 1988;52:484–487.)

In animals and humans, some strains of AEEC are pathogenic despite failure to secrete enterotoxins or cytotoxins. A heavy layer of plump coccobacilli may be found over the luminal aspect of enterocytes on villi throughout the small intestine, and on the surface of the large intestine. *The degree of diarrhea seems related to the extent of bacterial colonization, which is most consistent in lower small intestine and large bowel.* Enterocytes to which bacteria are adherent round up or contract, and exfoliate from the mucosa singly or in clumps, resulting in mild to severe atrophy of villi in the small bowel, and attenuation of surface cells, or microerosions, in the large intestine. Fusion of villi may occur in small intestine, and goblet-cell numbers are depleted in both large and small bowel. There is moderate mucosal congestion, and local infiltration by neutrophils.

Diarrhea is presumably related to maldigestion and malabsorption of nutrients and electrolytes in small intestine, perhaps with the additive effect of increased mucosal permeability, overloading the colon, the absorptive ability of which is also compromised by damage to surface cells. *Microscopic diagnosis is based on recognition of bacteria on the mucosal surface.*

In **pigs**, EPEC belonging to serogroups O45 and O103, infecting small and large intestine, are responsible for some cases of postweaning diarrhea. In **dogs**, and occasionally in cats, EPEC have been associated with diarrhea, often as a component of co-infections with viral or protozoal agents. Microscopic lesions characteristic of AEEC are typically found in the jejunum and ileum, less commonly in the colon, and, in dogs, sometimes in the stomach.

A distinct subset of EPEC is the **Shiga toxin-producing *E. coli*** (STEC), also known as **enterohemorrhagic *E. coli*** (EHEC). In addition to their ability to attach and efface, these strains produce cytotoxic Shiga toxins (Stx1, and its homologue Stx2 with its variants, c, d, e, f). Shigatoxin 1 is structurally identical to the Shiga toxin produced by *Shigella dysenteriae,* which has a profound cytopathic effect. Due to their effect on Vero cells in culture, these *E. coli* are also referred to as **verotoxin-producing *E. coli*** (VTEC). Shiga toxins, encoded in the genome of bacteriophages, are composed of an A subunit that has enzymatic activity and a B subunit that binds the toxin to the glycolipid receptor globotriaosylceramide (Gb3) on the cell surface. Once endocytosed and transferred via the Golgi apparatus to the rough endoplasmic reticulum, the toxin inhibits protein synthesis, which may be lethal to the target cell, and via separate mechanisms may induce apoptosis. The presence or absence of Gb3 on cell surfaces is a major determinant of the distribution of tissue susceptibility to Shiga toxins, which mainly affect intestinal epithelium and vascular endothelium. Some EHEC also produce hemolysins, which may assist survival in the gut by increasing iron availability. Acid tolerance may also promote colonization efficiency by enhancing survival in the stomach.

The EHEC strains produce disease predominantly in humans, although involvement of domestic animals has been highlighted in the public health arena due to the tendency for cattle and some other species to carry the organism asymptomatically, adherent to epithelium over lymphoid follicles in the rectal mucosa. The most widely recognized EHEC serotype is **O157:H7**, a major pathogen in humans, although over 200 other STEC serotypes have been identified. In addition to Shiga toxin production, virulence is attributable to attaching and effacing capability, encoded on the LEE.

In **calves under 4 weeks of age** (generally over 3 days of age, and most commonly in the second week of life), strains of EHEC (O5:NM, O8:H9, O26:H11, O103:H2, O111:NM, O111:H8, and O111:H11) have been associated with a syndrome of *erosive fibrinohemorrhagic enterocolitis*, with the development of dysentery. Fever is not characteristic, and animals may remain bright until the effects of dehydration and blood loss supervene. Death may occur within several days of onset of illness, but some cases will recover in 7–10 days.

At necropsy, gross lesions are usually confined to the spiral colon and rectum, though the ileum and cecum are occasionally involved with mild fibrinous or fibrinohemorrhagic enteritis/typhlitis. In the colon, changes vary from mild patchy congestion of the mucosa to marked mucosal reddening, with adherent mucus, necrotic debris, and blood; colonic contents are fluid and frequently blood-tinged (Fig. 1.133). There may be congestion of the margins of mucosal folds in the rectum, or overt fibrinohemorrhagic proctitis. Mesenteric lymph nodes are often enlarged, especially along the ileum, and occasionally there are lesions (arthritis, serositis) suggesting septicemia.

Microscopically, *in affected small intestine the profile of villi is ragged or markedly scalloped, and they are blunted, moderately atrophic, or fused.* Epithelial cells on villi in small bowel, and on the colonic surface, where lesions are most severe, are short, rounded up, and in some cases exfoliating singly or in small clumps, causing focal microerosions. Cells in some areas may be markedly attenuated. The microvillus border is indistinct, and covered by a heavy layer of prominent gram-negative coccobacilli (Fig. 1.134). Lesions in large bowel may extend down into glands, which may be dilated, lined by flattened epithelium, and filled with sloughed epithelium and leukocytes. In the small intestine, foci of bacterial adhesion may be patchy, on the sides of the upper third of villi, with extensive surrounding areas of normal epithelium. Crypts in areas of atrophic small intestine may be elongate, with numerous mitotic figures. In severely affected bowel, the mucosa and submucosa are congested, edematous, and occasional microvascular thrombi may be present. Sloughed enterocytes, erythrocytes, neutrophils, fibrin, and bacteria are in the lumen.

In **dogs**, STEC have been associated with dysentery, and in some dogs, hemolytic uremic syndrome and cutaneous edema and ulceration. In Greyhounds, the syndrome involving this triad has been termed *cutaneous and renal glomerular vasculopathy*, and has been attributed to consumption of beef contaminated with O157:H7 *E. coli*, and other STEC. Renal and cutaneous lesions are attributable to vascular damage caused by Shiga toxin (see Vol. 2, Urinary system; Vol. 1, Skin and appendages).

Edema disease and postweaning *E. coli* enteritis

Edema disease *is a distinct syndrome in pigs, characterized by sudden death, or the development of nervous signs, associated with enteric colonization by STEC*, especially serotypes O138, O139, and O141. The disease occurs most commonly in pigs within a few weeks after weaning, or after other change in feeding or management. It often occurs in association with outbreaks of postweaning *E. coli* enteritis. Rare reports exist of edema disease in suckling and mature animals. The disease may be sporadic or occur as an outbreak, usually affecting the best animals in a group, and mortality often approaches 100% of affected animals. Edema disease and postweaning *E. coli* enteritis have apparently declined in prevalence in parts of North America, perhaps with the use of concentrate rations based largely on soybeans and corn, rather than other grains.

Bacterial colonization of the gut is mediated by F18ab fimbriae. Susceptibility of pigs is genetic and related to the presence of receptors for the fimbriae. A Shiga toxin (Stx2e) producing vascular injury and edema has been incriminated in the pathogenesis of edema disease, and vaccination with Stx2e toxoid almost entirely prevents edema disease.

Some strains of *E. coli* that cause edema disease also produce secretory enterotoxin. Diarrhea is not a usual concomitant of edema disease in individual animals. Significant gross or microscopic lesions in the intestinal mucosa do not occur in edema disease, which appears to be a *classical enterotoxemia*, the active principle being absorbed from the gut and acting at a distant site. However, the means by which the toxin enters the circulation is unknown.

Experimentally, the target of Stx2e, like other Shiga toxins, is *vascular endothelium*, particularly of small arteries and arterioles. Preferentially affected organs include spinal cord, cerebellum, eyelid, and colon. However, a study to determine preferential binding

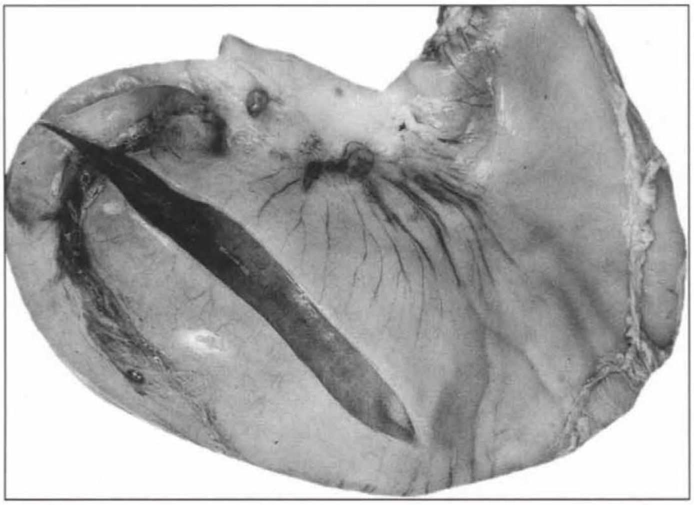

Figure 1.135 Edema of stomach wall in **edema disease** in a pig.

sites for Stx2e found receptors on a variety of tissues, not just the aforementioned. Stx2e causes *angiopathy*, which, in its early stages in experimental intoxication, is recognized by swelling of endothelial cells and mild intramural and perivascular hemorrhage. Pyknosis and karyorrhexis of smooth-muscle nuclei, often accompanied by fibrinoid degeneration or hyaline change in the tunica media, may be seen in subacute spontaneous cases. Proliferative mesenchymal elements are found in the tunica media and tunica adventitia in more advanced cases. However, inflammation is not at any stage a prominent component of the angiopathy, nor of the associated edema in most sites, and thrombosis of vessels is rarely encountered. Edema is probably due to vessel damage during the early stages of the angiopathy. The lesions are distinct from those expected with endotoxemia.

Swine with **edema disease** may die without premonitory signs. Others may have anorexia, or, more characteristically, show nervous signs, usually of less than a day's duration. An unsteady staggering gait, knuckling, ataxia, prostration and tremors, convulsions, and paddling occur. A hoarse squeal, the hoarseness attributed to laryngeal edema and dyspnea, may also be noted clinically.

At necropsy, **gross lesions** in acute deaths may be subtle or absent. Typically, *edema is variably present in one or more sites*. However, it may be mild and must be carefully sought, especially by "slipping" the suspected area over subjacent tissue. Subcutaneous edema may be present in the frontal area and over the snout, in the eyelids, and in the submandibular, ventral abdominal, and inguinal areas. Internally, there may be some hydropericardium, and serous pleural and peritoneal effusion, perhaps accompanied by mild or moderate pulmonary edema. More commonly, the serous surfaces merely appear glistening and wet. Edema of the mesocolon, of the submucosa of the cardiac glandular area of the stomach over the greater curvature, and of mesenteric lymph nodes is most consistently found. The gastric submucosal edema should be sought by carefully cutting through the muscularis to the submucosa. The edema fluid is clear, and slightly gelatinous (Fig. 1.135). It is rarely blood-tinged, and overt hemorrhage is usually not present in uncomplicated edema disease. The stomach is often full of feed, but the small intestine is relatively empty and the mucosa is grossly normal. The colon may contain somewhat inspissated feces.

In swine dying after a more prolonged clinical course, gross edema is often not present, though enlargement of mesenteric lymph nodes is present in a large proportion of cases. A few pigs may show foci of yellow malacia, usually bilaterally symmetrical, in the brainstem at various levels from basal ganglia to medulla.

Microscopically, edema in the sites of predilection mentioned above is the main lesion in swine dying acutely. It is generally devoid of much protein and contains few erythrocytes and inflammatory cells. A proportion of animals will also have meningeal edema and distended Virchow–Robin spaces in the brain. Vascular lesions may not be well developed in pigs dying suddenly. When present they usually consist of edema, hemorrhage, myocyte necrosis, and hyaline degeneration in the tunica media. Angiopathy is more consistently found in cases of longer standing. Affected vessels may be found in any tissue in the carcass. Brain edema and focal encephalomalacia in the brainstem are associated with the presence of lesions in cerebral vessels; necrosis may be a sequel to edema and ischemia. "Cerebrospinal angiopathy of swine" is probably a manifestation of edema disease.

A **diagnosis** of edema disease is based on nervous signs or sudden death in growing pigs, in association with typical gross and microscopic lesions, when they are present. In acute cases, heavy growth of hemolytic *E. coli* of one of the serotypes known to produce Stx2e is essential.

Edema disease must be differentiated from enteritis and endotoxemia due to *E. coli* in postweaning pigs; from mulberry heart disease in animals dying suddenly; and from salt poisoning, *Salmonella* meningoencephalitis, and other infectious encephalitides, in animals with nervous signs.

Postweaning *E. coli* enteritis (coliform enteritis of weaned pigs) typically occurs during the first week or two following weaning, or after some other change in feed or management. Postweaning diarrhea may be caused by classical enterotoxigenic F4 (K88) *E. coli*, but it is often associated with hemolytic *E. coli* of the same serotypes primarily implicated in edema disease, as well as serotype O149. The two diseases often occur in the same population of pigs, though usually affecting different animals. Typically, postweaning colibacillosis is a disease of high morbidity and variable mortality, with loss of condition in pigs suffering prolonged illness. Diarrhea is usually yellow and fluid, and stains the perineum. Deaths that occur may or may not follow a prior episode of diarrhea, and often appear to be related to endotoxemia.

In fatal cases, there may be blue-red discoloration of the skin and evidence of dehydration. Deep red *gastric venous infarcts* are present in almost all cases (Fig. 1.136). The small intestine is flaccid. The mucosa may be normal in color and the content creamy. In other animals the mucosa of the distal small intestine will be congested and the contents watery and perhaps blood-tinged or brown with flecks of yellow mucus or fibrin (Fig. 1.137). Cecal and colonic lesions are usually mild, but there may be some congestion and fibrinous exudate in the proximal large bowel. Mesenteric lymph nodes may be somewhat enlarged, congested, and juicy. Other organs are usually unremarkable grossly.

The **pathogenesis** of postweaning *E. coli* enteritis due to non-F4 *E. coli* is poorly understood, and the microscopic pathology is not well described. In swine with diarrhea, *E. coli* may be attached to the surface of villi by F18ac fimbriae. Atrophy of villi does not seem to be evident, and diarrhea is presumed to be mediated by enterotoxins. Mortality in animals with prolonged diarrhea and few gross intestinal

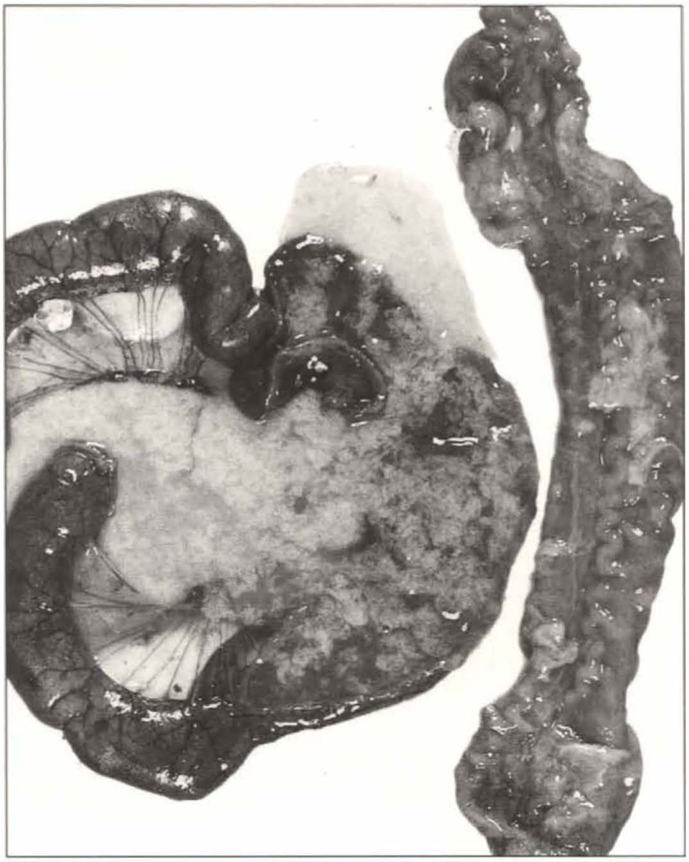

Figure 1.137 Acute catarrhal enteritis, with congested, flaccid small intestine in **postweaning colibacillosis** in a pig.

or extraintestinal lesions may be ascribed to dehydration. In animals dying of more acute disease, there is local microvascular thrombosis in sections of congested mucosa (Fig. 1.138), and the gross and microscopic lesions in other organs, especially those related to gastric mucosal and submucosal thrombosis and venous infarction, are suggestive of endotoxemia. Hemolytic *E. coli* of the implicated strains are consistently isolated in virtually pure culture from the lower small intestine and colon. However, they are present in the spleen and liver in only a few cases, suggesting terminal bacteremia.

The factors predisposing to the massive colonization of hemolytic *E. coli* are unclear. Loss of lactogenic immunity, a favorable environment for proliferation of bacterial strains with specific nutrient requirements, and promotion of epithelial colonization by the effects of antecedent *Rotavirus* infection, have been variously implicated.

A **diagnosis** of postweaning colibacillosis is suggested by the gross lesions in animals dying acutely or subacutely, and it is confirmed by culture and serotyping of associated strains of *E. coli*. The fatal disease must be differentiated from edema disease, proliferative hemorrhagic enteropathy, salmonellosis, and swine dysentery. Postweaning diarrhea due to uncomplicated *Rotavirus* infection, transmissible gastroenteritis, or associated with attaching-effacing O45:K "E65" *E. coli*, is usually nonfatal.

Enteroinvasive *E. coli*

Strains of *E. coli* are recognized, infecting humans and certain other species, which have the capacity to invade or to be internalized by surface enterocytes of the small and large intestine, in which they multiply. In this sense they resemble *Shigella* in primates, and *Salmonella*. The enteroinvasiveness of *Shigella* and some strains of *E. coli* appears to be correlated with the presence of a high-molecular-weight plasmid coding for outer-membrane proteins involved in invasion. Multiplication of the organism within epithelial cells results in *local erosion and ulceration*, associated with acute inflammation in the mucosa.

Among domestic animals, *enteroinvasive colibacillosis has only been confirmed experimentally in neonatal swine*, using a strain of O101 *E. coli*. Spontaneous enteritis that appears to be due to enteroinvasive *E. coli* is rarely encountered in piglets up to weaning and in calves under 2 weeks of age. Diarrhea in experimentally infected piglets is described as gray-yellow, watery, and containing small clots. The gross findings may not be remarkable, or the intestine may appear congested in comparison with that in most diarrheic piglets. In spontaneous cases suspected of being due to enteroinvasive *E. coli*, the gastric fundus may also be congested, and this correlates with the presence of venous infarction visible microscopically. Experimental enteroinvasive colibacillosis in piglets causes villus atrophy that is comparable in severity to that induced by the common viruses of neonates. Enterocytes appear cuboidal or flattened and some are seen lysing. The lamina propria is edematous; capillaries are congested and infiltrated by neutrophils and other inflammatory cells. In spontaneous cases, thrombi may be evident in proprial capillaries and submucosal lymphatics. Neutrophils and tissue fluid effuse into the lumen between villi through epithelial discontinuities. Similar microthrombosis, proprial inflammation, enterocyte destruction, and effusion may be found in the cecum and colon. Intracellular organisms of O serogroup 101 were demonstrated by immunoperoxidase staining in the experimental study, but are not generally recognized in spontaneous cases suspected to be due to enteroinvasive *E. coli*. Edema and neutrophil accumulation in sinusoids of mesenteric lymph nodes are present. Experimental enteroinvasive colibacillosis in piglets has been associated with malabsorption and protein loss into the gut, presumably due to villus atrophy and effusive enteritis, respectively.

Septicemic colibacillosis

Generalized systemic infection with *E. coli* occurs commonly in *calves*, and less commonly or sporadically, especially among young animals of the other domestic species. Predisposition to infection is a prerequisite for *E. coli* septicemia. This usually results from reduced transfer or absorption of maternal colostral immunoglobulin, or from intercurrent disease or debilitation. But certain strains of *E. coli*, especially O8, O9, O15, O26, O35, O45, O78, O86, O101, O117, and O137 in calves and lambs, and O115 in pigs and calves, are particularly associated with septicemia, and may possess characteristics that enhance their ability to invade and proliferate systemically in compromised animals.

Among factors conferring virulence upon these strains are plasmids coding for colicin V (Col V). Col V plasmids carry genes coding for aerobactin, a bacterial hydroxamate siderophore permitting survival in low-iron extracellular environments; outer-membrane proteins resisting bactericidal effects of serum, such as complement activation; and hydrophobic properties that impede phagocytosis, conferred by a capsule. Some produce cytolethal distending toxin, or fimbriae which impede phagocytosis. Endotoxin released by dying bacteria causes the vascular damage and shock associated with *E. coli* septicemia.

The portal of entry of *E. coli* causing septicemia probably varies somewhat. The navel in the neonate, the upper respiratory tract and possibly the tonsil, and the intestine are likely sites. In calves, adhesins such as P, F17, AfaE-VIII, and CS31A may promote enteric colonization and invasion. Enteritis is not a necessary, or even common, concomitant of colisepticemia in animals.

Colisepticemia is most commonly a disease of neonates, and may vary from peracute septicemia and endotoxemia resulting in sudden death, to subacute or chronic disease in which signs are related to sites of bacterial localization, especially in the meninges, joints, and eyes.

The lesions associated with colisepticemia in young animals of any species, especially calves, lambs, and foals, may vary from subtle to obvious. Mortality in hypogammaglobulinemic neonates may occur acutely with little in the way of abnormal gross findings. These may be limited to mildly congested or blue-red, slightly rubbery lungs, and a firm spleen, perhaps with evidence of omphalitis. *Microscopic changes* in the lungs include thickening of alveolar septa by mononuclear cells and neutrophils, and effusion of lightly fibrinous exudate and a few neutrophils into alveoli. There may be a corona of neutrophils around white pulp in the spleen, and neutrophils may be present in abnormal numbers in circulation in many organs, including lung and hepatic sinusoids. Kupffer cells may also be prominent in sinusoids in the liver. Fibrin thrombi may be evident in pulmonary capillaries, glomeruli, and hepatic sinusoids. Some calves will develop acute interstitial nephritis with foci of neutrophil accumulation, which with time evolve into "white-spotted kidney" in surviving animals.

More severe acute cases will show evidence of serosal hemorrhage, with perhaps some serosanguineous pericardial fluid. The lungs may be deep red-blue, rubbery, and fail to collapse. Interlobular septa may be slightly separated by edema, and froth or fluid may be present in the major airways. Meningeal vessels may be congested, and the meninges wet. The abomasum or stomach may have focal superficial ulcers, or more extensive deep red areas of venous infarction. There may be evidence of diarrhea and dehydration, with congestion of the small intestine. Microscopic lesions resemble those previously described, with more severe congestion, thrombosis, and edema in lungs, and perhaps other tissues. In cases not examined for some time after death, clumps of small bacilli may be seen in vessels throughout the body. The vascular permeability, thrombosis, and hemorrhage reflect endotoxemia and its sequelae.

Subacute cases may develop localized infection on serous surfaces, in the joints and meninges. Fibrinous peritonitis, pleuritis, and pericarditis, fibrinopurulent arthritis and meningitis, and hypopyon are commonly found, alone or in various combinations. Affected animals may have a history of lameness ascribable to arthritis, nervous signs due to meningitis, or general debilitation. Microscopic examination reveals the lesions already described in animals with active systemic disease, with the addition of extensive congestion and edema of inflamed serous surfaces, associated with an acute fibrinous inflammatory exudate.

In *lambs*, congestion and edema of the mucosa of turbinates and sinuses, perhaps with mucopurulent to hemorrhagic sinusitis, have been described. Fibrinous polyserositis and arthritis are sporadic manifestations of *E. coli* septicemia in growing or adult swine, and must be differentiated from the more significant *Haemophilus, Mycoplasma,* and streptococcal infections causing these lesions. Colisepticemia is a sporadic cause of mortality in litters of young puppies.

Diagnosis of colisepticemia is based on the isolation of *E. coli* in large numbers from more than one parenchymatous organ or other internal site, other than mesenteric lymph node (preferably liver, spleen, lung, or kidney), or from a site of serosal localization, in conjunction with compatible gross and/or microscopic lesions.

"**Watery mouth**," a syndrome characterized by drooling, depression, loss of appetite, and abomasal and abdominal distension, is associated with *E. coli* infection/bacteremia in lambs under 3 days of age in the UK. At necropsy, affected lambs are in poor condition. They may have unclotted milk and mucinous fluid in the distended abomasum; there is gas in the abomasum and intestine, and meconium retention is common. It is hypothesized that *E. coli* colonize the bowel, and in some manner cause loss of motility and functional obstruction. Fluid and gas accumulate in the abomasum. Bacteremia/ septicemia is terminal.

Salmonellosis

The **taxonomy of *Salmonella*** is confusing and has recently been modified, based on molecular genetic analysis. The genus *Salmonella* is now considered to be comprised of two species, ***S. bongori*** and ***S. enterica***. There are six subspecies of *S. enterica* (*enterica, salamae, arizonae, diarizonae, indica,* and *houtenae*) and many (>2200) antigenically distinct serotypes or serovars. About 60% of *Salmonella* serotypes belong to *S. enterica enterica*, and occur in birds and mammals. Members of *S. e. enterica* are the predominant cause of salmonellosis in humans and domestic animals, but fewer than 50 of these serotypes have been isolated from mammals or birds with any frequency worldwide. The remainder of *S. enterica* and *S. bongori* serotypes are found in ectothermic animals or in the environment. In conventional terminology, the serotypes have been treated as species, but in the new terminology, the names of serotypes are capitalized, but not italicized (e.g., *S. enterica* Typhimurium when first used, followed later by *S.* Typhimurium). They are usually named on the basis of the locality in which the serotype was first isolated or identified, or on their host association and the clinical syndrome they may produce. Identification of isolates at the subserotype level, by phage typing, plasmid profile analysis, or other molecular techniques, is desirable when there is evidence of zoonotic transmission, or when epidemiologic tracing is necessary.

The **clinical and pathologic syndromes of salmonellosis** typically vary from localized enterocolitis to septicemia; abortion may also occur, with or without obvious systemic disease. While some serotypes are strongly host-adapted, others have a very wide host range. Highly host-adapted serotypes, such as *S.* Typhi (humans), *S.* Dublin (cattle), and *S.* Choleraesuis (swine), tend to produce severe systemic disease in adult, as well as juvenile animals, whereas serotypes with a broad host range, e.g., *S.* Typhimurium, tend to affect predominantly young animals in most species, and mainly cause enterocolitis, though septicemia may occur. There may be overlap between the two forms of disease, and if the animal survives, a carrier state of variable duration usually follows.

Asymptomatic ***Salmonella* carriage** may be common, depending on the species, and transmission can occur directly, or indirectly, by contamination of feed, water, or the environment from which the organism is ingested or inhaled. Stressors that compromise immune competence or disrupt the enteric bacterial ecosystem are often implicated in salmonellosis, and disease is usually more common and severe in young animals. The more common "*stressors*" associated with salmonellosis in domestic animals include transportation, starvation, changes in the ration, overcrowding, pregnancy, parturition, exertion, anesthesia, surgery, intercurrent disease, immunosuppressive drugs, and oral treatment with antibiotics and anthelmintics. Consequent changes in the anaerobic bacterial ecosystem that alter the volatile fatty acid composition of the enteric environment are permissive of *Salmonella* colonization.

There are many examples of enhanced susceptibility to salmonellosis associated with intercurrent disease. The best known is that between the *Classical swine fever virus* and *S.* Choleraesuis, an association so close as to have caused early pathologists to disregard the bacterium as a significant pathogen. The disease in adult cattle is usually sporadic, and often there are predisposing conditions, such as parturient paresis, ketosis, mastitis, and parasitic infestations. The stress of anesthesia and surgery may account in part for the serious outbreaks of salmonellosis that occur in hospitalized animals, especially horses, at veterinary schools.

The **pathogenesis of salmonellosis** may be divided into several stages: *entry* of the bacteria into the host and attainment of the primary site of infection, usually the enterocyte; attachment to the surface (*colonization*); and *invasion* of enterocytes.

For infection to take place, *Salmonella* must be present in sufficient numbers; generally a minimal infective oral dose of 10^7–10^9 organisms is needed to infect large domestic animals. After ingestion, the *Salmonella* must overcome nonspecific resistance factors, including the bactericidal effects of salivary enzymes, and the acid pH of the gastric environment. Mucus and lysozymes in the glycocalyx, peristalsis, and constant sloughing of enterocytes may interfere with attachment. Those organisms that survive the nonspecific resistance factors may colonize and invade enterocytes.

Invading *Salmonella* in some species enter the mucosa through M cells in the Peyer's patches, and host specificity of some *Salmonella* serotypes may be associated in part with specific receptor sites on these cells. *Salmonella* have been demonstrated in the Peyer's patches as early as 6 hours postinoculation. When bacteria invade through M cells, smaller numbers of *Salmonella* may enter through enterocytes in other areas of the small intestine. However, the M cell is not the main site of attachment in some circumstances, for instance in *S.* Typhimurium infections of calves and pigs.

In salmonellosis characterized primarily by enterocolitis, the organisms do not usually disseminate beyond the mucosa and the mesenteric lymph nodes, and the ensuing inflammation remains confined to the intestine. In those cases where bacteremia ensues, the organisms must be able to survive and replicate in macrophages and disseminate to other systemic sites, e.g., liver, lung, joints, meninges, or placenta and fetus.

The ability to attach, invade, and penetrate enterocytes is crucial to virulence, and the first step in the development of salmonellosis. A number of known virulence factors contribute to the pathogenesis of salmonellosis, including motility, pili, or fimbriae, effector proteins modifying the metabolism or causing death of host cells, and lipopolysaccharides. The information for such virulence attributes is often encoded in chromosomes in clusters of genes known as *Salmonella* pathogenicity islands (SPI).

Invasion of enterocytes, especially those in the ileum, occurs within 12 hours of oral infection. Ability to invade cells is dependent on a type III protein secretion system encoded in SPI-1. Protein targets of the secretion system are translocated into host cells, where they facilitate bacterial invasion by causing changes in the cytosol and ruffling of the cell membrane.

Motility, associated with the presence of flagella, is characteristic of many *Salmonella* serovars. Bacterial motility is generally not considered to be an important virulence determinant. However, it may enhance the movement of bacteria through the glycocalyx and facilitate attachment to specific receptor sites on enterocytes.

Fimbriae (pilus adhesins) encoded in chromosomes and on virulence plasmids are present on salmonellae, and they may play a role in colonization of the gut. Adherence of *Salmonella* to intestinal epithelial cells takes place in two stages. The first step is reversible, since the organisms can be easily washed off. Weak ionic and nonionic interactions between bacterial and host cell membrane surfaces are thought to be the binding forces responsible for this attachment. The second stage, referred to as "receptor-mediated endocytosis," is irreversible. It occurs after a lag period and it is characterized by degeneration of the microvilli on the epithelial cells, "ruffling" of the cell membrane, and macropinocytosis, resulting in the formation of membrane-bound vacuoles (endosomes) containing *Salmonella*.

The ultrastructural changes of *Salmonella* infection in the intestine were first described in experimental infections of guinea pigs. Large numbers of organisms are present in the lumen, on the surface of the brush border, and in enterocytes. There is an increase in the number of neutrophils in the gut lumen and within intercellular spaces, and some of these contain bacteria. Degeneration of microvilli, characterized by loss of filamentous cores, is associated with close adherence of bacteria. Other changes consist of elongation, swelling, budding and fusion of microvilli, and loss of the terminal web.

The organisms usually invade the cells through the brush border; however, they may also enter the mucosa through the intercellular junctional complex. In the cytoplasm, the bacteria are located within membrane-bound vacuoles, which may also contain remnants of microvilli and cytoplasmic debris. Most organisms remain intact and multiply during their transcellular migration in endosomes. Often, many bacteria are present in a single enterocyte during the early stages of infection, but cellular damage is mild and transient. The *Salmonella*–receptor complex dissociates as a result of the acidification of the endosomal content, allowing the receptor site to return to the apical plasma membrane and repeat the processes of endocytosis. After 24 hours, most bacteria are located within membrane-bound vacuoles in macrophages in the lamina propria. Many organisms are evident in the lumina of crypts, but invasion of cryptal epithelial cells evidently does not take place.

The **lipopolysaccharide** (LPS) moiety of *Salmonella* with smooth cell walls consists of an *O-specific side chain, a core portion, and a lipid A portion*. Most *Salmonella* isolated from animals have smooth cell walls, which influences virulence in several ways. These strains are more invasive, and are more successful at avoiding phagocytosis, and lysis in phagolysosomes after invasion, than are "rough" counterparts with incomplete LPS. LPSs reduce the susceptibility of the organisms to the host's cationic proteins; they stimulate local prostaglandin synthesis; and they prevent the activation and deposition of complement on the bacterial surface.

The main function of LPS may be to facilitate survival in the intestinal mucosa and eventual entry into deeper tissues. The involvement of LPS in invasion apparently varies among *Salmonella* serotypes, since some strains of *S*. Typhimurium do not require intact LPS to invade epithelial cells in vitro. On the other hand, more host-specific *Salmonella* serotypes, such as *S*. Typhi and *S*. Choleraesuis, require intact LPS or O-side chains. The lipid A portion of LPS is responsible for the endotoxin-mediated effects of *Salmonella* infection that are seen in systemic disease. Septicemia (endotoxemia) typically causes fever, leukopenia, hemoconcentration, lactic acidosis, coagulopathies, hypotension, and death.

Diarrhea in salmonellosis is not mediated by enterotoxins such as those involved in cholera and *E. coli* infections. Rather, *effector proteins* associated with SPI-1 induce secretory diarrhea by blocking chloride channel closure, while others attract neutrophils, and induce apoptosis of enterocytes. Proteins encoded in SPI-5 also promote neutrophil recruitment and electrolyte secretion. Mucosal inflammation leads to the accumulation of a number of mediators, including prostaglandin E_2, capable of causing hypersecretion of chloride by enterocytes, and consequent passive osmotic movement of water into the lumen. Loss of enterocytes, dying as a sequel to *Salmonella* invasion and neutrophil-induced tissue injury, results in a reduction in absorptive surface area, and causes defects in mucosal integrity, through which the protein- and neutrophil-rich exudate leaking from permeable vessels effuses.

Thus diarrhea is an outcome of active secretion of electrolyte, malabsorption due to reduced mucosal surface area and enterocyte competence, and inflammatory exudation, which may contain sufficient fibrinogen to form a pseudomembrane over the affected surface. The volume of fluid originating in lesions in the small intestine may overwhelm the capacity of the colon to compensate; as often as not in salmonellosis, the large intestinal mucosa is also involved, further compounding the compromise to electrolyte and water homeostasis in the gut.

Thrombosis of mucosal venules is common in *Salmonell*a enteritis, and may contribute to loss of mucosal viability. Such lesions may be due in part to the large amounts of **endotoxin** absorbed through the damaged mucosa, or released locally.

Enteritis in salmonellosis is thus characterized by fibrinous or fibrinohemorrhagic exudates over denuded small and large intestinal mucosae, directly mediated by the apoptosis and necrosis induced by invading bacteria, and by the necrotizing effects of local neutrophil activity and microvascular thrombosis.

The **systemic outcome of an infection with *Salmonella*** is determined by the genetic virulence determinants of the invading organism and the ensuing innate, humoral, and cell-mediated immune response of the host. *Salmonella* are considered to be *facultative intracellular pathogens*, and invading strains must have the ability to survive and replicate within macrophages in order to cause bacteremia or septicemia. This capacity is conferred by components coded in SPI-2, perhaps largely through inhibition of NADPH oxidase-mediated oxidative killing of *Salmonella* in cytoplasmic vacuoles, and in some species by factors encoded in SPI-2 and SPI-3. The virulence of several serotypes commonly associated with systemic infections in animals, including *S*. Typhimurium, *S*. Dublin, and *S*. Choleraesuis, is enhanced by intracellular survival in macrophages mediated by attributes encoded on virulence plasmids.

Salmonella taken up by resident macrophages elicit a *major immune response* in the host. There is considerable controversy about the roles played by cell-mediated and humoral immunity in the pathogenesis of salmonellosis, but *Salmonella* infection results in the release of cytokines by specifically stimulated T lymphocytes. They activate macrophages that phagocytose the organisms, and in such a circumstance, cell-mediated immunity is of paramount importance.

Once *Salmonella* bacteria have crossed the mucosa, they may enter the bloodstream via the lymphatics, perhaps carried in macrophages, and cause septicemia or transient bacteremia. Or they may remain indefinitely in the gut-associated lymphoid tissues and mesenteric lymph nodes. Increased susceptibility to salmonellosis in animals with intercurrent disease, or subjected to stress, may be related to relaxation of cell-mediated immunity to the organism. Septicemia may be of variable duration and severity but, as a rule, it is rapidly fatal in young animals. If, however, there is transient bacteremia, the organisms are removed by fixed macrophages, especially those of the spleen, liver, and bone marrow. They may continue to proliferate in such extravascular locations and subsequently may cause another bacteremic phase that may result in fatal septicemia or secondary localization in other tissues.

The carrier state is important in the epidemiology of the disease. Whether *Salmonella* can maintain themselves in the intestinal lumen is not clear; to some extent, at least, fecal shedding is likely to depend on intermittent seeding from the bile, or from macrophages in the lamina propria and gut-associated lymphoid tissue. The duration of the carrier state may be prolonged, or animals may rid themselves of the infection, probably by means of cell-mediated immunity. The carrier state is an unstable one, for it appears that if the carrier is subjected to some stress or debilitating disease it may succumb to disease; this often seems to occur in adult cattle. The carrier animal is a potential threat to any other animal that it contacts, either directly, or through the medium of its excreta, or byproducts such as bone or meat meal.

Salmonellosis in swine

Many serotypes of *Salmonella* have been isolated from swine, and with poultry and cattle they form an *important reservoir of the organism*. The bacteria are carried in the lamina propria of the intestine, but also in the regional lymph nodes of the alimentary tract, so that carrier animals may not excrete the organism in the feces.

Three syndromes are associated with *Salmonella* infections in swine. (1) *Septicemic salmonellosis* is usually associated with the host-adapted *S.* Choleraesuis var. *kunzendorf*, although enteric lesions may be present with this serovar. Sporadic infections with *S.* Dublin have also been associated with septicemia in nursing pigs. (2) *Salmonella* Typhimurium most commonly causes *acute or chronic enterocolitis*, including necrotizing proctitis which may lead to rectal stricture. (3) *Salmonella* Typhisuis infection is characterized by *ulcerative enterocolitis*, as well as caseous tonsillitis and lymphadenitis.

***Salmonella* Choleraesuis** was once thought to be the cause of classical swine fever (formerly hog cholera) because gross lesions of septicemic salmonellosis and acute classical swine fever are similar. The latter disease is often complicated by *S.* Choleraesuis, the bacterium being recovered from 10–50% of pigs with classical swine fever.

The major clinical manifestations of *S.* Choleraesuis infection are *septicemia and enteritis*; they usually occur separately. Septicemia is more common. Oral inoculation of *S.* Choleraesuis initially results in septicemia and acute enterocolitis, followed in some cases by large necrotic and ulcerative lesions ("*button ulcers*") in the colonic mucosa. Enteritis is not necessarily chronic, or even clinically evident. Interstitial pneumonia and multifocal hepatic necrosis are the most consistent systemic lesions. In Europe, infection has also been associated with the development of fulminant fibrinous pneumonia. Immunohistochemical techniques reveal the preferential location of *S.* Choleraesuis in the colon and surface of ileal M cells in Peyer's patches. The invasive capability of this serovar is indicated by the presence of large numbers of organisms in proprial macrophages and regional lymph nodes.

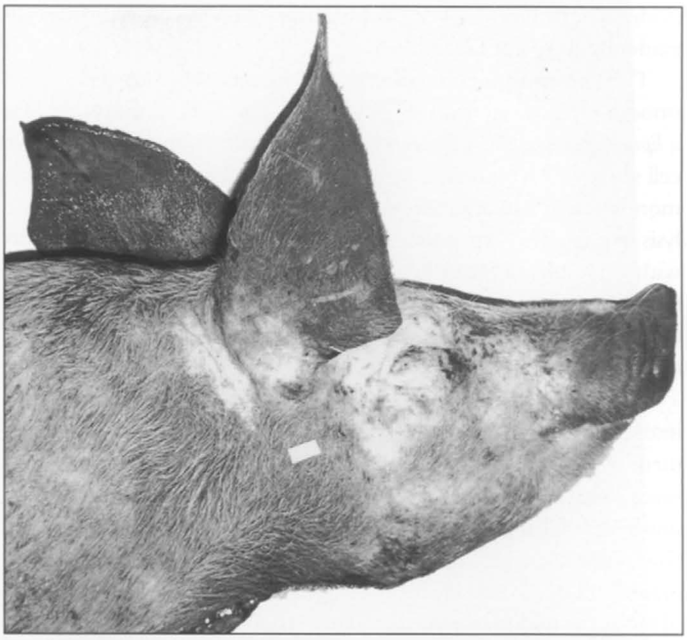

Figure 1.139 Note blue-red congestion of skin of ears, snout, and neck due to microvascular thrombosis caused by endotoxemia in **septicemic salmonellosis** in a pig.

Salmonellosis that is clinically septicemic is usually fatal. Death may occur quickly without observed illness, or after a course of a week or more. There is a high fever; characteristic but not pathognomonic blue discoloration of the skin, especially of the tail, snout, and ears (Fig. 1.139); caudal weakness; dyspnea that often leads to misdiagnosis of primary pneumonia; and sometimes terminal convulsions. Sows may abort during the septicemic phase of infection. Pigs recovered from this phase may have dry gangrene of the ears and tail, caudal paralysis, blindness, and diphtheritic enteritis. The *chronic or enteric form* may develop from the acute, but is usually insidious from the onset. It is characterized by loose yellow feces containing flakes of fibrin, progressive emaciation and debility, and eventual death. Some recover but fail to thrive, often partly owing to chronic bronchopneumonia.

At **autopsy**, there is blue or purple discoloration of the *skin*, which may be very intense about the head and ears. There may be superficial ischemic necrosis of the ears. Typically there are petechial hemorrhages in many organs and tissues. The lymph nodes are almost invariably hemorrhagic. The visceral nodes are more frequently and obviously involved than the peripheral ones, with the exception of those of the throat, which are usually hemorrhagic. The mesenteric lymph nodes are greatly enlarged, and they may be speckled with hemorrhages.

There may be hemorrhages, petechial or as small discrete blebs, on the *laryngeal mucosa* (Fig. 1.140). The *lungs* do not collapse because there is frothy fluid in the respiratory passages. They may be pale blue or purple. Beneath the visceral pleura there are small dark foci of hemorrhage. The lungs are wet and there is fluid in the interlobular tissue. The changes are best appreciated in the caudal lobes, because the cranial lobes are often the seat of acute lobular pneumonia. These pulmonary changes, attributable in part to endotoxin, account for the respiratory signs observed clinically. The *pneumonia* is interstitial due to endotoxemia and embolic organisms. The lobar cranioventral pneumonia may be due to ascending *Salmonella* alveolitis and bronchiolitis. Occasionally, the injury to the alveolar septa by *Salmonella* results

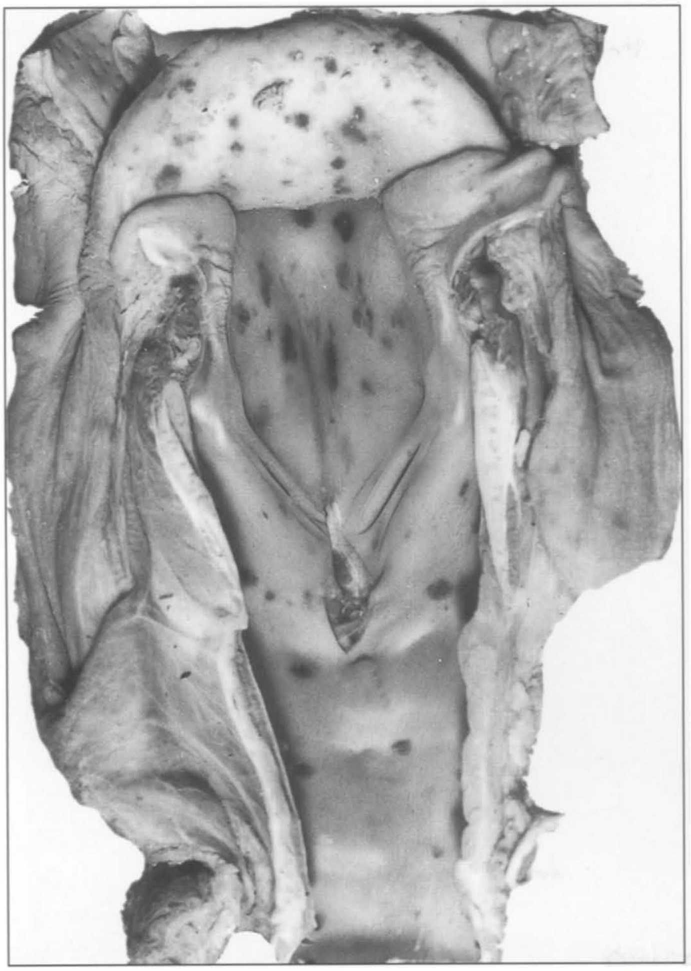

Figure 1.140 Laryngeal hemorrhages in **porcine salmonellosis**.

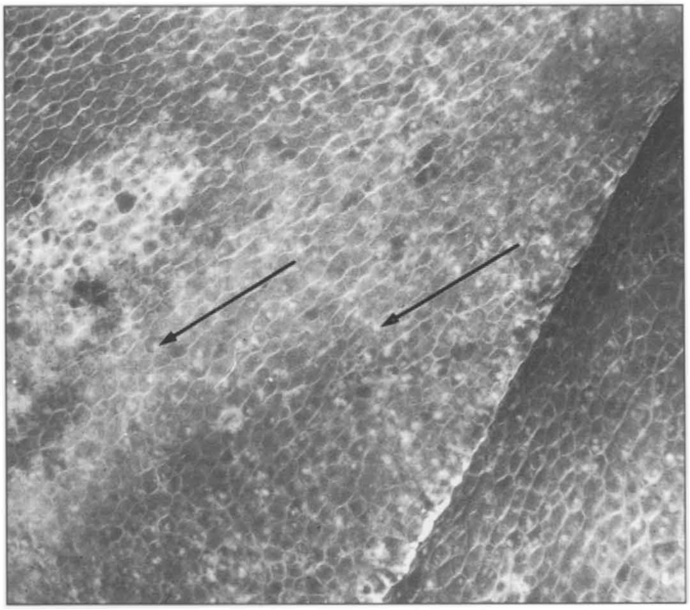

Figure 1.141 Paratyphoid nodules (arrows) in liver, in *Salmonella* septicemia in a pig.

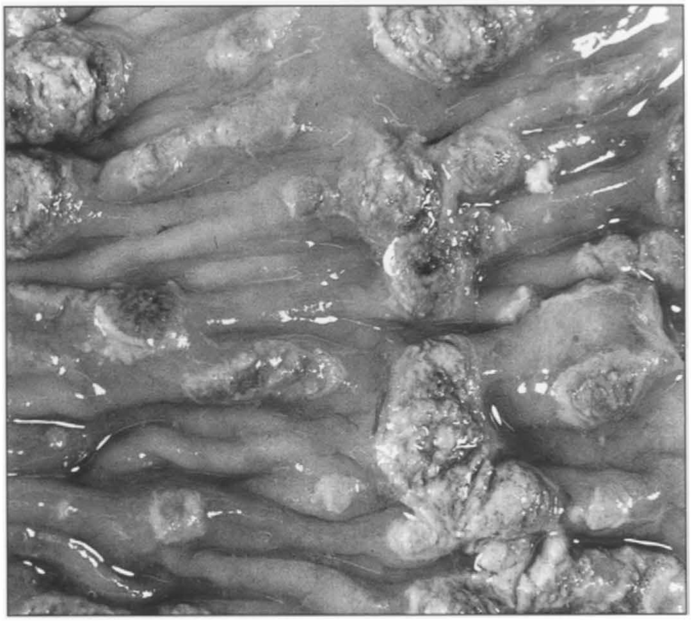

Figure 1.142 Button ulcers in colon in porcine salmonellosis.

in extensive fibrinous pneumonia of the caudal lobes. The cardiac serosae often bear petechiae, and in some more virulent infections there is fibrinohemorrhagic pericarditis with scant fluid exudation.

The *spleen is enlarged*, deep blue, firm with sharp edges; little blood oozes from the cut surface. There may be petechiae on the capsule, but the marginal infarcts of classical swine fever are not present. Other causes of splenomegaly, such as erysipelas, other septicemias, and African swine fever, must be differentiated.

The *liver* is usually congested, and focal hemorrhages may be visible in the capsule. In some cases the hemorrhages are very large, involving up to half of the central area in a lobule. They may be scattered at random throughout the liver or grouped, often at the edge of a lobe. In some, there are tiny yellow foci of necrosis, referred to as "*paratyphoid nodules*" (Fig. 1.141). Pinpoint hemorrhages are consistently present in the renal cortex. There may be only a few in each kidney or they may be so numerous as to cause the "turkey egg" appearance.

The *stomach* shows the intense red-black color of the severe congestion and venous infarction common to endotoxemia in pigs. If the animal survives a week or more, the superficial necrotic layer of the affected gastric mucosa sloughs. There may be no lesions in the *intestine*. There may be catarrhal enteritis or, more frequently, the enteritis is hemorrhagic, increasing in severity lower in the tract and terminating in a hemorrhagic ileitis. The mucosae of the colon and cecum may be normal but, if the course is prolonged, there is hyperemia, fibrinohemorrhagic inflammation, or button ulcers (Fig. 1.142).

Petechial hemorrhages may occur in the *meninges and brain*, but there is no gross inflammation. Localization sometimes occurs in *synovial membranes*, producing polysynovitis and sometimes **polyarthritis**. It is more usual to have an increase in the volume of fluid with red velvety hypertrophy of the synovial villi. The gross features described are usually not all present in any one case.

The **histologic changes** that occur in internal organs in acute disease are mainly associated with *endothelial damage due to endotoxin*, and *focal localization of bacteria*. The discoloration of the skin is initially due to intense dilation, congestion, and thrombosis of capillaries and venules in the dermal papillae. There is activation and necrosis of the endothelial cells in affected vessels. The renal lesions vary but principally affect the glomeruli. In some there is diffuse glomerulitis, and this is associated with mild nephrosis and hyaline casts. In others, the glomerulitis is exudative and hemorrhagic and in these a great many capillary loops contain hyaline thrombi. Embolic bacterial colonies are occasionally seen in the glomerular and intertubular capillaries. Fibrin thrombi may also be found in the afferent arterioles and interlobular arteries.

The pulmonary lesions are also characterized by thrombosis and vasculitis and a largely mononuclear cellular response in alveolar septa. There is flooding of the alveoli by edema fluid and moderate numbers of alveolar macrophages. This is the usual histologic picture; the extremes are acute fibrinous inflammation or a few scattered parenchymal hemorrhages.

In the liver, the *paratyphoid nodules* may be found in all transitional stages from foci of nonspecific necrosis to reactive granulomas. Typically there are few neutrophils, and whether the nodules are necrotic or reactive depends on their duration. The initial change is focal coagulative necrosis. About the margin, the macrophages accumulate and form small histiocytic granulomas which expand and displace the surrounding parenchymal cords.

In the spleen there are some scattered hemorrhages, but the overall histologic impression is of increased histiocytes with a scattering of neutrophils. The follicles are small and rather inactive. Very small foci of necrosis, containing many bacteria, may be sparse or relatively numerous, and these develop a reactive macrophage response and form the typical paratyphoid nodules.

Meningoencephalomyelitis occurs in a proportion of cases of septicemic salmonellosis. The lesion is fundamentally a vasculitis. There may be petechiae in the meninges but, microscopically, there is infiltration of large mononuclear cells in the pia-arachnoid and concentrated about the veins. The organism is relatively fastidious and cultures from postmortem samples may not be uniformly positive.

***Salmonella* Typhimurium** infection in swine produces a syndrome that differs from *S.* Choleraesuis in a number of ways. Clinically, the disease occurs in *feeder pigs* and is characterized by fever, inanition, and yellow watery diarrhea that may contain blood and mucus, especially in the later stages. The diarrhea may be chronic and intermittent. There is high morbidity but low mortality. Most pigs recover but may remain *carriers* for variable periods of time, and some may develop rectal stricture. The organism persists in tonsils, lower intestinal tract, submandibular, and ileocolic lymph nodes.

The pathogenesis and morphology of the enteric lesions differ from those described for *S.* Choleraesuis enteritis. The lesions with *S.* Typhimurium infection are mainly confined to the colon, cecum, and rectum, with minor involvement of the distal small intestine. There is acute enterocolitis with formation of a pseudodiphtheritic membrane on the mucosal surface (Fig. 1.143). Button ulcers are not associated with this or other nonhost-adapted serovars. Systemic dissemination and septicemia are rare.

Rectal stricture is thought to be a *sequel in most cases to ulcerative proctitis of ischemic origin,* caused by *S.* Typhimurium. It is characterized clinically by marked progressive distension of the abdomen, loss of appetite, emaciation, and soft feces. At autopsy, there is marked dilation of the colon, which is caused by narrowing of the rectum, 1–10 cm cranial to the anus (Fig. 1.144). The stricture is usually <1.0 cm in diameter and varies in length from 0.5 to 20 cm. There is marked fibrous thickening of the rectal wall, which may contain microabscesses. The dilation of the colon, proximal to the stricture, may consist of a well-demarcated widened area several centimeters long and wide. The colonic mucosa in this area is usually

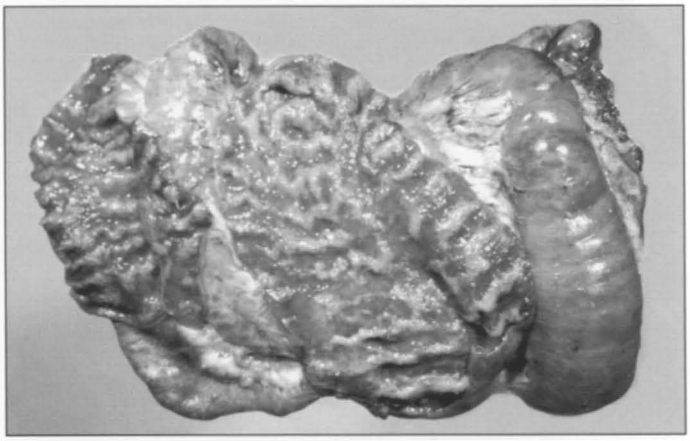

Figure 1.143 Fibrinous colitis in a pig infected with *Salmonella* Typhimurium.

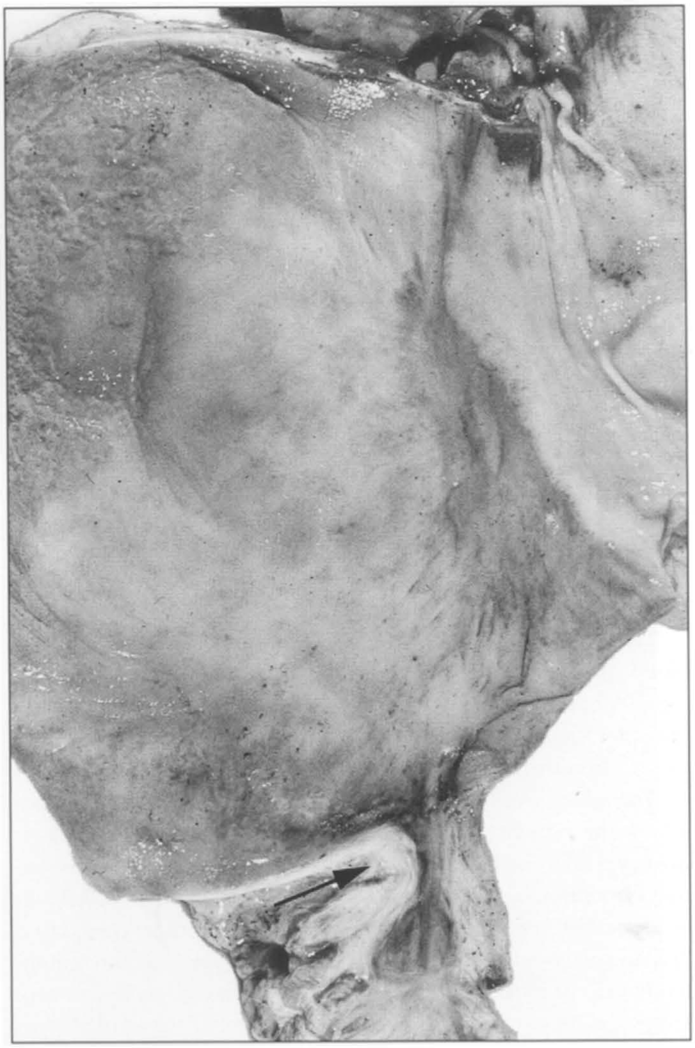

Figure 1.144 Rectal stricture in porcine salmonellosis. Opened colon is massively dilated proximal to stricture in rectum (arrow).

ulcerated and may be covered by fibrinous exudate. In some cases, there is more gradual but sometimes massive dilation of the entire colon and cecum, which are full of digesta, with ulceration of the mucosa just proximal to the stricture. The mucosa is always excessively corrugated; this is mainly the result of marked thickening of the internal muscularis. Anastomoses of the small intestine and/or colon to the dilated portion of the descending colon may occur. Localized chronic peritonitis is often associated with the dilated segments of the colon.

The stricture is located in an area of rectum that has a relatively poor blood supply, namely the junction of the circulatory fields of the caudal mesenteric and pudendal arteries. Ulcerative proctitis is consistently found in swine with typhlocolitis due to *S.* Typhimurium infection. Granulation of such lesions probably leads to cicatrization and stricture. The location, the persistent nature of this lesion in some pigs, and its limited capacity to heal are probably related to the restricted blood supply of the affected area.

***Salmonella* Typhisuis** infection is an *uncommon* condition in pigs. The disease, called *paratyphoid* in Europe, is now known to cause disease in pigs in the Americas and Asia. It is a progressive disease of 2–4-month-old pigs that is clinically characterized by intermittent diarrhea, emaciation, and frequently, massive enlargement of the neck region, the latter associated with caseous palatine tonsillitis, cervical lymphadenitis, and parotid sialoadenitis. There is also circular or button-like, to confluent, ulceration of the mucosa of the ileum, cecum, colon, and rectum. Other less frequent findings are caseous lymphadenitis of the mesenteric lymph nodes, interstitial pneumonia, hepatitis, and pericarditis.

Salmonellosis in horses

The most common serovar in horses in most areas is ***S.* Typhimurium**, and its prevalence is increasing, especially that of multidrug-resistant definitive phage type 104 (DT104). Other serovars are usually associated with sporadic cases of disease. *Many horses are Salmonella carriers, and when they are stressed, diarrhea follows.* Abortion of pregnant mares has been associated with *S.* Abortusequi. *Salmonella* Infantum has been associated with disseminated infection localizing in a variety of tissues, including muscle, in a horse.

Treatment with antibiotics, especially orally, increases the risk of salmonellosis. Resistance to certain antibiotics is associated with the presence of *resistance (R) plasmids* that may be transferred to other bacteria, of the same or different species, by conjugation or transduction. Antibiotic-resistant *Salmonella* may not respond to treatment, and antimicrobial therapy may increase the potential for infection and disease, due to the suppression of the normal flora. Antibiotic-resistant strains have been associated with outbreaks of salmonellosis at veterinary teaching hospitals.

Salmonellosis in horses may be manifested clinically as *peracute* (usually septicemic), *acute*, and *chronic* forms, and as an *asymptomatic carrier state.*

The septicemic form occurs most commonly in foals 1–6 months of age. These animals are usually with their dams at pasture and predisposing factors are unclear. The infection in foals tends to be fatal. Affected animals are lethargic and develop severe diarrhea, often with characteristic green color, which may contain casts and blood. They are febrile and waste rapidly, to die in 2–3 days. Some survive for a week or more and these may develop signs of pneumonia, osteitis, polyarthritis, and meningoencephalitis.

The primarily enteric forms of the disease are more likely to occur in older horses. Most of the predisposing factors mentioned earlier apply to horses. *Salmonellosis is an occupational hazard of horses*, since most are exposed to long periods of transport, and to exertion due to overwork or excessive training.

Clinically, the acute disease is characterized by diarrhea and fever for a period of 1–2 weeks, followed by recovery or death. The chronic form persists for weeks or months. Affected horses pass soft, unformed manure that resembles cow feces. They lose their appetite, with subsequent progressive loss of weight and condition. In later stages, they become dehydrated and emaciated.

The gross lesions are those of enteritis and/or septicemia; the former are most consistently found at autopsy. As a rule, the longer the course, the lower in the intestine does one find the most severe lesions.

Acute septicemic cases show small hemorrhages on the serous or mucosal membranes. The visceral lymph nodes are always enlarged, juicy, and often hemorrhagic. Marked pulmonary congestion and edema, and renal cortical pallor and medullary congestion may occur. The main lesions are in the stomach and intestines. In **peracute or septicemic cases**, there is intense hyperemia of the gastric mucosa, probably venous infarction, with some edema and scattered hemorrhage. The small intestine may be congested with a mucous or hemorrhagic exudate. In **acute cases**, there is diffuse and intense fibrinohemorrhagic inflammation of the cecum and colon overshadowing any lesions in the upper intestine, and leading rapidly to superficial necrosis of the mucosa and a gray-red pseudomembrane (Fig. 1.145A). In **chronic salmonellosis**, enteric lesions may be few or subtle. Some animals have extensive or patchy fibrinous or ulcerative lesions of the cecum and colon. In others, raised circumscribed lesions about 2–3 cm in diameter may be evident, with a gelatinous submucosa and ulcerated mucosa. Some such lesions are more fibrinous, and resemble button ulcers (Fig. 1.145B).

Histological alterations of significance are usually limited to the intestine. However, in septicemic animals lesions typical of endotoxemia are present in lung, liver, kidney, spleen, and adrenal. There may be acute ileocecocolic lymphadenitis, and inflammation in sites of localization, such as growth plates in long bones, and the meninges. Depending on the duration of the enteritis, hemorrhage, necrosis, or diphtheresis may predominate, but the infiltrating leukocytes are largely mononuclear. The superficial coagulative necrosis of the mucosa may extend over large areas. A layer of fibrinocellular exudate may cover the necrotic mucosa. Fibrin thrombi are frequently present in the capillaries or venules of the lamina propria (Fig. 1.145C). There is usually marked congestion of submucosal vessels, which is accompanied by considerable edema.

Salmonellosis in cattle

The serotypes usually incriminated are **S. Typhimurium** and **S. Dublin**; both are distributed worldwide. Wherever S. Dublin is found, it tends to be adapted to cattle and to occur in epizootics, whereas other serotypes usually cause more sporadic disease.

It is unusual to find salmonellosis in **calves** less than a week of age, in contrast to enteric and septicemic colibacillosis, which usually affect very young animals. *In calves, salmonellosis is a febrile disease typified by dejection, dehydration, and usually diarrhea.* Diarrhea is not always present, but when it is, the feces are yellow or gray, and have a very unpleasant odor. In older calves, there may be blood and mucus in the feces. In less acute cases, there may be delayed evidence of localization in the lung and synovial structures. Morbidity and mortality may be considerable, especially in calves that are confined, such as in vealer operations. Experimental infections in calves indicate that survival is inversely related to the numbers of *Salmonella* in the inoculum, and directly to the age of the calves.

The general appearance at **autopsy** of a calf with salmonellosis may resemble one with septicemic colibacillosis. However, *enlargement of mesenteric lymph nodes and gross enteric lesions* are generally observed in salmonellosis. There is moderately severe gastrointestinal inflammation, acute swelling, and hemorrhage of the visceral lymph nodes, and some petechiation of serous membranes. The enteritis may be catarrhal, but sometimes it is hemorrhagic or more commonly causes exudation of yellow fibrin (Figs 1.146 and 1.147). The mucosa overlying the lymphoid tissues may become necrotic and slough. In animals with fibrinous enteritis, the bowel wall is somewhat turgid and the serosa may have a ground-glass appearance. There is often diffuse, but perhaps mild, fibrinous peritonitis.

The intestinal lesions are usually most severe in the ileum, especially during the early stages of the disease. With time the jejunum and colon become involved but the duodenum remains relatively normal. The regional distribution of the lesions may, in part, be related to differences in the level of bacterial colonization of the mucosa. Twelve hours after oral infection of calves with S. Typhimurium, the numbers of bacteria are generally lower in the abomasum and duodenum than in the lower intestinal tract, while they are relatively constant from the jejunum through to the rectum.

The early **microscopic lesions** in the small intestine consist of a thin layer of fibrinocellular exudate on the surface of short and blunt villi (Fig. 1.148). This is followed by extensive necrosis and ulceration of the mucosa, with fibrin and neutrophils exuding from the ulcerated areas into the lumen (Figs 1.149 and 1.150). The lamina propria may be moderately infiltrated by mononuclear inflammatory cells. Fibrin thrombi are often evident in proprial capillaries and venules. There is also marked submucosal edema and the centers of lymphoid follicles in the Peyer's patches are completely involuted. Similar erosion, ulceration, and fibrinous effusion occur in the proximal large bowel.

Scanning electron microscopy of small intestine shows large numbers of bacteria on a tattered mucosal surface. Clusters of enterocytes slough off short villi (Fig. 1.151). Strands of fibrin emerge from the mucosal defects and cover the mucosa. Ultrastructurally, the lesions are similar to those described originally in guinea pigs, except that there is more damage to epithelium in calves experimentally infected with S. Typhimurium.

Characteristic changes usually occur in the *liver and spleen*, but may be absent in peracute septicemic cases. There is often fibrinous cholecystitis. In acute cases, the spleen is enlarged and pulpy as a result of congestion, but this is soon replaced by acute splenitis, present as miliary, tiny foci of necrosis or as reactive nodules. The liver is often pale with many minute *paratyphoid nodules*. In the spleen, macrophage reaction is sometimes diffuse. "Paratyphoid" granulomas may also be found microscopically in the kidney, lymph nodes, and bone marrow. These probably represent a cell-mediated immune response to embolic bacteria. In those animals that survive the acute phase of the disease, the inflammatory changes in lymphoid tissues progress

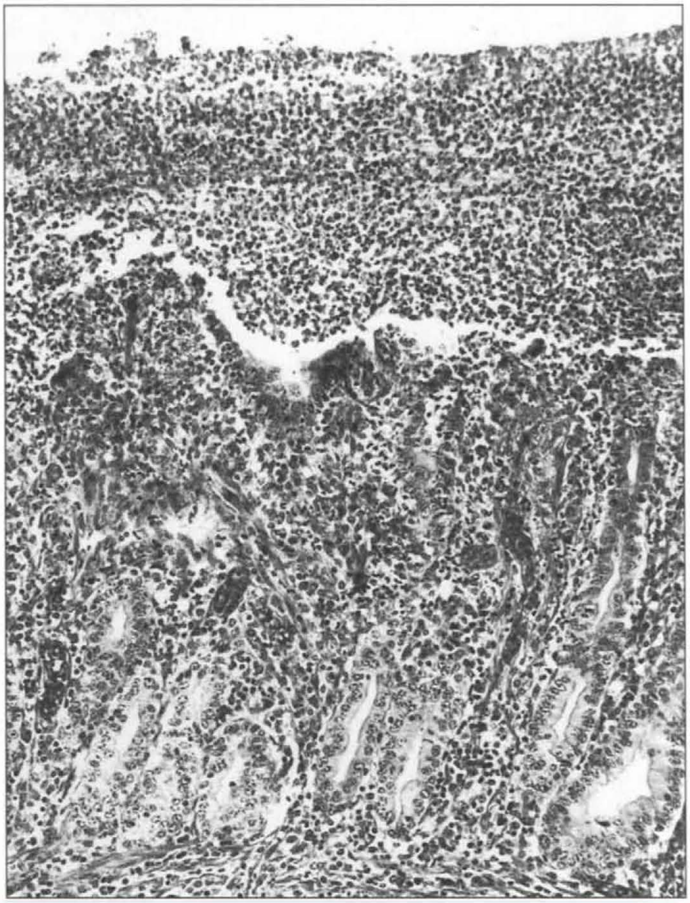

Figure 1.149 Atrophy of villi, erosion, and effusion of neutrophils and fibrin into the lumen of the small intestine of a calf. Some thrombosis of proprial vessels 36 hours after inoculation with **S. Typhimurium**. (Courtesy of R Clarke, CL Gyles.)

to an immunologic response, characterized by a diffuse reaction of medium-sized and large lymphocytes in the follicles, and plasma cells in the sinusoids. There may be marked cortical atrophy of the thymus. In calves with acute septicemia, pulmonary congestion and edema are visible at necropsy, with interstitial thickening of pulmonary alveolar septa by mononuclear cells in tissue section. There may be thrombosis of septal capillaries, and some effusion of edema fluid and macrophages into alveolar spaces.

In subacute salmonellosis of calves, there may be cranial bronchopneumonia, usually with adhesions and abscessation. Purulent exudate is in synovial cavities, and the organism is recoverable in pure culture from such affected joints and tendon sheaths. It may be mixed with *Arcanobacterium pyogenes* and *Pasteurella* in the lungs.

Salmonellosis in **adult cattle** may occur in *outbreaks* as it does in calves, but more often it is sporadic, and it may cause *chronic diarrhea and loss of condition*. The source of infection is usually the carrier animal. Other sources, such as feed containing protein of animal origin, or bone meal, should be considered when the disease is caused by an uncommon serovar. *Abortions* are most common with *S.* Dublin, but may occur with any serovar. In some herds, this may be the only clinical evidence of infection, although other animals often excrete the offending serovar in the feces. The *carrier state* of *S.* Dublin infection in adult cattle may persist for years, sometimes for life, in contrast to infections with other serovars, which rarely persist for more than 18 months. Dairy cows may persistently shed *Salmonella*, especially *S.* Dublin, in milk and cause infections in humans who drink raw milk. The morbid changes in adult cattle correspond to those in calves except that there is more pleural hemorrhage and the enteritis may be more hemorrhagic and fibrinous. The histologic changes in the liver and other organs are the same as those seen in calves.

Of serious concern for both cattle and humans is the emergence of a new multidrug-resistant strain of *S.* Typhimurium. This new strain, known as *Salmonella* Typhimurium definitive phage type 104 (DT104), was first seen in the UK in the late 1980s. It has now spread worldwide and in some parts of the USA is the leading cause of bovine salmonellosis. The potential for this strain to emerge as a major foodborne pathogen has caused great consternation among both agricultural and public health communities.

Salmonellosis in sheep

As well as abortion caused by *S.* Abortus-ovis, abortion and neonatal death may follow infection of pregnant ewes by any species of *Salmonella*. While the prevalence of *S.* Abortus-ovis in the UK seems to be waning, *S.* Montevideo, on the other hand, has been associated with abortions in several flocks in the British Isles.

Salmonellosis is not a common disease in sheep, but outbreaks are always severe and may cause very heavy losses. Predisposing influences are necessary, and these are usually provided by circumstances that enforce congregation. Deprivation of food and water for 2–3 days may be sufficient and, coupled with fatigue, is the usual predisposing factor when sheep are transported or confined in holding yards. Deaths usually continue for 7–10 days after debilitating circumstances have been remedied.

The serovars usually found in sheep are ***S.* Typhimurium**, ***S.* Arizonae**, and ***S.* Enteritidis**. *Salmonella* Dublin is increasing in prevalence in the UK and the midwestern states of the USA. Experimental inoculation of sheep with *S.* Arizonae produces infection but rarely disease. Under natural conditions this host-adapted organism is frequently considered to be an infection secondary to some other disease, or an incidental finding in apparently healthy animals. Most serovars produce the same sort of disease, which closely resembles that seen in cattle both clinically and at autopsy. The major findings are fibrinohemorrhagic enteritis, and septicemia.

Salmonellosis in carnivores

Salmonella can often be recovered from apparently healthy dogs and cats. However, primary disease rarely occurs. *Salmonella* has been recovered in high frequency from normal sled dogs lacking clinical disease. Raw meat fed to dogs has been shown to have a high incidence of *Salmonella* contamination. In dogs and cats, nosocomial infections are sometimes associated with hospitalization and antibiotic therapy. In dogs, salmonellosis may be secondary to canine distemper. It can cause bronchopneumonia, acute hemorrhagic gastroenteritis, swelling of the spleen and mesenteric lymph nodes, serosal hemorrhages, and foci of necrosis in the liver and other organs. Septicemia in puppies has been associated with *S.* Dublin infection. Salmonellosis has been reported in dogs with lymphosarcoma, shortly after the initiation of chemotherapy. The immunosuppressive effect of the treatment, or depressed cell-mediated immunity, probably predisposes to the development of disease.

Various serovars have been isolated from cats and most of these appear to cause subclinical infections. However, salmonellosis may be a problem in catteries and hospitals, affecting animals that are subjected to stressful conditions. Immunosuppression associated with *Feline leukemia virus, Feline immunodeficiency virus, Salmonella*-contaminated panleukopenia vaccine, or other intercurrent diseases is thought to predispose to salmonellosis in cats. *S.* Typhimurium is most commonly associated with such outbreaks. The disease is characterized by gastroenteritis and septicemia or a more chronic, nonspecific febrile illness, with neutrophilia and left shift. Conjunctivitis and abortions have also been associated with *Salmonella* infection in cats.

Because of their close association with humans, especially children and the aged, dogs and cats that are carriers are a potential source of zoonotic infection.

Yersiniosis

Yersinia enterocolitica and *Y. pseudotuberculosis* are gram-negative organisms that, in domestic animals, cause *enterocolitis, mesenteric lymphadenitis*, and, less commonly, *septicemia*. There are sporadic reports of placentitis with abortion or perinatal mortality, epididymitis-orchitis, and mastitis in sheep and goats, and of abortion and pneumonia in cattle. *Y. pestis*, the cause of plague in animals and humans, is not considered here.

The *epidemiology* of yersiniosis is complex and poorly understood. These organisms may be shed in the feces by asymptomatic animals in the herd or flock, and by other species, such as rodents and birds, in the environment. The organisms can survive and grow in the environment at low temperatures, and in cool weather environmental contamination by *Yersinia* spp. may be considerable, resulting in significant oral challenge. Disease may in part be due to compromise of cell-mediated immunity, permitting establishment of invading organisms, or recrudescence of latent infection. Often, outbreaks occur under stressful circumstances, such as poor weather, flooding, after transport, during the breeding season, or in animals on a poor plane of nutrition.

Subsequent to ingestion, *the organisms invade through the intestinal epithelium or M cells* overlying Peyer's patches and attain the lamina propria or submucosal lymphoid follicles. Enormous recruitment of neutrophils and ensuing destruction of cytoarchitecture of the Peyer's patch and overlying epithelium result in formation of suppurative foci in place of follicles in Peyer's patches, and microabscesses in the lamina propria of the small or large intestine if invasion occurs elsewhere. *Yersinia* disseminates via lymphatics and hepatic portal venous drainage to mesenteric lymph nodes or to liver and the systemic circulation.

A number of *virulence factors* are recognized; all are related to the ability to invade cells or to evade the inflammatory response. These include expression of an adhesin termed invasin, which binds to beta-1 integrins expressed on the surface of intestinal M cells, promoting uptake of *Yersinia* by these and normally nonphagocytic cells, and causing epithelial cells to produce cytokines chemotactic for inflammatory phagocytes. A plasmid-encoded type III secretion system translocates effector proteins termed "yops" from bacteria into host cells. These enable invasive *Yersinia* to remain extracellular, evading phagocytosis and killing by neutrophils and macrophages by a variety of mechanisms. Although *Yersinia* reside extracellularly as microcolonies in suppurative foci in the lamina propria and lymph nodes, at least some appear to reside intracellularly, since a T-cell-mediated immune response is required to clear infection. Giant cells wall off foci of infection in subacute to chronic lesions, hence the specific name *pseudotuberculosis*.

Disease may be gradual in onset, subtle and chronic, producing a syndrome of diarrhea and ill-thrift, in cattle, sheep, and goats. Mild diarrhea with low mortality has been reported in Australia in weaned pigs with *Y. pseudotuberculosis*. More fulminant disease, characterized by severe, sometimes hemorrhagic, diarrhea, systemic infection, and prostration, may occur in cattle, some species of deer, especially chital and red deer, water buffalo, and exotic ungulates. Yersiniosis is an apparently uncommon cause of diarrhea, and occasionally fatal enterocolitis, mesenteric lymphadenitis, and systemic infection in carnivores. *Yersinia* also causes sporadic pneumonia and septicemia in foals.

Yersiniosis has been described worldwide, as a cause of disease in sheep, cattle, goats, deer, and pigs. The lesions of *Y. pseudotuberculosis* and *Y. enterocolitica* cannot be differentiated reliably grossly or microscopically.

In all species, **gross lesions** in clinically subacute to chronic yersiniosis may be mild. They are usually limited to abnormally fluid intestinal content, with congestion, edema, roughening, and perhaps small foci of pallor, focal hemorrhages, erosion, or mild ulceration and fibrin effusion. Raised nodules up to 5 mm in diameter, with depressed centers, may be evident in affected large bowel. Mesenteric lymph nodes are enlarged, congested, and edematous, perhaps with foci of necrosis. There may be mild fibrinous cholecystitis, and pale foci of necrosis scattered in the liver.

The infection is characterized **histologically** by *masses of gram-negative coccobacilli forming microcolonies*, in the lamina propria of villi and around the necks of crypts in the distal half of the small intestine, in Peyer's patches, and in the superficial mucosa of the large intestine. Intense local infiltrates of inflammatory cells, predominantly neutrophils, accumulate to form *microabscesses* up to about 300 μm in diameter around the bacteria, and effuse into the lumen through microerosions on the mucosal surface or in crypts. Small crypt abscesses may be present. In small intestine, there may be moderate atrophy of villi and hyperplasia of crypts, associated with increased infiltrates of chronic inflammatory cells. Microabscesses, or pyogranulomas surrounded by macrophages or giant cells, and sometimes containing bacterial microcolonies, may be present in the subcapsular and medullary sinuses of mesenteric lymph nodes.

In fulminant *Yersinia* infection in all species, there is *fibrinous or fibrinohemorrhagic enterocolitis*, with heavy local mucosal colonization by masses of coccobacilli, and marked neutrophil infiltration. Peyer's patches may be particularly involved, with grossly visible foci or confluent masses of caseous necrotic debris, as may be found in draining mesenteric lymph nodes, which are enlarged. There may be serosal hemorrhages on the gut, fibrinous peritonitis, and pleuritis, and foci of necrosis may also be present in the liver, lungs, and occasionally other parenchymatous organs; the characteristic microcolonies of coccobacilli are usually evident in them.

Caseous mesenteric lymphadenitis, with mature pyogranulomas containing microcolonies of bacteria, surrounded by neutrophils and giant cells, may occasionally be found as an incidental lesion, or in animals with *Yersinia* abscesses in other organs.

Yersiniosis is **diagnosed** in tissue section by finding characteristic microcolonies of coccobacilli in microabscesses (Fig. 1.152), and is confirmed by bacterial isolation. Microscopic lesions may not be detected in the intestinal mucosa of some clinically affected animals from which isolates are made, perhaps because lesions are patchy. Since *Yersinia* spp. are psychrophiles, cold enrichment and culture at temperatures below 37°C are used in their isolation.

Lawsonia intracellularis infection

Lawsonia intracellularis infects a variety of species, including swine, horses, donkeys, deer, hamsters, guinea pigs, mice, rabbits, foxes, dogs, ferrets, several species of nonhuman primates, ostrich, and emus. In most, it causes a *characteristic proliferative lesion of cryptal epithelium in distal small intestine and/or large bowel*, associated with a diarrheal syndrome, ill-thrift, and, in emus, rectal prolapse.

L. intracellularis is a gram-negative, curved or S-shaped rod, that is microaerophilic and nonflagellated. It is an *obligate intracellular organism*; hence, cultivation requires the use of tissue culture.

Lawsonia is prevalent in swine worldwide, and it is in this species that infection is most important. Once infected, pigs shed the organism for weeks.

Formerly referred to as *intestinal adenomatosis complex*, and characterized by a number of syndromes (*porcine intestinal adenomatosis, necrotic enteritis, regional ileitis, and proliferative hemorrhagic enteropathy*), the conditions in swine now known to be caused by *L. intracellularis* are lumped as **porcine proliferative enteropathy** (PPE). The multiplicity of names reflects the fact that the etiology of these syndromes eluded definition for decades. PPE was associated with *Campylobacter mucosalis* or *C. hyointestinalis*, until it was finally reproduced by a newly discovered bacterium, "ileal symbiont intracellularis," the taxonomy of which was formalized as *Lawsonia intracellularis* in 1995. Although proliferative enteropathy due to *L. intracellularis is primarily a disease of swine*, it has been reported uncommonly in a number of other species, the most important among domestic animals being the *horse*, in which it mainly affects animals 3 months to 2 years of age.

Disease occurs most commonly in feeder pigs. However, piglets as young as 3 weeks of age, and adults, may have lesions of PPE. Clinical effects may vary from subtle subclinical disease with a mild decrease in growth rate to diarrhea and unthriftiness. Animals with extensive lesions may have anorexia, intermittent or persistent diarrhea, and severe weight loss. Death may follow a period of diarrhea and progressive cachexia, or it may occasionally occur as a result of perforation of an ulcerated intestine, or through peracute hemorrhage. Mortality may be very high.

The **pathogenesis** is dependent on undefined interactions with other bacteria in the gut, because gnotobiotic pigs inoculated with *L. intracellularis* fail to develop disease, whereas conventional pigs are quite susceptible. The pathogenicity of *L. intracellularis* is related to its active uptake by epithelial cells, in which they replicate, and cause to become hyperplastic. It has been theorized that it disrupts intestinal cell differentiation, but specific virulence attributes of *L. intracellularis* are poorly understood, as are molecular details of the agent–host cell interaction. In PPE, infection of cells lining mucosal glands may occur initially in the vicinity of Peyer's patches and mucosal lymphoid aggregates in the ileocecocolic region. In some experimental studies, lesions were first seen here, and in mildly affected spontaneous cases, lesions sometimes seem associated with these structures preferentially. Later, cells in cecal and colonic crypts become infected. *L. intracellularis* organisms internalized within membrane-bound vesicles are released into the apical cytoplasm of glandular epithelium where they lie free and replicate. Cell division is required for bacterial replication, which may explain its tissue tropism. Bacteria are passed on to daughter epithelial cells and exit via extrusion from the cytoplasm of enterocytes on villi or between crypt openings.

Infected epithelium is transformed to a population of highly mitotic cells, and goblet cells disappear. Glands are lined by crowded, dysplastic pseudostratified columnar epithelium, with basophilic cytoplasm (Fig. 1.153A). Nuclei may be open and vesicular with prominent nucleoli, or laterally compressed. The cytologic and biochemical characteristics of these cells suggest that they are poorly differentiated. Infected glands become elongate, dilated, and branching, causing thickening of the mucosa. Isolated plaques of affected mucosa may project above adjacent tissue. The use of the term "*adenomatosis*" to describe such a change is obvious. Hypertrophic glands sometimes protrude into lymphoid tissue in the submucosa. Occasionally, microscopic foci of adenomatous epithelium may be found in submucosal lymphatics or the regional lymph node.

Villi in infected small intestine undergo progressive atrophy, so that they may be entirely absent in well-established lesions. However, the proliferative lesion in the crypts seems primary, and not a hyperplastic response to increased epithelial exfoliation. Adenomatous areas merge sharply with adjacent normal mucosa. Masses of *L. intracellularis* are readily recognized in silver-stained tissue sections, as *curved rods*, infecting especially the *apical cytoplasm of cells in adenomatous glands* (Fig. 1.153B). These organisms have also been identified ultrastructurally in degenerate cells and macrophages in the lamina propria. Proprial and submucosal inflammation in areas of uncomplicated adenomatosis is not marked.

In the least complicated forms of the disease, **lesions** *are always found in the terminal portion of the ileum*, extending proximally from the ileocecal-colic orifice for usually less than a meter, though sometimes they can be found more cranially. In a proportion of cases, they occur in the cecum and proximal third of the spiral colon, but not without ileal involvement. In mild cases, which are likely to be subclinical, only a few ridge or plaque-like thickened areas project above the remainder of the mucosa. However, more typical widespread lesions cause the thickened mucosa to form irregular longitudinal or transverse folds or ridges. The surface may be intact, but commonly, small foci of fibrin exudation or necrosis may be evident.

Thickening of the adenomatous mucosa, and perhaps some edema of the submucosa, is reflected in accentuation of the normal reticular pattern on the serosa of the ileum (Fig. 1.154A). This results in a *cerebriform or gyrate pattern of projections and depressions on the serosal aspect of the intestine which is readily recognized, and virtually pathognomonic for this condition.* Mucosal lesions in the large intestine often form thickened plaque-like or almost polypoid masses, which may be confluent in

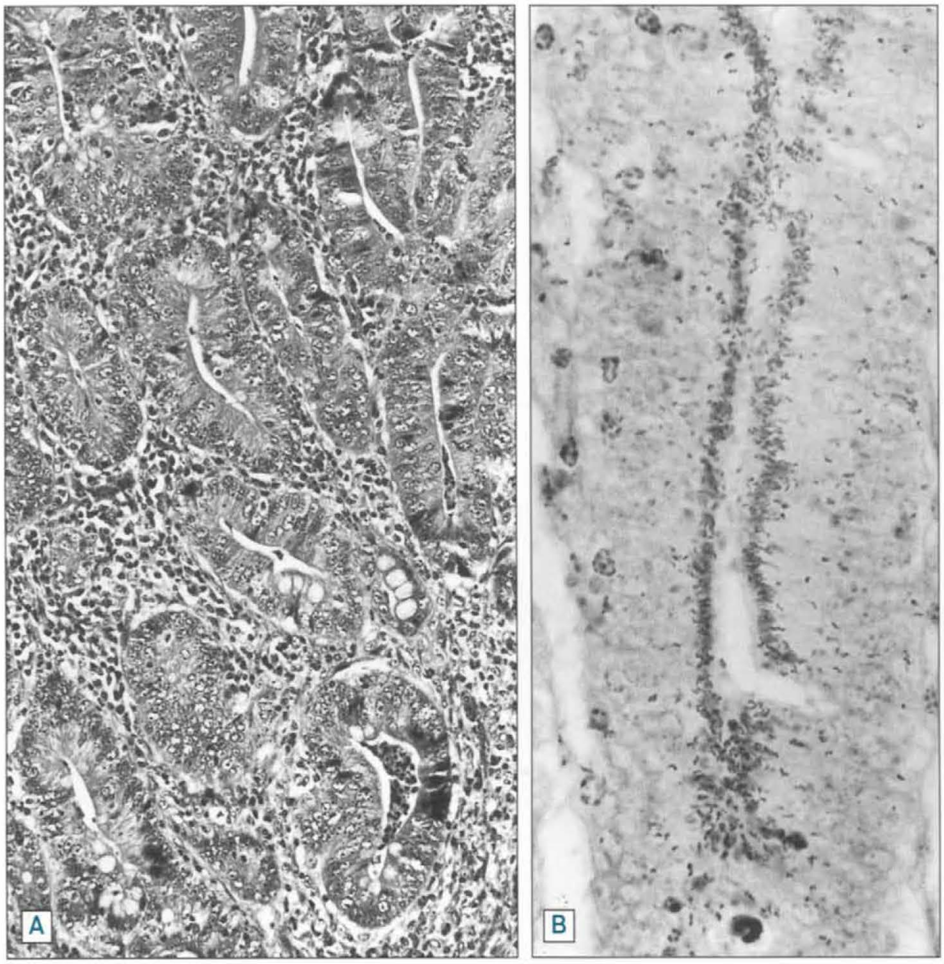

Figure 1.153 Porcine proliferative enteropathy. A. Adenomatous change in glands in the lamina propria. **B.** Masses of silver-stained ***Lawsonia* organisms** in cytoplasm of hyperplastic epithelium lining intestinal glands.

some areas, and are often eroded, with fibrin exudation (Fig. 1.154B). Serosal folds may be evident on extensively affected large intestine. The ileocolic lymph nodes are enlarged and hyperplastic.

Coagulative necrosis of adenomatous mucosa commonly occurs and is referred to as **necrotic enteritis**. It may be partly the result of pathogenic anaerobic large-bowel flora, colonizing the affected terminal ileum and large intestine. There may be effusion of fibrin from superficial lesions, and a pseudodiphtheritic membrane or luminal fibrin cast may be present. Caseous yellow-brown or blood-tinged necrotic mucosa may be found focally or widely in the distal ileum and proximal large intestine. The cerebriform pattern of serosal folding is evident in such cases (Fig. 1.155). While necrotic enteritis may be a sequel to other enterocolitides in swine, *adenomatosis is the most common primary lesion.*

Microscopically, coagulative necrosis of the mucosa may be focal and superficial, with local effusion of neutrophils and fibrin into the lumen, and an acute inflammatory infiltrate at the margin of the necrotic tissue. Frequently, necrosis extends to involve most the thickness of the mucosa, sometimes penetrating to the submucosa. A few islands of viable adenomatous crypts or glands may be left deep among the necrotic debris. Masses of bacteria, presumably fecal anaerobes, are found superficially in the necrotic tissue. With time, granulation tissue develops in ulcerated areas. Tissue in the upper ileum at the proximal margin of the zone of mucosal necrosis should be examined for adenomatosis since, in severe cases of necrotic enteritis, no remnants of such mucosa may persist elsewhere.

As the distal ileum experiences bouts of proliferation, necrosis, and ulceration, such granulation of ulcerated gut may result in progressive stricture of the lumen. This is the syndrome of PPE known as **regional ileitis**. There is often hypertrophy of the external muscle layer. Idiopathic ileal muscular hypertrophy also occurs in swine, apparently independent of antecedent PPE.

Acute or subacute intestinal hemorrhage and anemia occur in PPE, and were considered a distinct syndrome, **proliferative hemorrhagic enteropathy**, within the porcine intestinal adenomatosis complex. Animals may exsanguinate so quickly as to die without passing blood. Others pass dark-red feces for several days. This syndrome is more common in young adults, rather than growing pigs. It is usually sporadic, or of relatively low morbidity, but up to half the clinically recognized cases may die.

Animals dead of this *massive intestinal hemorrhage* are pale, and the perianal area may be smeared with blood. The typical cerebriform pattern is evident on the external surface of the distal ileum, which is thickened and turgid (Fig. 1.156A). Fluid blood or a loose or firm fibrin and clotted blood may be present in the ileum (Fig. 1.156B), and the contents of the cecum and colon may contain dark bloody digesta and feces. The mucosa of the affected ileum usually resembles that in uncomplicated PPE, and overt points of hemorrhage or ulceration are rarely discernible grossly. Rather the animals appear to suffer widespread diapedesis from the mucosa.

In tissue sections from animals dead with the hemorrhagic syndrome, there are extensive erosion and necrosis of proliferative

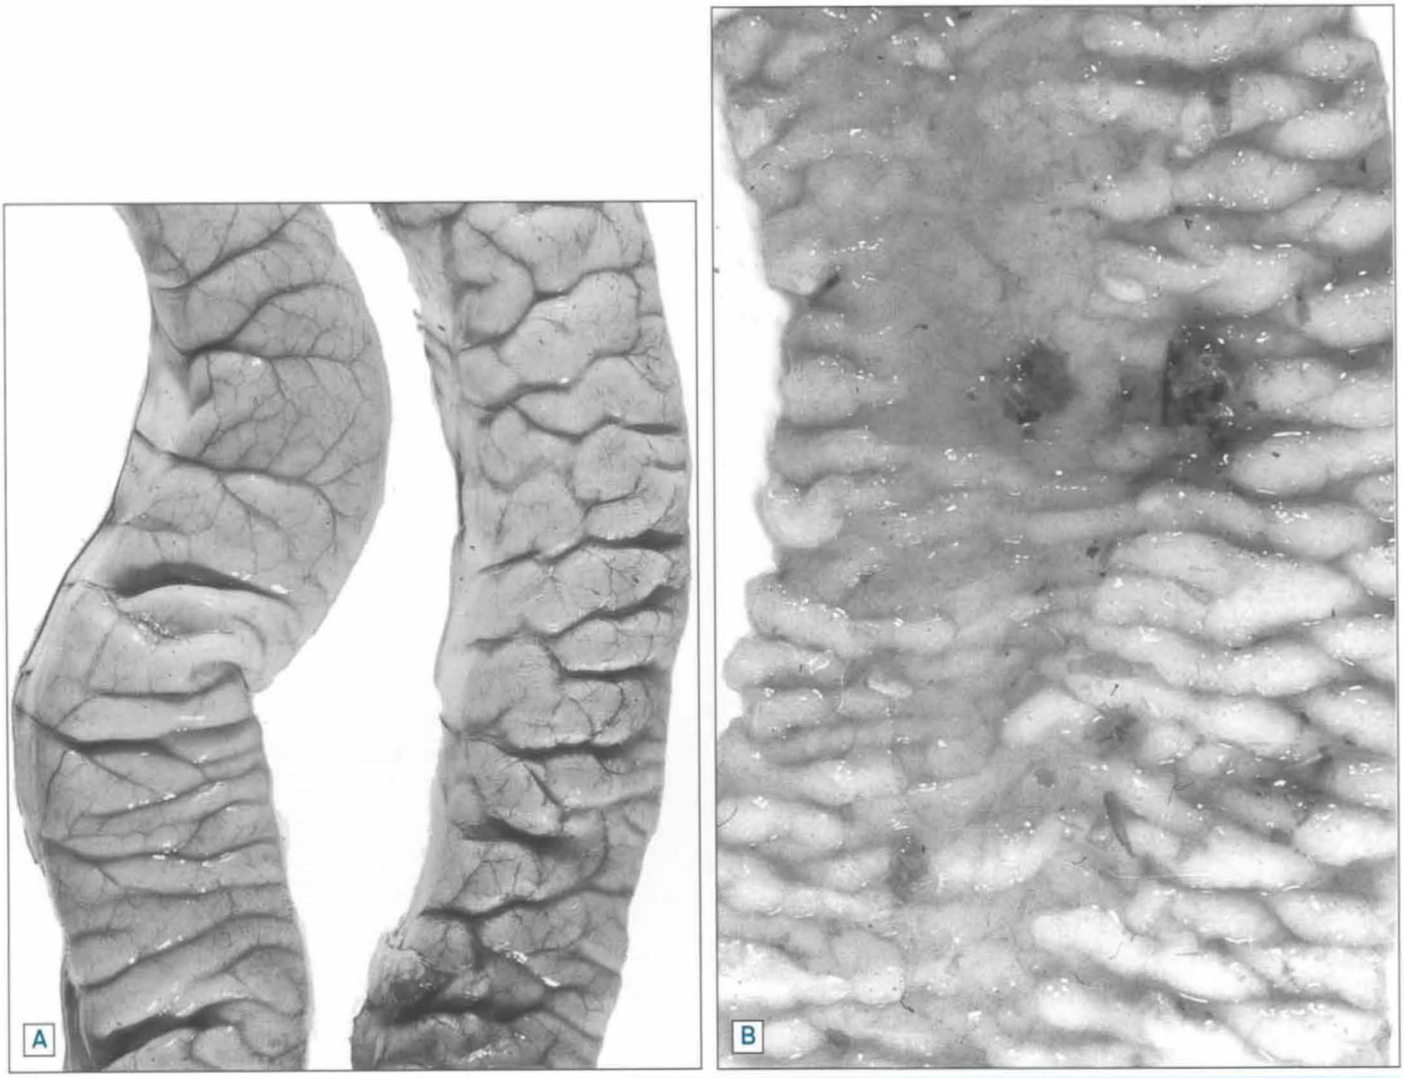

Figure 1.154 Porcine proliferative enteropathy. A. Exaggerated **reticular pattern of folds** on serosal aspect of the ileum. **B.** Raised nodular or **ridge-like areas of thickened mucosa** in the ileum, resulting from hypertrophy of glands.

epithelium in the superficial mucosa (Fig. 1.157). An acute inflammatory infiltrate is present in the upper lamina propria, small vessels are thrombosed, and heavy effusion of neutrophils on to the mucosal surface and into lumina of glands is evident. Fibrin and hemorrhage emanating from superficial mucosal vessels are in the intestinal lumen. More extensive coagulative necrosis of the mucosa is occasionally associated with this hemorrhagic clinical entity of PPE.

In **other species**, the lesions and pathogenesis of **proliferative enteritis** seem similar to those in PPE. In all species, including swine, *diarrhea is probably related to loss of functional mucosal surface area in distal small intestine and large bowel, while ill-thrift or wasting syndromes are attributable to protein-losing enteropathy*. Clinical signs and lesions associated with hypoproteinemia predominate in young horses, and diarrhea is an inconsistent finding, perhaps related to the large absorptive capacity of the equine colon. In horses, adenomatosis may involve a considerable amount of the small intestine.

A presumptive **diagnosis** of PPE in swine, and of proliferative enteritis in other species, can be based on typical gross and histologic lesions, accompanied by Warthin–Starry staining to visualize the intracellular bacteria. Confirmation can be obtained by immunohistochemistry using a specific antibody for *L. intracellularis* or by specific polymerase chain reaction.

Enteritis associated with Campylobacter spp.

Campylobacter jejuni and ***C. coli*** are common causes of diarrhea in humans, and *C. jejuni*, at least, is also capable of causing enteritis in animals. *C. jejuni* penetrates the surface mucus layer and adheres to the epithelium. Virulent strains enter cells by directed endocytosis caused by the products of a type III secretion system translocated from the bacteria into the cytoplasm of the cell. They often attain the lamina propria, inhabiting inflammatory cells there, from which organisms ultimately reach the systemic circulation. Many human infections are acquired by drinking raw milk, or from other animal foodstuffs, especially poultry products. *Chickens* are common asymptomatic shedders of *C. jejuni*; *C. coli* comes more commonly from *swine*.

C. jejuni has been associated with diarrhea characterized by the presence of blood and mucus in some dogs, despite the fact that it can often be isolated from a high proportion of asymptomatic animals. It has also been isolated from dogs with parvoviral enteritis and other viral infections; pre-existing infections may predispose to the development of pathologic effects of *C. jejuni*. The role of *Campylobacter* as a significant primary pathogen in dogs has been demonstrated in a few cases. These usually involve communal housing situations and often young dogs. *C. jejuni* can be implicated as the cause of lymphoplasmacytic inflammation centered on ileum and colon by ruling out other known etiologies, and demonstrating the organism in large numbers in association with the lesion. *Mild to moderate enteritis and colitis* has been described in naturally infected dogs, while in

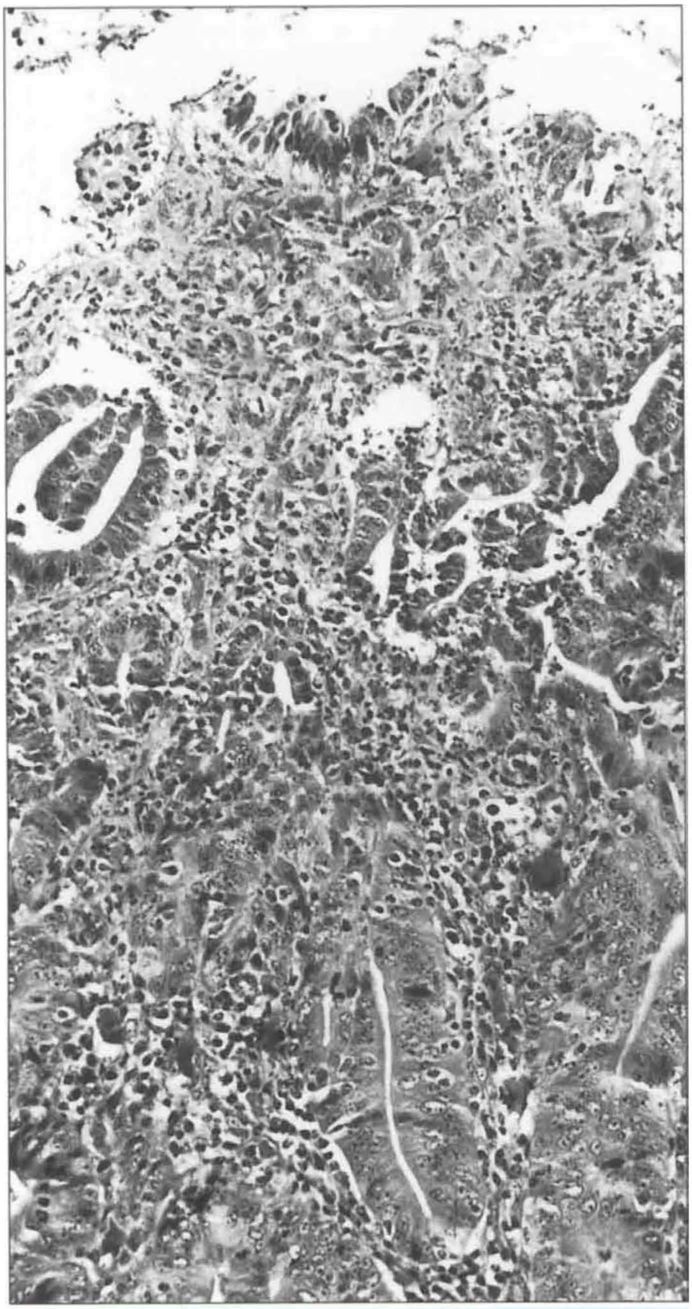

Figure 1.157 Proliferative hemorrhagic enteropathy, with superficial necrosis of mucosa associated with thrombosis of small vessels, hemorrhage, and effusion of fibrin and neutrophils, in porcine intestinal adenomatosis complex.

experimentally infected gnotobiotic and conventional dogs, lesions are limited to mild mucosal colitis. Erosive colitis has been associated with *C. jejuni* infection in mink, and was reproduced experimentally. Cats are merely asymptomatic carriers of *C. jejuni*.

"Weaner colitis" in sheep is a diarrhea of high morbidity and low mortality, reported from southeastern Australia, and associated with an unidentified *Campylobacter* species, not *C. jejuni*. At necropsy, there is abnormally fluid colonic content, but mucosal lesions are not seen; chronically affected animals may have edema and loss of body condition suggestive of enteric protein loss. Microscopically, there is erosive typhlocolitis. Goblet cells are depleted in number, and multifocal erosion, or occasionally, ulceration, of the mucosa is evident. Consistently, a layer of bacteria is present covering surface epithelial cells and in crypts. The disease has been reproduced by inoculation of the thermophilic catalase-negative *Campylobacter*-like organism, which is isolated from spontaneous cases on modified mycoplasma agar base medium.

Spirochetal colitis in swine

Swine dysentery, caused by ***Brachyspira*** (formerly *Serpulina, Treponema*) ***hyodysenteriae***, is a well-recognized production-limiting disease of swine worldwide, characterized by *large-bowel diarrhea* with mucus, blood, or fibrin in the feces. It is now recognized that at least one other spirochete, ***B. pilosicoli***, can cause colitis in feeder swine, in a disease referred to as *porcine colonic spirochetosis*.

Swine dysentery occurs as a highly infectious disease, mainly of weaned pigs. As long ago as 1924, swine dysentery was known to be experimentally transmissible by dosing young pigs with colonic contents from affected pigs. *B. hyodysenteriae* is a gram-negative, anaerobic but oxygen-tolerant, *spirochete*, 6–9 μm long and 0.4 μm in diameter. It produces strong beta hemolysis on blood agar plates. The organism is motile, moving in serpentine fashion; it is loosely coiled and has 7–13 periplasmic flagella. Originally thought to have a very narrow host range, *B. hyodysenteriae* has also been associated with necrotizing typhlocolitis in rheas.

Swine dysentery can be reproduced by feeding pure cultures of *B. hyodysenteriae* to specific-pathogen-free and conventionally reared swine. Experimental reproduction of the disease in gnotobiotic pigs requires the presence of anaerobic bacteria indigenous to the normal colon, along with *B. hyodysenteriae*. There is apparently a *synergistic action between the spirochete and other anaerobes*, mainly *Bacteroides* and *Fusobacterium*. Several studies have documented the importance of a diet low in fiber and high in rapidly fermentable carbohydrates for the successful establishment and pathogenicity of *B. hyodysenteriae*.

The **pathogenesis** of swine dysentery is still incompletely understood. The only virulence factor consistently associated with

B. hyodysenteriae is the production of hemolysin, and how or whether it contributes to disease is unclear. Other potential virulence attributes await definitive correlation with severity of disease.

B. hyodysenteriae colonizes the mucus on the mucosal surface, in the lumen of colonic glands, and in goblet cells. Lesions, including exfoliation of surface epithelium, are associated with the presence of *large numbers of spirochetes and other anaerobic bacteria on the mucosa.* By in situ hybridization, large numbers of *B. hyodysenteriae* can be seen colonizing the mucus layer, the surface epithelium, and the crypts. Their association with epithelium appears random. Attachment of spirochetes to host cells has not been observed in vivo, and invasion is not essential for epithelial loss to occur. When spirochetes invade surface epithelial cells, they appear to do so through lateral membranes, and do not attach to and penetrate the luminal membrane. *Brachyspira* do not usually invade beyond the epithelial cells. The factors responsible for local necrosis or exfoliation of superficial epithelium in *B. hyodysenteriae* infection are unknown. However, the suite of associated lesions – hyperplasia of the proliferative compartment in crypts; goblet-cell hyperplasia; premature exfoliation of surface epithelium between crypt openings; and an associated mixed mucosal inflammatory cell infiltrate – is reminiscent of the changes in cell-mediated villus atrophy in the small intestine, raising the possibility that the lesion is at least in part immune-medicated.

The result is *mucosal colitis,* characterized by superficial erosion, with hyperplasia of cells in colonic glands, hypersecretion of mucus, and a mixed inflammatory infiltrate in the lamina propria. Thrombosis of capillaries and venules in the superficial areas of the colonic mucosa and in the gastric fundic mucosa (gastric venous infarction) is probably due to absorption, through the damaged mucosa, of endotoxin released by gram-negative bacteria.

The diarrhea in swine dysentery is due to *malabsorption of fluids and electrolytes in the colon.* This presumably results from damage to the superficial colonic epithelium. The normal colon of the pig has tremendous absorptive capacity. Interference with colonic absorption results in severe diarrhea and dehydration. Active fluid secretion by the colon, associated with bacterial enterotoxins, does not occur in swine dysentery. Fluid and electrolyte transport are normal in the small intestine.

There is usually an introduction of pigs, presumably *carriers,* into a herd prior to an outbreak. Once established in a herd, the infection tends to remain *enzootic,* and although treatment can effect a rapid clinical amelioration, it may not be curative, and relapses at greater or lesser intervals can occur. Apparently infection is not followed by a substantial immunity, although individual carrier pigs are resistant to further challenge with *B. hyodysenteriae* after recovery from disease. The morbidity may reach 90% and mortality 30%.

The disease occurs in pigs of all ages over ~2–3 weeks old, but particularly in pigs 8–14 weeks of age. Once initiated, it spreads rapidly by pen contact. The disease is initially febrile, but, with the onset of diarrhea, fever tends to subside. The initial diarrheic feces are thin, semisolid, and without blood or mucus; it is usually only after 1–2 days of diarrhea that blood and mucus appear in the feces. Some pigs die peracutely without showing diarrhea, and many that show diarrhea do not have dysentery, but pass feces which contain much mucus.

Grossly, pigs that die of swine dysentery are usually gaunt with a contracted abdomen; the eyes are sunken; and there may be blue discoloration of the abdominal skin. Associated lesions may include pericardial serous effusion, and intense congestion of the gastric mucosa due to venous infarction. The intestinal lesions, especially in young pigs dying acutely, and those that have been treated, can be easily overlooked because the mucosal colitis may be mild, patchy, and often more catarrhal than fibrinous.

In typical cases, dehydration gives a semiopaque ground-glass appearance to the serosa, and the wall of the cecum and colon is thickened. The colonic content in these cases is usually scant, and porridge-like dirty gray to red-brown and greasy in appearance. The mucosa, with patchy foci of light fibrin exudation, has the velvety thickening of catarrhal secretion (Fig. 1.158A). The most severe lesions approach those of salmonellosis in the extent and severity of fibrin effusion. The production of mucus in swine dysentery becomes copious in many chronic cases due to *remarkable goblet-cell hyperplasia.*

The earliest **microscopic lesions** are characterized by discrete areas of epithelial erosion on the superficial mucosa. Thin layers of fibrinocellular exudate cover the eroded areas. In more advanced cases, these areas become more diffuse but remain merely erosive, and exudation is more copious (Fig. 1.158B). There may be minor bleeding from small vessels in eroded mucosa. Fibrin thrombi are evident in the capillaries and venules of the superficial lamina propria. There is usually some edema of the lamina propria, submucosa, and serosa. Initially mucus is expelled from the basilar portions of the crypts (Fig. 1.159A). In concert with the increased turnover of epithelial cells associated with the superficial erosion, there is hyperplasia of cells deeper in the glands. The crypts are elongated, lined by proliferative basophilic epithelial cells that have large nuclei, and few differentiated goblet cells (Fig. 1.159B). Often, crypts subsequently become dilated and contain necrotic debris. Others have marked goblet-cell hyperplasia, and copious mucus production.

Porcine intestinal spirochetosis is caused by ***Brachyspira* (*Serpulina*) *pilosicoli*** (formerly *Anguillina coli*), which differs from *B. hyodysenteriae* in that it is only weakly beta-hemolytic and is capable of hippurate hydrolysis. *B. pilosicoli* has a wide host range, having been isolated from a number of other species of animals with lesions of intestinal spirochetosis, and it may be zoonotic.

Porcine intestinal spirochetosis has been seen in most major swine-producing areas of the world. The disease is characterized by *generally transient watery to mucoid diarrhea without blood.* Depression of weight gain is a significant clinical finding. Grossly, there may be mesocolonic edema, and the large intestine has abundant watery contents, with variable degrees of mucosal erosion. In more severe cases there may be a diphtheritic membrane.

Virulence attributes of *B. pilosicoli* are poorly defined, but motility and chemotaxis for mucus may be important. The organism is capable of polar attachment by one end of the organism to the apical membrane of enterocytes, resulting in displacement or effacement of microvilli. Histologically, spirochetes can often be seen as a dark fringe or "false brush border" on the luminal surface early in infection (Fig. 1.160). The organism can invade paracellularly, especially at the extrusion zone between colonic crypt units, attaining the lamina propria, where it may be phagocytosed by macrophages; ultimately, in some cases, it reaches draining lymph nodes. A mixed inflammatory infiltrate, including lymphocytes and macrophages, is present in the lamina propria between crypts. Later in infection, when epithelial attachment is rare, the organism persists in crypt lumens and mucus in goblet cells, and goblet-cell hyperplasia is evident, along with inflammatory cells and cellular debris in gland

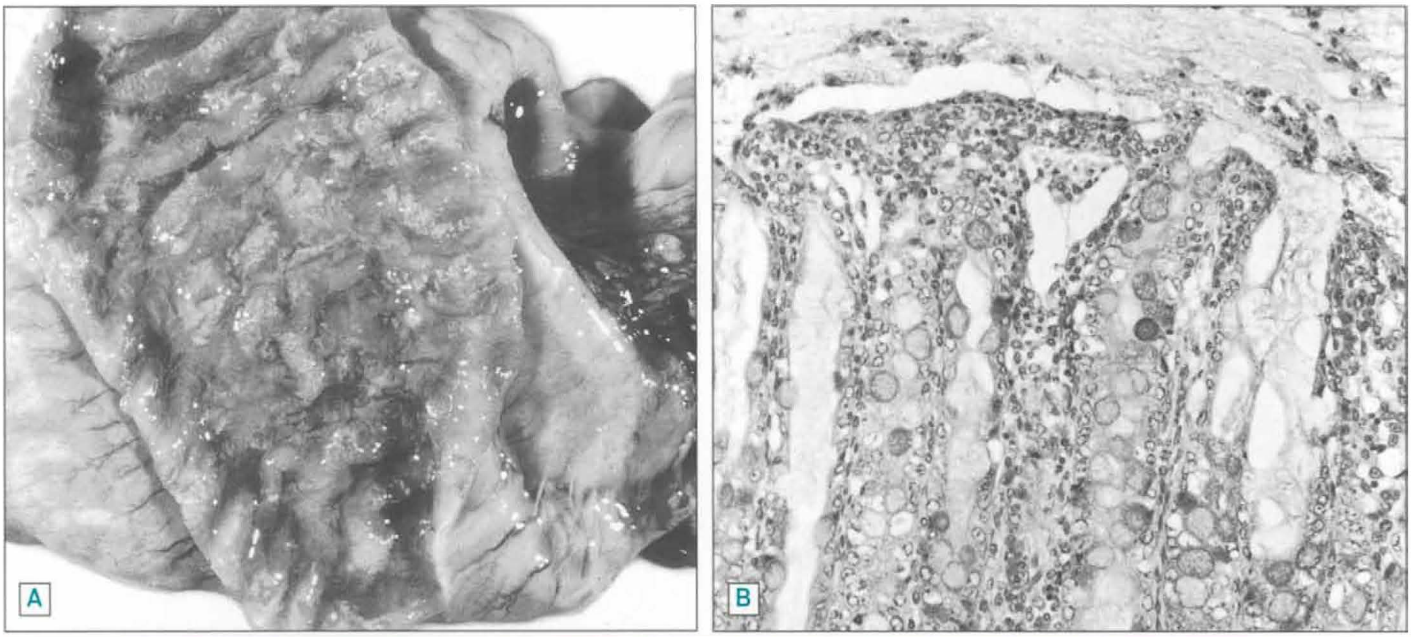

Figure 1.158 Swine dysentery. **A.** Patchy fibrinocatarrhal exudate on the colonic mucosa. **B.** Flattened and exfoliating epithelium on mucosal surface, and edema of superficial lamina propria. Mucus in glands and on surface, mixed with neutrophils and exfoliated epithelium.

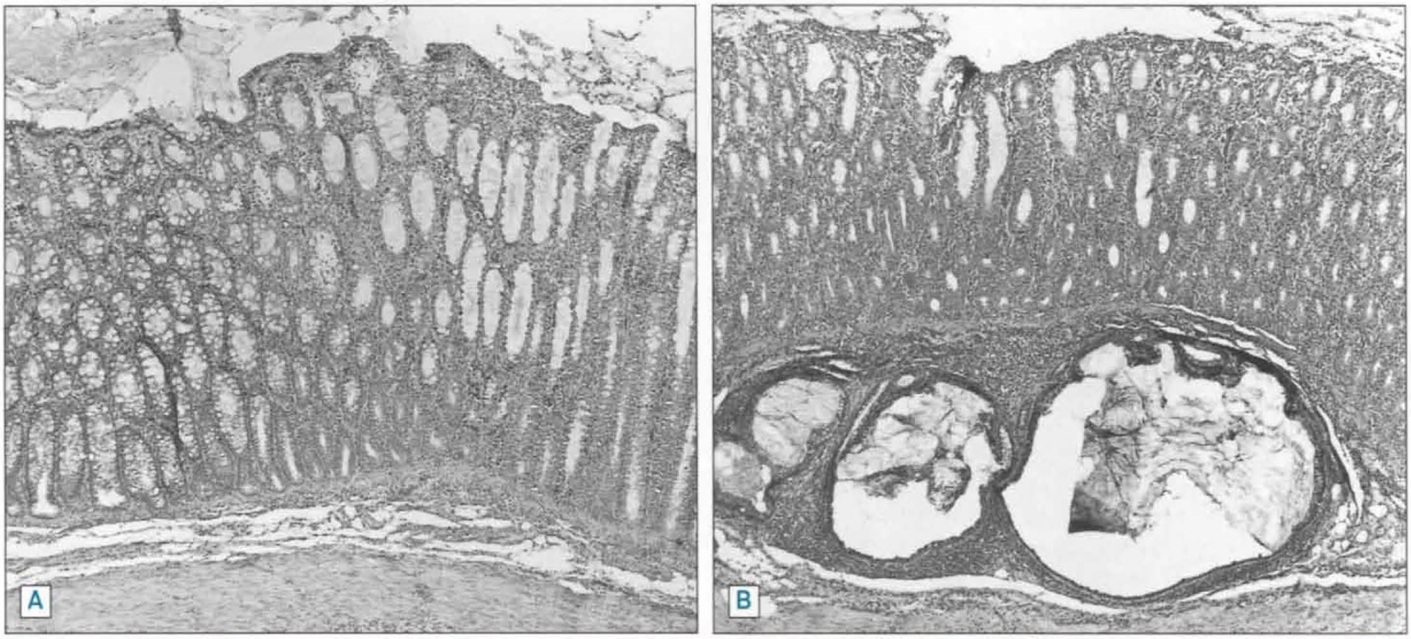

Figure 1.159 Swine dysentery. **A.** Hyperplastic glands with few goblet cells adjacent to mucosa with normal density of goblet cells. Copious mucus on surface. **B.** Hyperplastic glandular lining virtually devoid of goblet cells; "colitis cystica profunda," or herniation of mucous glands into submucosal lymphoid tissue.

lumens. The diarrhea and ill-thrift characteristic of infection may be related to loss of absorptive function, secondary to disruption of the brush border of enterocytes, and increased exfoliation of poorly differentiated cells at intercrypt extrusion zones, perhaps with enteric loss of plasma protein.

In **dogs, colonic spirochetosis** with mucosal colitis has also been described, in association with *B. pilosicoli* and perhaps with other *Brachyspira* spp., but a causal relationship has not been established experimentally.

Diseases associated with enteric clostridial infections

Most of the important enteric clostridial diseases occur in herbivores and are caused by one of the five toxigenic types of ***Clostridium perfringens***. Enteritis in dogs is associated with *C. perfringens* and ***C. difficile***, and the latter agent is implicated in fibrinous enteritis, especially in horses, neonatal pigs, and dogs. ***C. piliforme*** (formerly *Bacillus piliformis*) causes Tyzzer's disease, characterized by enteritis and colitis, usually with multifocal necrotic hepatitis and myocarditis, in many animal species. ***C. chauvoei*** may affect the tongue and the smooth muscle of the lower alimentary tract, causing blackleg-like myositis (see Vol. 1, Muscle and tendon), while ***C. septicum*** causes clostridial abomasitis (braxy) in sheep and calves, discussed in the section on Stomach and abosmasum, above. ***C. botulinum*** causes toxicoinfectious botulism in horses, and by ingestion of toxin, botulism in cattle (see Vol. 1, Nervous system).

Table 1.2 Relationships among the five types of *Clostridium perfringens* A–E and the four major exotoxins (alpha, beta, epsilon, and iota)

	Toxin			
C. perfringens	Alpha	Beta	Epsilon	Iota
Type A	++	–	–	–
B	+	++	+	–
C	+	++	–	–
D	+	–	++	–
E	+	–	–	++

++ = significant amount of toxin, + = small amount, – = none detected.

There are five types of *C. perfringens*, designated *A–E*, which are differentiated on the basis of their production of the *four major antigenic exotoxins*, which, along with an enterotoxin, are the most significant virulence attributes of *C. perfringens* in the gut. *The major exotoxins are alpha, beta, epsilon, and iota*; the relationships among the five types and the four toxins are illustrated in Table 1.2.

Eight minor toxins are produced by *C. perfringens*, and some of these may be useful in identification of types and in division of types A, B, and C into varieties. Genetic evaluation of clostridial species may ultimately also provide more specific classification. There is not always a clear distinction among the different types of *C. perfringens*. Some strains lose their ability to produce one or more of their toxins when stored or cultured, and this complicates the identification of isolates and the assessment of their significance in disease outbreaks.

The **alpha toxin** is a lecithinase that acts on cell membranes, producing hemolysis or necrosis of cells. The **beta toxin** is a pore-forming toxin that induces a variety of neurologic effects; it appears to have a paralyzing effect on the intestine. The **epsilon toxin** is produced during active growth, as an inactive prototoxin that is activated by enzymic digestion. In culture, the appropriate enzymes (the minor toxins kappa and lambda) may be produced by the organism; in the intestine, trypsin is an effective activator. The **iota toxin** is also elaborated as a prototoxin and activated by proteolytic enzymes either in culture (lambda toxin) or in the intestine; it increases capillary permeability. **Kappa toxin** is a collagenase, and **lambda** a nonspecific proteinase. An additional toxin, **beta$_2$**, which, despite its name, is not related to beta toxin, has been implicated in enteric disease in swine and in typhlocolitis in horses caused by *C. perfringens* types A and C. Its pathogenicity is uncertain, but it may at least act as a virulence marker. Other minor toxins include **mu**, a hyaluronidase, and **delta**, a hemolysin.

Clostridial diseases of the intestine are often called **enterotoxemias**. Disease produced by *C. perfringens* type D, whose epsilon exotoxin is elaborated in the intestine but exerts its important effects on distant organs such as brain and kidney, is a true enterotoxemia. The hemolytic disease attributed to type A is also an enterotoxemia, but *in general the other types produce local intestinal lesions*. The production by some types of *C. perfringens*, especially type A, of an **enterotoxin**, distinct from the classical exotoxins, is potentially confusing. This enterotoxin is only elaborated by sporulating cells and is released upon lysis of vegetative cells. It is produced by all strains, but is not effective in type E. This enterotoxin is not involved in the pathogenesis of enterotoxemia ("*pulpy kidney disease*") caused by type D. Most significant in food poisoning by type A strains in humans, it has also been associated with antibiotic treatment-related diarrhea and infantile diarrhea. It is activated by proteolysis and alters plasma membrane permeability of the mammalian cell.

The **pathogenesis** of enteric infection with *C. perfringens* and *C. difficile* requires a *change in the enteric microenvironment* favorable to massive expansion of luminal populations of clostridia. Such changes may include a change in feed, abnormally nutrient-rich digesta, antibiotic therapy, altered pancreatic exocrine function or trypsin inhibitors, reduced motility, and primary infections with agents such as *Canine parvovirus*, or coccidia in piglets and chickens. These clostridia produce disease in thee general ways: (1) *local necrotizing effects of toxin* on the mucosa, causing hemorrhagic, fibrinous, or necrotic enteritis; (2) *secretory effects of locally acting enterotoxin*, causing diarrhea and minor mucosal lesions; or (3) *systemic absorption of (entero) toxin*, with effects at sites distant from the gut.

Alpha toxin produced by *C. perfringens* type A and beta toxin produced by types B and C probably account for the *severe mucosal necrosis and/or hemorrhage* evident in these infections. Bacteria alone are not pathogenic; exotoxins are required to induce disease. Beta toxin is trypsin-labile, and circumstances such as low enzyme levels in young animals, very high levels of toxin, or trypsin inhibitors could be important. Sows' colostrum contains a trypsin inhibitor, but it is not known if colostrum in other species possesses this factor. "Pig bel," a necrotizing jejunitis of humans in New Guinea that is probably caused by the beta toxin, has been causally related to consumption of heat-stable trypsin inhibitors in sweet potatoes. Naturally occurring protease inhibitors in soybeans appear to have a similar effect in guinea pigs. Intraduodenal inoculation of *C. perfringens* type C in combination with soybean flour produces acute fatal hemorrhagic enterotoxemia in lambs.

C. difficile produces two exotoxins, A, which is an enterotoxin, and B, which is a cytotoxin. Tissue damage is probably due to the effects of both toxins, which glycosylate and inactivate Ras GTPases, disabling signaling pathways in the cell. As well, they glycosylate Rho, which regulates the actin cytoskeleton; it condenses, tight junctions open, cells round up, and undergo apoptosis. They also cause release of proinflammatory mediators, attracting neutrophils, and activate secretion stimulated by the enteric nervous system. Hence, disease is characterized by fluid intestinal content, with patchy areas of colonic epithelial necrosis, through which neutrophils exude into the lumen, producing a so-called "volcano" lesion. Although not all isolates of *C. difficile* are toxigenic, over 20 toxinotypes or ribotypes have been described, based on sequence variations in the genes for the A and B toxin molecules, while 14 serotypes are recognized. Molecular epidemiologic investigation may permit associations of toxinotype with virulence.

C. piliforme, the cause of Tyzzer's disease, as an obligate intracellular agent infects epithelial cells, causing necrotizing and inflammatory lesions. The pathogenesis of Tyzzer's disease is not clearly dependent on toxin production, though some strains do produce cytotoxic proteins.

Diagnosis of disease due to the toxin-producing clostridia is dependent on demonstration of toxin or enterotoxin in gut content or feces of affected animals, by the most specific test available. While the presence of large numbers of a particular type of *C. perfringens* is suggestive of involvement with disease, this organism is commonly present in the gut in a variety of circumstances, where it cannot be implicated as an etiologic agent.

Clostridium perfringens type A

C. perfringens type A is the *most common of the five types* and is the only one associated with the microflora of both soil and intestinal tract; it may be part of the normal intestinal microflora of domestic livestock species. Its major toxin is the *alpha toxin*; it also produces beta$_2$ toxin and the enterotoxin.

This is one of several clostridia that produce *gas gangrene* in humans and animals. The production of gas gangrene in wound and puerperal infections is probably a composite effect of the major and minor toxins elaborated by the organism. The necrotizing and hemolytic activity of the alpha toxin is assisted by the collagenase and hyaluronidase that disrupt connective tissues and permit the infection to spread. It is also associated with *alimentary syndromes* in domestic animals, including enteritis in foals; enterocolitis in horses; necrotizing enterocolitis in neonatal piglets; enterotoxemia and hemorrhagic enteritis in lambs and neonatal calves; diarrhea, and hemorrhagic enteritis in dogs; as well as necrotic enteritis in chickens. Type A has been suspected of causing disease in cattle but proof is often lacking. Calves inoculated intraruminally with *C. perfringens* type A developed anorexia, depression, bloat, and diarrhea and some of these calves died. Lesions included variable degrees of abomasitis and abomasal ulcers, discussed more fully with gastritis.

In **foals** infected with *C. perfringens* type A, lesions have been more localized to small intestine, the mucosa of which was dark purple. Microscopic lesions were confined to the gut, mainly the small intestine, and were characterized by marked diffuse necrosis of the mucosa. The remnants of necrotic villi were covered by large numbers of gram-positive rods consistent with clostridia. There was also marked hyperemia and hemorrhage of the lamina propria, submucosa and subserosa without a significant leukocytic reaction. Intravenous inoculation of *C. perfringens* type A in ponies resulted in acute colic and hemorrhagic gastroenterocolitis. The syndrome of adult equine clostridial colitis is covered below, in the section on Other clostridial diseases.

C. perfringens type A has been associated with white scours in suckling **pigs** and diarrhea in feeder pigs, although this association is not commonly recognized. The pigs had necrotizing enterocolitis, villus atrophy, and serositis, and enterotoxigenic strains may be associated with the syndrome.

A very rare disease of **calves** and **lambs** characterized by *acute intravascular hemolysis* is also associated with type A infections. Affected animals may be found dead or moribund, and jaundice and hemoglobinuria may be evident clinically. At autopsy, icterus, anemia and other changes of severe, acute, intravascular hemolysis are prominent. Severe diarrhea may occur in calves but enteric lesions are likely to be obscured by rapid autolysis. This hemolytic disease must be distinguished from other causes of acute intravascular hemolysis such as leptospirosis, bacillary hemoglobinuria caused by *C. novyi* type D (*haemolyticum*), and chronic copper poisoning. Presumably the hemolytic effect of the exotoxin is responsible for the intravascular hemolysis. Given that type A strains are commonly found in the intestines of ruminants, and that alpha toxin given intravenously is destroyed rapidly, it is apparent that there must be complex pathogenetic requirements for the development of this disease. The pathogenesis may be somewhat analogous to that of enterotoxemia caused by type D, which is discussed below.

Strains of *C. perfringens* type A, some determined to be enterotoxin-secreting, have been associated with diarrhea, sometimes bloody, in dogs. **Hemorrhagic canine gastroenteritis** (canine gastrointestinal hemorrhage syndrome) is a sporadic, peracute, hemorrhagic gastroenteritis, associated in some cases with *C. perfringens* type A, though in other cases the type involved has not been identified. Dogs with the peracute hemorrhagic disease are often found dead lying in a pool of bloody excreta; sometimes hemorrhagic diarrhea is noted prior to death. Autopsy reveals hemorrhagic enteritis and colitis (Fig. 1.161), and sometimes hemorrhagic gastritis is present. Colonic lesions tend to be more severe. Microscopically there is hemorrhagic necrosis of the gastrointestinal mucosa, which extends from the luminal surface into the mucosa. Numerous clostridia may line the necrotic intestinal structures or be distributed through the detritus, but they do not invade the intact tissue (Fig. 1.162). Recurrent diarrhea, sometimes bloody, has been associated with enterotoxin-secreting type A strains. Multiple serotypes of clostridia have been associated with nosocomial, usually nonfatal, cases of diarrhea in dogs. *C. perfringens* enterotoxin has been demonstrated twice as frequently in hospitalized dogs with diarrhea compared to controls without diarrhea.

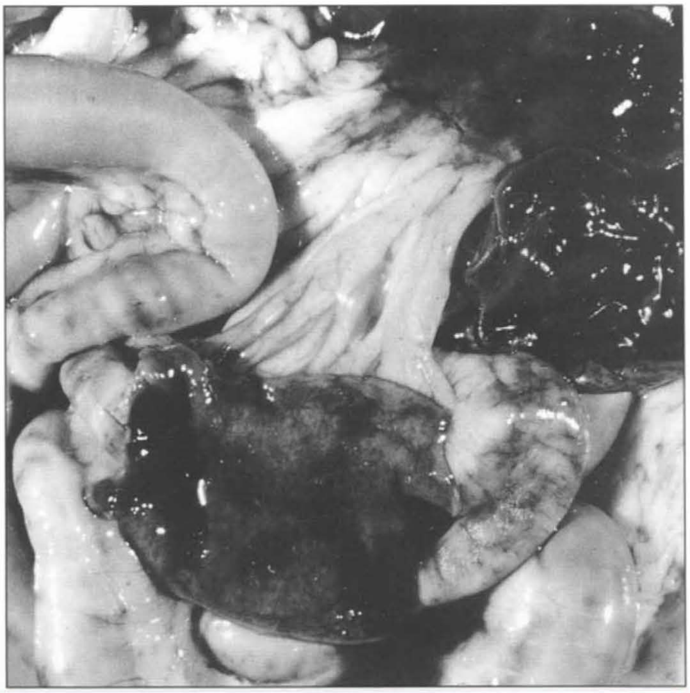

Figure 1.161 Hemorrhagic enteritis in a dog with **canine gastrointestinal hemorrhage syndrome**, associated with *Clostridium perfringens*.

Hemorrhagic bowel syndrome has been described in mainly *dairy cattle* in the USA. Affected cattle become acutely ill, with bloating, gut stasis, and melena. The lesions relate to necrohemorrhagic enteritis with extensive intraluminal hemorrhages and the lumen may contain large amounts of clotted blood (Fig. 1.163). The condition is associated with very high mortality. *C. perfringens* is present in large numbers in the feces from affected animals, and there may be an association with *C. perfringens* type A, though whether there is a causal relationship is uncertain.

Clostridium perfringens type B

Clostridium perfringens type B is reported from Europe, South Africa, and the Middle East, but not from North America and Australasia. It causes "*lamb dysentery*," usually in lambs up to ~10–14 days of age, dysentery in calves of approximately the same age, and dysentery in foals within the first few days of life.

In **lambs**, death may occur without premonitory signs, but there is usually abdominal pain, especially when animals are forced to rise, and passage of semifluid dark feces mixed or coated with blood. The abdomen is often tympanitic. A more chronic form in older lambs, which among other diseases is known as "pine" in England, is characterized by unthriftiness and depression, reluctance to suckle, and a peculiar stretching when the animal rises; such cases are reputed to respond well to specific antiserum.

Typical lesions are usually present, although in exceptional peracute cases they may be indistinct. The first impression on opening the abdominal cavity is that there is mesenteric torsion, a not uncommon accident in young lambs. The characteristic lesion is *extensive hemorrhagic enteritis*. The peritoneal cavity often contains a small amount of serous or blood-stained fluid.

In cases with more severe and deeply penetrating mucosal ulcerations, there may be overlying peritonitis with red fibrin strands on the local mesentery and intestinal adhesions. On the mucosal surface, they are irregular but well defined by a sharp margin and rim of intense hyperemia, and they contain a yellow necrotic deposit; they may coalesce to form extensive areas of necrosis. Usually the intestinal contents are blood-stained and may appear to be composed of pure blood, but in lambs that live for 3–4 days, there may be little or no hemorrhage evident. Histologically the wall of the intestine is hemorrhagic, and the areas of necrosis extend deeply into the mucous membrane, in some cases penetrating to the external muscle layers and serosa. There are large numbers of typical bacilli in the necrotic tissue, but few inflammatory cells.

The lesions present in other organs are those of *severe toxemia*. The liver is usually pale and friable, but may be congested. The spleen is normal or slightly enlarged and pulpy. The kidneys may be enlarged, edematous, pale, and soft from toxic degeneration. The pericardial sac contains abundant clear gelatinous fluid, the myocardium is pale and soft, and hemorrhages beneath the serous membranes of the heart are almost constant. The lungs are often slightly congested and very edematous.

The disease in **calves** caused by type B *C. perfringens* closely resembles that in lambs, usually affecting sucklings less than 10 days of age, with a course of 2–4 days characterized by prostration and dysentery. Older calves up to 10 weeks of age are sometimes affected. It appears that calves are more likely to recover, albeit slowly, than are lambs. The intestinal lesion is acute hemorrhagic enteritis with extensive mucosal necrosis and patchy diphtheritic membrane formations, especially in the ileum.

Although both "lamb dysentery" and "hemorrhagic enterotoxemia" occur in pastured animals, they are most serious in animals that are confined.

Clostridium perfringens type C

Clostridium perfringens type C is present worldwide, and causes disease in adult sheep and goats, feeder cattle, and in neonatal lambs, calves, foals, and pigs.

In adult **sheep**, *C. perfringens* type C causes "*struck*," a disease of pastured animals that has a mortality rate of 5–15% in some areas. The disease in adult **goats** is probably similar in most respects to that in sheep. Death usually occurs suddenly with terminal convulsive episodes, but some animals, with infections not so peracute, stand in a straining position that probably indicates acute abdominal pain. In adult sheep, diarrhea or convulsions do not occur.

At necropsy, the peritoneal cavity contains up to 3 liters of clear, pale-yellow fluid that clots on exposure to air and that becomes stained with hemoglobin if necropsy is delayed. The small intestine is intensely hyperemic, either in patches or along most of its length, and in the zones of hyperemia there may be ulcers that may attain several centimeters in size. Ulcers are usually present, mostly in the jejunum, and are surrounded by a zone of hyperemia with a deep red base, although in some the necrotic material is dark green and adherent. The large intestine is normal. The primary intestinal lesion is superficial mucosal necrosis that advances more deeply, with a peripheral leukocytic reaction, congestion, and hemorrhage. The organisms are limited to the necrotic tissue.

The disease in feedlot **cattle** is similar to "struck." Animals are found either dead or moribund, and congestion and hemorrhage of the gastrointestinal tract are prominent. The jejunal and ileal content are bloody with fibrin clots and necrotic debris. Excessive straw-colored pleural and pericardial fluid and petechiation of epicardium and endocardium are present. Autolysis and postmortem bloat occur rapidly, and differentiation from ruminal tympany and other clostridial diseases is necessary.

The diseases caused by type C in **lambs**, **calves**, **pigs**, and **foals** are very similar and will be discussed together. Affected animals are usually young sucklings, which contract the disease within the first few days of life, often within the first 12 hours if they have been confined. Foals and most clinically affected lambs die, but in calves and pigs, subacute disease may occur in which there is diarrhea and unthriftiness.

Often, affected animals are found dead. Sick lambs may shiver, show abdominal pain, abdominal distension, dysentery, and prostration, and die in 12 hours or less. Sick calves show abdominal pain, some show diarrhea of sudden onset, and death is preceded by spasmodic convulsions.

Similar lesions occur at autopsy in all species, but may be less severe in lambs. In lambs, the intestinal changes vary from catarrh to acute hemorrhagic enteritis with mucosal necrosis that, like lamb dysentery, suggests strangulation. *The most prominent changes occur in the jejunum and ileum*, the lumen of which may contain *free blood*, which forms a clotted cast in fresh cadavers. Sometimes there is merely acute hyperemia of a segment of jejunum with edema of the wall, scant creamy intestinal content, and a few small ulcerations of the mucosa. The peritoneal cavity contains a small quantity of serous blood-stained fluid, and the local mesentery and peritoneum are often mildly inflamed, hyperemic, and bear red strands of fibrin. The mesenteric nodes are enlarged, wet, and congested. There is usually excess pericardial fluid and pulmonary interstitial edema. Ecchymoses on the serous membranes are nearly constant, and in a few cadavers all tissues, but especially the meninges and brain, are liberally sprinkled with small hemorrhages. These are sites of *bacterial embolism*, due to a massive terminal bacteremia by *C. perfringens*.

C. perfringens type C causes *hemorrhagic enteritis* of suckling **piglets** in many parts of the world. Rarely, epizootics occur in 2–4-week-old pigs and in weaned pigs. The disease occurs as epizootics in affected herds and regions, and may then remain enzootic. Poor hygienic conditions, overcrowding, and antibiotic treatment are thought to be predisposing factors in some outbreaks. Affected animals pass blood-stained feces in the terminal stages and there is marked hyperemia of the anus just prior to death. The predominant lesions occur in the small intestine, especially the jejunum, but the cecum and spiral colon are often involved, and occasionally lesions are confined to the large intestine. Lesions are similar in all areas, and in acute cases consist of *intestinal and mesenteric hyperemia, extensive necrosis of the intestinal mucosa, and blood-staining of the contents* (Fig. 1.164). There may be emphysema of the intestinal wall, which becomes fragile. Mesenteric lymph nodes are red, and sanguineous peritoneal and pleural fluid is present. Fibrinous intestinal adhesions may develop.

Microscopically, the necrotic process extends deeply and sometimes penetrates the muscularis mucosae. Numerous typical bacilli line up along the margin of involved villi and inhabit the necrotic tissue. Older pigs may not show intestinal hemorrhage but do have mucosal necrosis, and peritoneal and pericardial effusion.

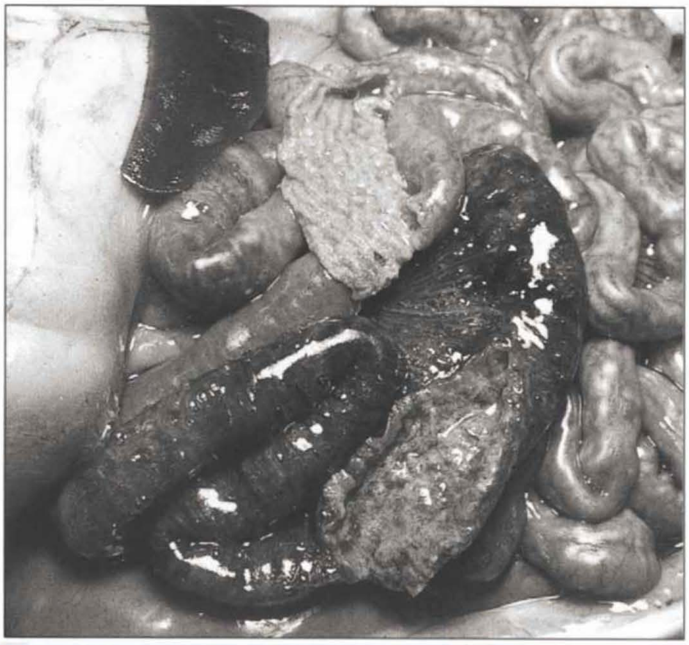

Figure 1.164 Necrotizing enteritis in a piglet, caused by ***Clostridium perfringens* type C** infection. (Courtesy of M. Bergeland.)

The disease due to *C. perfringens* type C in **foals** has been reported from the USA, Canada, and Australia. It usually occurs in foals <4 days of age. Typical clinical signs include weakness, yellow to brown watery diarrhea or dysentery, colic, and dehydration. Affected foals usually die in <24 hours. Macroscopic lesions are those of *acute hemorrhagic necrotizing enteritis*, usually in the distal two-thirds of the small intestine, although in some cases most of the small and large intestine may be affected. The microscopic lesions are similar to those described previously in the other species. In foals, the lesions must be differentiated from those seen with other clostridia.

Clostridium perfringens type D

Enterotoxemia (*"pulpy kidney" disease, "overeating" disease*) caused by the toxins of *Clostridium perfringens* type D is an important disease of *sheep and goats* with a worldwide distribution. It occurs occasionally in calves, and very rarely in horses. *Focal symmetrical encephalomalacia* (FSE) of sheep is caused by the epsilon toxin of type D. Epsilon toxin binds to receptors on endothelial cells, especially in the brain and renal tubular epithelial cells, resulting in changes described below.

In most **lambs** and **calves** with type D enterotoxemia, the course is peracute and the animal is found dead. Lambs and calves may die in a few minutes in convulsions, and calves often bawl as from severe pain. Animals that survive longer may show drooling, rapid breathing, hyperesthesia, straining, opisthotonos, and terminal coma or convulsions. In adult sheep, in which the clinical course may be several days, diarrhea with the passage of dark semifluid feces is common. In sheep, subacute cases may occur and be followed by recovery. In some such cases, neurological signs may develop. These include blindness, ataxia, head pressing, and caudal paraparesis; the lesions of FSE are present in the brains of such cases. On other occasions these lesions are not preceded by signs of enterotoxemia. In **goats**, signs of enterotoxemia similar to those in sheep and lambs may be seen, but chronic enterotoxemia characterized by abdominal distension and pain, depression, and dark-green diarrhea may persist for several days to weeks. Nervous signs do not occur.

Lambs fed large amounts of grain or concentrate are highly susceptible – thus the synonym "overeating disease." The manner in which overeating leads to clostridial enterotoxemia is complex. Cultures of *C. perfringens* type D given orally are largely destroyed in the rumen and abomasum. The few organisms that reach the intestine proliferate rapidly and produce toxin, but when the numbers are no longer reinforced by escapees from the stomachs, they are rapidly cleared from the intestine by peristalsis.

The critical factor is almost certainly the *presence of starch in the small intestine*, providing a suitable substrate for these saccharolytic bacteria, and they proliferate to immense numbers – perhaps more than 10^9 organisms per gram of intestinal contents – and produce correspondingly large amounts of toxin. When the animal is suddenly provided with excessive quantities of food, or food of a different type, there is a delay before the ruminal flora can adapt. In this period, undigested or partially digested food may escape into the intestine, and if starch is there, as it is with overeating on grain, *C. perfringens* type D is likely to take advantage of it. The epsilon prototoxin is activated by digestive enzymes, especially the combination of trypsin and chymotrypsin.

A high concentration of epsilon toxin facilitates its own absorption from the intestine, probably in part by increasing the permeability of the mucosa. Necrosis of epithelium and moderate atrophy of villi are evident in some animals with type D enterotoxemia, and it is reasonable to assume that epithelial damage precedes the facilitated absorption.

Probably the disease develops in the same way in the calf as in the sheep. The virtual confinement of the disease to calves that are overfed suggests that this is the case. The acute disease in goats likely has a similar pathogenesis but the chronic disease, with lesions confined to the intestine, appears to be caused by local effects of type D toxins.

In lambs dead of acute enterotoxemia, the carcass is usually well nourished. In those with a course of 1–2 days, there is often evidence of a dark scour about the rump. Putrefactive changes occur rapidly. Often there is excessive straw-colored pericardial fluid that clots on exposure to air and congestion and edema of the lungs that may be severe enough to produce froth in all the respiratory passages; and hemorrhage beneath the endocardium of the left ventricle. There may be hemorrhages beneath other serous membranes (Fig. 1.165) such as the epicardium, and blotchy hemorrhages beneath the parietal peritoneum are characteristic. Sometimes the liver is congested and the spleen enlarged and pulpy. There is no gastrointestinal inflammation visible at necropsy. Short lengths of the small intestine are distended with gas, and are hyperemic.

Epsilon toxin binds to receptors on distal renal tubular epithelial cells and causes selective degeneration of distal tubules in a variety of species. In experimental cases and natural cases in lambs examined immediately after death, there may be medullary congestion, hemorrhage, and tubular degeneration (Fig. 1.166). However, rapid autolysis or delayed necropsy can also produce "pulpy kidney." The renal "lesions" can be useful diagnostic aids, as are the hyperglycemia and glucosuria associated with the toxemia, if they can be detected.

In adult sheep, the lesions are the same as those in lambs, but are more consistent and more advanced, with the exception of renal autolysis, which occurs less rapidly, and less commonly progresses to the stage of "pulpiness."

Brain lesions occur in lambs with subacute enterotoxemia and these are sufficiently consistent to be of diagnostic significance. They

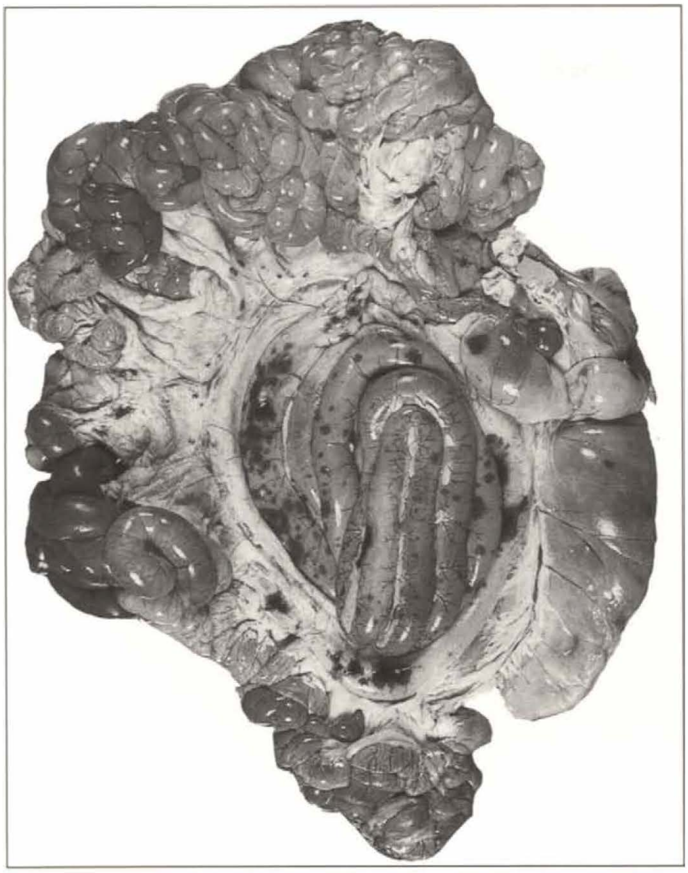

Figure 1.165 Peritoneal hemorrhages in a sheep with ***Clostridium perfringens* type D** enterotoxemia.

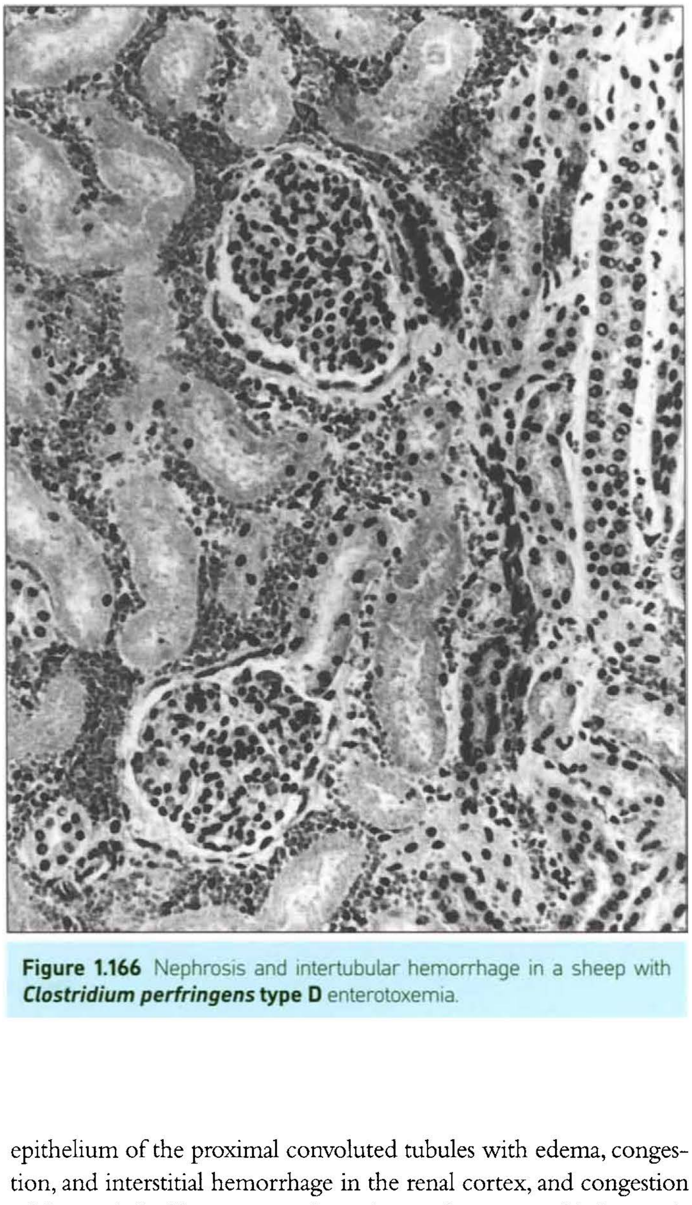

Figure 1.166 Nephrosis and intertubular hemorrhage in a sheep with ***Clostridium perfringens* type D** enterotoxemia.

develop in two patterns; each is bilaterally symmetric, hence the term **focal symmetrical encephalomalacia**. The commonest pattern involves the basal ganglia, internal capsule, dorsolateral thalamus, and substantia nigra; there are some minor variations of the pattern, but the lesions are always of the same type (Fig. 1.167). The second pattern affects the white matter of the frontal gyri, sparing only the communicating U fibers. The lesion begins with edema and the leakage of plasma and then red cells from the venules and capillaries in the affected areas. The altered permeability of the vessels is diffuse throughout the brain, sparing only heavily myelinated tracts such as the optic tracts and corpus callosum. This is well demonstrated by vital staining with trypan blue. The least change visible by light microscopy is the accumulation of protein droplets around small venules. Electron microscopically, *severe damage to vascular endothelium* is apparent and there is swelling of protoplasmic astrocytes. The foot processes around blood vessels and the processes around neurons are most severely swollen. Edema and hemorrhage lead to malacia in the affected areas.

Lesions in calves dying of enterotoxemia caused by *C. perfringens* type D may resemble those in lambs. Affected calves are usually 1–3 months of age. Splenic swelling is more common in calves than in lambs, and rapid autolysis of the kidney is not a prominent finding, as it is in lambs. However, subcapsular congestion and hemorrhage occur (Fig. 1.168), and sometimes a black clot of blood up to 1.0 cm thick forms around the kidney.

The *histologic changes* in enterotoxemia include, in addition to the brain lesions described above: mild degeneration and necrosis of the epithelium of the proximal convoluted tubules with edema, congestion, and interstitial hemorrhage in the renal cortex, and congestion of the medulla (these are autolytic changes but are useful diagnostically); superficial desquamation in the intestine with congestion, and numerous typical bacilli in the contents; congestion and hemorrhage of the spleen with disruption of reticulum; subepicardial hemorrhage and degeneration in the Purkinje network; and proteinaceous edema fluid in the lungs. All of these changes are secondary to endothelial damage produced by the epsilon toxin.

Type D enterotoxemia may be seen in both adult **goats** and kids. Four forms of the disease are recognized in goats: *peracute, acute, chronic, and subclinical.* The peracute disease is similar to that seen in lambs, and usually manifests as sudden deaths. The acute form is characterized by diarrhea and severe abdominal discomfort. Affected animals either recover or die within 2–4 days after the onset of clinical signs. The chronic form of the disease may last for a few days or weeks. Weight loss and diarrhea are its main clinical features. The principal macroscopic lesions in the acute and chronic disease are mild to severe hyperemia of the mucosa, especially of the distal small intestine, cecum, and spiral colon. The affected areas may be covered by a thin layer of fibrin. The intestinal contents are olive-green to red and mucoid. The mesenteric lymph nodes are enlarged and edematous. Hydropericardium, pulmonary edema, and "pulpy" kidneys may be seen, but are inconsistent, and brain lesions are absent.

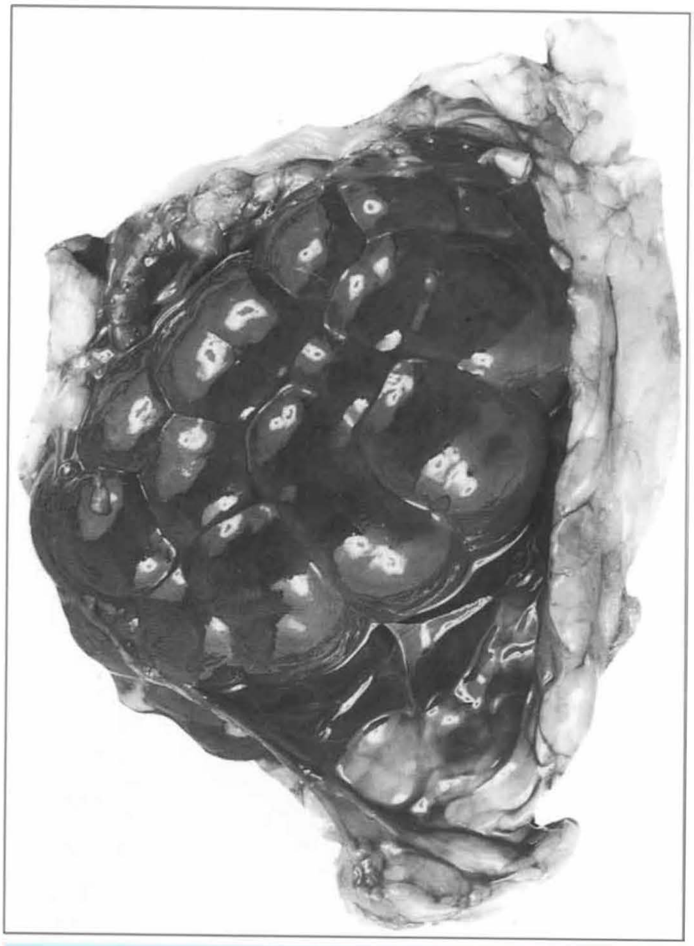

Figure 1.168 Renal cortical hemorrhage in a calf with *Clostridium perfringens* type D enterotoxemia.

In natural cases, the microscopic lesions in the small intestine vary from a mild pleocellular leukocytic reaction in the lamina propria to a mild fibrinous, or, rarely, hemorrhagic enteritis. In the latter, the tips of the villi are necrotic, eroded, and covered by fibrinocellular exudates or blood. Villus atrophy may follow. The leukocytic reaction in the lamina propria extends into the edematous submucosa. The proprial and submucosal vessels are congested. Essentially similar lesions occur in the large intestine, bearing in mind the anatomic differences. There is lymphocytolysis in the centers of the lymphoid follicles of the mesenteric lymph nodes. Lesions in the lungs and kidneys may be similar to, but are less consistent than, those seen in lambs. Cerebral edema may be present, but FSE has not been reported in goats with enterotoxemia, except after experimentally induced disease.

Experimental intraduodenal inoculation of whole cultures of *C. perfringens* type D in kids mainly results in colitis of the spiral colon. The reasons for the different manifestations of enterotoxemia in sheep and goats are unknown.

Other clostridial diseases

Clostridium difficile is a gram-positive to gram-variable inhabitant of the soil and gut. This organism causes pseudomembranous colitis in humans, often, but not necessarily, with a history of antibiotic treatment. Its role in enteric disease of animals is just emerging, and perhaps with the exception of swine, evidence in most species is associative, rather than conclusively causal. Definition of its diagnostic significance is dependent on identification of the A and B toxins in gut content or feces by tests with high sensitivity and specificity.

C. difficile is increasingly being recognized as a cause of diarrhea due to *fibrinous colitis* in **neonatal pigs**, under about a week of age, and the disease has been reproduced experimentally using pure cultures of the organism. Piglets have diarrhea, dyspnea, scrotal edema, and mild abdominal distension. Hydrothorax and characteristic, though not pathognomonic, *edema of the mesocolon* (Fig. 1.169) are evident grossly, usually in association with patchy to extensive fibrinous typhlocolitis, with yellow pasty to fluid content and feces. Microscopically, there is exfoliation and attenuation of surface enterocytes, and patchy focal erosions on the colonic mucosa, through which fibrin and neutrophils exude, producing the "volcano" lesions. Occasionally deeper necrosis of the mucosa and colonic wall may occur.

C. difficile and its cytotoxin have been demonstrated in feces of **dogs** with diarrhea. Descriptions of lesions are not available, however, since there are no necropsies or biopsies reported. However, the organism is frequently shed in feces of normal puppies and their bitches, which makes its significance difficult to interpret.

In **horses**, *C. difficile* may be incriminated in diarrheal syndromes, including *"proximal enteritis"* and *hemorrhagic enteritis* in foals, and *colitis* in horses of all ages. Diarrhea and colic have been reproduced in foals using inocula of *C. difficile* spores and vegetative cells.

Equine intestinal clostridiosis is still undergoing definition; many cases probably fall into the syndrome formerly described as "colitis X," the etiology of which has been undefined. The syndrome is one of *severe acute-to-peracute colitis*, and it is probably related to dysbacteriosis and clostridial overgrowth, instigated by antibiotic therapy, stress, or changes in feeding regimens.

The clostridia most commonly incriminated in this syndrome include beta$_2$ toxin-secreting *C. perfringens* type A and *C. difficile*. There is a positive association between the disease and the presence of *C. perfringens* enterotoxin and/or *C. difficile* toxin A. Lesions are usually confined to the large bowel. There is extensive hemorrhage and edema in the mucosa, submucosa, and mesocolon. Microscopically, full-thickness necrosis of the mucosa is associated with thrombosis of small vessels; variable numbers of bacilli may be visible in section, but the lesion is not readily differentiated from other forms of severe acute colitis, for instance salmonellosis.

Tyzzer's disease is caused by the obligate intracellular bacterium ***Clostridium piliforme***. It is an uncommon affliction of many species of mammals, among them horses, cats, and dogs, though there seem to be bacterial strain differences that determine host susceptibility. Affected animals are often very young, or appear to be immunocompromised in some way.

While the lesions are not limited to the intestinal tract, animals become infected initially through the epithelium of the ileum, cecum, and colon, where lesions may vary from subtle catarrhal to fibrinohemorrhagic. Bacilli can be demonstrated using silver stains in enterocytes, often forming characteristic "pick-up-sticks" arrays. Ultimately, in most cases they disseminate elsewhere in the body, especially to liver and myocardium, where they cause acute-to-subacute necrotic lesions. The disease is discussed more fully in Vol. 2, Liver and biliary system.

Paratuberculosis (Johne's disease)

Johne's disease is caused by ***Mycobacterium avium* subsp. *paratuberculosis*** infection. The etiologic agent of Johne's disease has been reduced to subspecies status within *M. avium* on the basis of the high (>90%) DNA homology among typical paratuberculosis strains and type strains of *M. a. avium*. The Johne's disease agent, which in culture is slow-growing, and dependent on mycobactin as a source of iron, possesses some unique cultural and biochemical traits. Genetically, a distinct difference from *M. a. avium* is the presence of the insertion sequence, **IS900**, of which *M. a. paratuberculosis* has 15–20 copies per organism.

The virulence attributes of *M. a. paratuberculosis* are poorly understood, but presumably reside in *resistance to killing in macrophages*, through inhibition of the conversion of phagosomes to phagolysosomes. The organisms proliferate in cytoplasmic vacuoles, and transmit to adjacent macrophages, expanding the population of infected cells and recruiting elements of the humoral and cell-mediated arms of the immune system to the site. Diffuse foci of granulomatous inflammation accumulate, reflected in a distinct profile of local cytokine expression. Infected macrophages traffic via lymphatics to the draining lymph nodes and via the portal venous drainage to the liver, ultimately gaining the central circulation.

The disease is most common in *domestic ruminants*, but infections by *M. a. paratuberculosis* can also be produced in pigs, and spontaneous disease occurs in a number of free-ranging and captive wild ruminants, camelids, and, rarely, in equids and captive primates. Numerous species of wild mammals, including lagomorphs, rodents, and carnivores, and several species of wild birds, are naturally infected, though not necessarily diseased. The infection can be transmitted experimentally to mice, hamsters, guinea pigs, rabbits, and macaques. A debate exists as to the role of *M. a. paratuberculosis* in the genesis of *Crohn's disease in humans*, a chronic granulomatous enteritis. *M. a. paratuberculosis* has been found in many of these cases, as detected by polymerase chain reaction of reactive fragments, but it is still undecided whether the association is causal or coincidental.

The **epidemiology and pathogenesis** of Johne's disease are best understood in cattle, and are assumed to be similar in sheep and goats. Infection is systemic, and organisms may be present in milk, semen, and urine, and may cross the placenta. However, exposure is mainly by ingestion of organisms shed in the feces. This may explain higher prevalence in dairy as opposed to beef animals. Susceptibility to infection is greatest in the first 30 days of life, although clinical disease does not usually develop in cattle until 2–5 years of age. This long incubation period has been termed "the iceberg effect" because, in any infected herd, although few animals may be showing clinical signs of Johne's disease, a much greater number are silently infected. Adults may become infected, but are less likely to develop the disease, and often recover from the infection. In addition, evidence is accumulating that the epidemiology is influenced by the soil and pasture type, presumably because these factors can affect the survival and proliferation of organisms in the environment.

Bacteria are taken up by M cells of the dome epithelium over lymphoid follicles and transported to macrophages in Peyer's patches. The immaturity of macrophages in younger animals, combined with the greater volume of organized intestinal lymphoid tissue, may help to explain the age susceptibility of infection. *The major lesions of Johne's disease are usually confined to the ileum, large intestine, and draining lymph nodes*. However, the infection is generalized, because in both clinical and subclinical cases, the organism can be cultured from a variety of parenchymatous organs and widely distributed lymph nodes. In fulminating infections, there is *bacteremia*, in blood or in infected phagocytes.

The incubation period of Johne's disease is protracted and irregular. Some carriers, in which bacteria persist in the mucosa and draining lymph nodes, may be infected for life without showing signs. The relationship between immune events and stages of the disease is speculative. Cell-mediated immunity clearly plays a role in the development of mucosal lesions and the onset of clinical disease. Exacerbations of clinical disease are often associated with parturition, a low nutritional plane, heavy milk yield, and intercurrent disease.

The pathogenesis of Johne's disease is related to the *granulomatous immunoinflammatory response in the lamina propria in the small intestine*, and the associated villus atrophy that develops. Malabsorption in the ileum, and filtration secretion from inflamed mucosa, overloads the capacity of the colon to resorb electrolyte and fluid; the function of the colon itself may be compromised by mycobacterial infection. There is malabsorption of amino acids, and enteric loss of plasma proteins, causing reduced productive efficiency, and when negative nitrogen balance occurs, a decline in body condition, and ultimate emaciation. Hypoproteinemia, when it develops, will further promote filtration secretion.

Clinically affected cattle are usually 2 years of age or older. The typical manifestation of Johne's disease is *profuse diarrhea passed effortlessly*. Clinical signs may be intermittent, with long intervening periods of remission. *Emaciation is progressive and ultimately fatal*, but the appetite is often retained and animals remain bright until the terminal stages.

Grossly, advanced cases of Johne's disease have marked loss of muscle mass and serous atrophy of fat depots, intermandibular edema, and fluid effusion in the body cavities. Plaques of intimal fibrosis and mineralization may be evident in the thoracic aorta. Specific gross lesions occur in the intestine and regional lymph nodes. The *mesenteric nodes, particularly the ileocecal, are always enlarged*, sometimes remarkably so, pale, and edematous, especially in the medulla. *Lymphangitis* is common, and the lymphatic vessels can often be traced as thickened cords from the intestinal serosa through the mesentery to the mesenteric nodes (Fig. 1.170). Often lymphangitis is the only recognizable gross change, and is specific enough to justify a presumptive diagnosis of Johne's disease at necropsy. The intestinal serosa often has a slight granular and diffusely opaque appearance because of subserosal edema and cellularity.

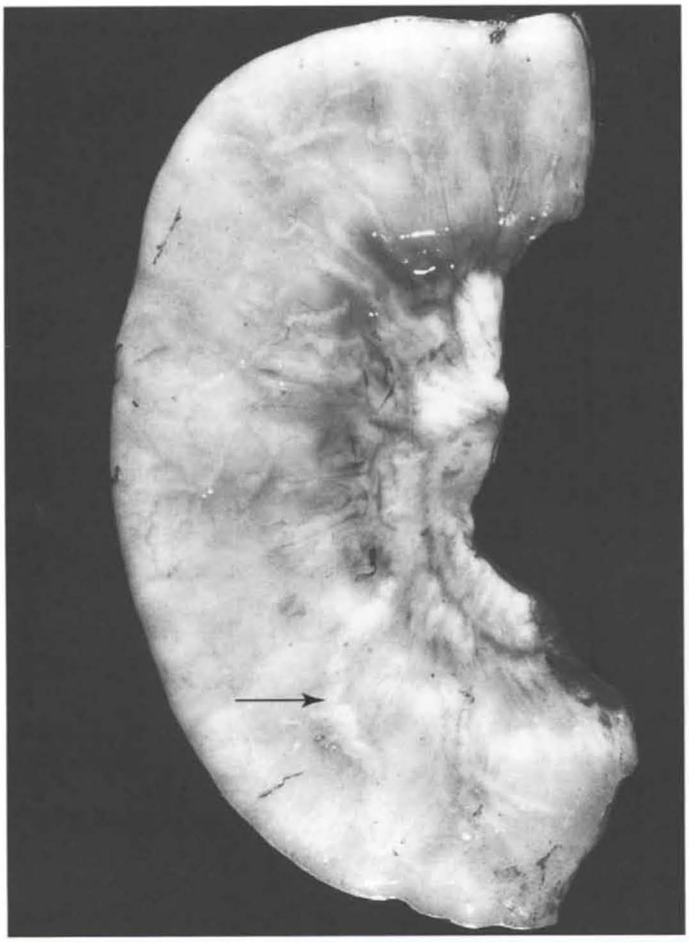

Figure 1.170 Serosal edema and **lymphangitis** (arrow) in a sheep with Johne's disease.

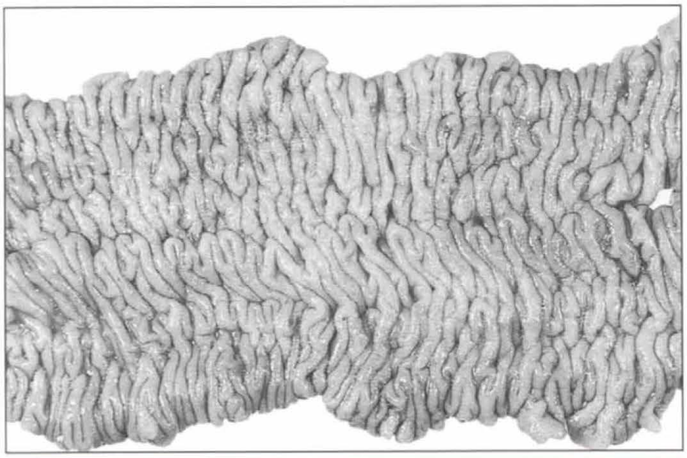

Figure 1.171 Thickened mucosal folds in the jejunum of a cow with **Johne's disease**.

Mucosal lesions may occur from the duodenum to the rectum; they may be segmental or continuous. They are usually best developed in the *lower ileum* (Fig. 1.171), and in the upper large intestine. The ileocecal valve is frequently described as enlarged, and this area is considered by some to be the earliest and most consistently affected, but abnormalities in this vicinity may not be notable.

The classical intestinal change is *diffuse thickening of the mucosa*, which is folded into transverse rugae, the crests of which may be congested. When well developed, the mucosal folds cannot be smoothed out by stretching. This lesion is due to accumulation of chronic inflammatory cells and edema in the mucosa and submucosa.

When gross lesions are well developed, the characteristic **microscopic change**, *transmural granulomatous enteritis*, is obvious. But in cattle in which gross changes are minimal or absent, the microscopic abnormalities are more subtle. In these the lamina propria is diffusely infiltrated with lymphocytes and plasma cells, and a large number of eosinophils. There may be very few macrophages (Fig. 1.172A), and the most characteristic change is an infiltrate of lymphocytes and plasma cells in the submucosa, and associated with the submucosal and mesenteric lymphatics.

In more clear-cut cases, villi are moderately to markedly atrophic, and macrophages are focally or diffusely distributed, in the villi, or deeper in the lamina propria, as part of an increased chronic inflammatory cell infiltrate. Giant cells may be present. The inflammatory infiltrate may abnormally separate and displace crypts, which are elongate, with hyperplastic epithelium. Crypts may be distended with mucus and exfoliated cells, probably due to compression and obstruction of their mouths by edema and inflammatory cells (Fig. 1.172B). *Masses of epithelioid macrophages may accumulate in the submucosa.* Foci of necrosis may occur within these aggregates of macrophages (Fig. 1.173), but in cattle, caseation and mineralization are extremely rare.

Lymphangitis is one of the most consistent changes. Initially the lymphatics are surrounded by lymphocytes and plasma cells and many contain plugs of epithelioid cells in the lumen. Granulomas may form in the wall and project into the lumen. These nodules may undergo some central necrosis.

Granulomatous lymphadenitis occurs in mesenteric lymph nodes in advanced cases. In the early stages, there is histiocytosis of the subcapsular sinus. Ultimately, nodular or diffuse infiltrates of epithelioid macrophages and giant cells may replace much of the cortex, and infiltrate the medullary sinusoids.

Of the other organs and tissues from which the bacilli may be isolated in cattle, lesions have only been described in the liver, hepatic lymph nodes, and, very rarely, the kidney and lungs. These are characteristically *focal granulomas*. They are most common in the liver, where foci of epithelioid cells and lymphocytes are found in the triads and scattered throughout the parenchyma. These lesions usually contain *demonstrable bacilli*, if macrophages are evident.

In sheep and goats, Johne's disease mainly occurs in adults and is characterized by *chronic wasting*; there may be breaks in the wool in sheep, and submandibular edema due to hypoproteinemia. The feces are often normal; they may be soft and unpelleted, but overt diarrhea is unusual, except intermittently in the terminal stages, perhaps because of the innately greater efficiency of electrolyte and fluid absorption in the colon of these species. In **farmed deer**, Johne's disease is clinically similar, but there are reports of disease in animals well under a year old.

In sheep, goats, and deer, enteric gross lesions are often mild, with little obvious thickening, and no transverse ridges; they are easily missed at necropsy. In sheep and goats, the bowel is occasionally quite remarkably thickened, and the lymphatics may be knotted as well as corded, the knots being focal granulomatous accumulations of epithelioid cells and lymphocytes, with relatively few organisms. Others may have an intestinal inflammatory infiltrate that is more lepromatous in

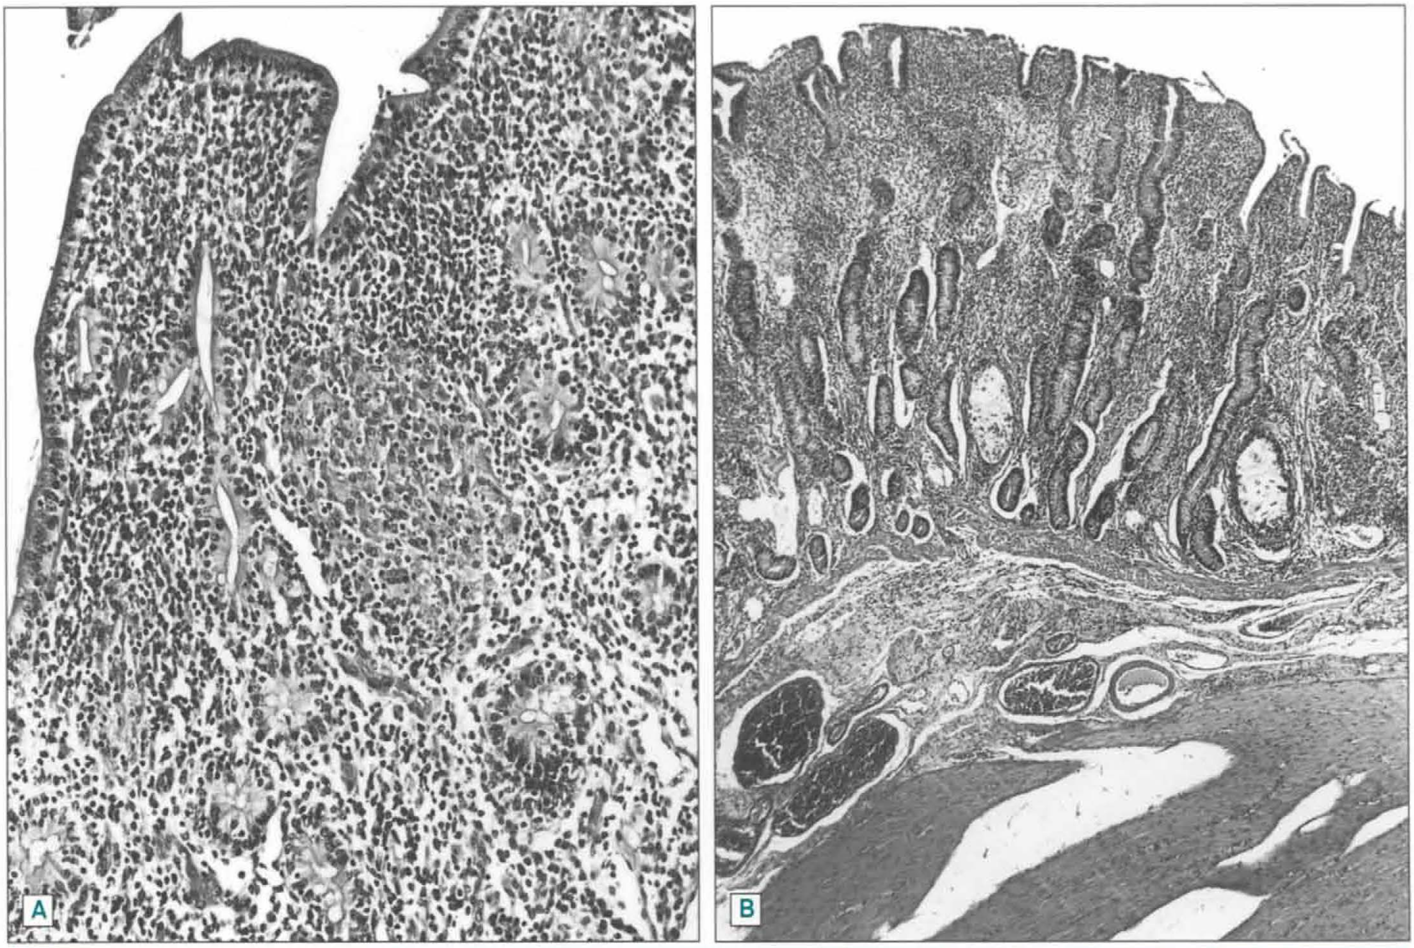

Figure 1.172 Johne's disease in a cow. **A.** Aggregate of **macrophages** in hypercellular lamina propria. **B.** Blunt **atrophic ileal villi**, and hyperplastic, and occasionally cystic, crypts. Edema of lamina propria, submucosa, and muscularis. Note heavy **inflammatory infiltrate** in lamina propria.

nature, with abundant organisms. In small ruminants, there may be lymphadenopathy affecting internal lymph nodes in particular, and variable lesions in the walls of blood vessels, meninges, liver, and spleen, all related to irregular lymphogranulomatous inflammatory foci. This latter lepromatous appearance is associated with negative intradermal skin test responses to johnin.

Goats, and some sheep, develop foci of tubercle-like caseation, often with mineralization, in the mucosa, submucosa, serosa, and lymphatics. Some may be grossly visible as white foci 1–4 mm in diameter, with modest surrounding fibrosis. Tubercles in the mucosa and lymph nodes of goats and deer may also mineralize (Fig. 1.174), and be large enough to replace much of the node. In sheep infected with the pigmented strain of the organism, the mucosa and lymph nodes may be orange. Scattered lymph nodes elsewhere in the body, and liver, lung, spleen, and other organs, may contain focal granulomatous lesions in sheep and goats. Some may mineralize. Lesions resembling those of lepromatous leprosy, with lymphocytic neuritis, have been described in the intestine of sheep, and axonal degeneration of the brachial and sciatic nerves has been reported in goats. Amyloidosis involving glomeruli, and occasionally other tissues, has also been reported in goats.

The organism is usually readily demonstrable in macrophages and giant cells in the lesions when appropriately stained by acid-fast techniques. However, in some clinical cases, especially the paucibacillary form in sheep, an extensive search may have to be made for individual macrophages or giant cells bearing a few acid-fast bacilli. Johne's disease in sheep, and especially in goats and deer, may resemble tuberculosis, on account of caseation and mineralization in granulomatous foci, and for such cases, and in any other situation where there is uncertainty about the acid-fast organism involved, positive identification of the etiologic agent is necessary. Antibodies with well-defined specificity for *M. a. paratuberculosis* have allowed the development of immunohistochemical tests, but these are not helpful when there are very few organisms. Polymerase chain reaction techniques are useful for confirming the diagnosis in individual cases. For isolation, the ileocecal lymph node, and affected segments of gut, are candidate sites for culture to confirm a diagnosis. Isolation may be difficult to accomplish, especially from sheep.

Rhodococcus equi enterocolitis of foals

Rhodococcus equi is an intracellular pathogen found in soil and as part of the normal intestinal flora of horses. There are both virulent and avirulent forms, with various *virulence factors* proposed, including capsular polysaccharide, cholesterol oxidase, cell wall mycolic acids, and a plasmid-encoded surface-expressed protein VapA. On farms where disease due to *R. equi* is endemic, there is a much higher proportion of virulent forms. Virulence factors may not be necessary for production of disease in an immunocompromised host. *R. equi* is usually associated with *suppurative bronchopneumonia of foals*. About half the pneumonic foals also have *ulcerative colitis*, and in some foals intestinal lesions alone occur.

The development of intestinal lesions appears to be dose-related, in that reproduction of the disease requires repeated oral infection. In natural disease, continual exposure to bacteria in swallowed respiratory exudate is probably an important source of infection in those animals with pneumonia.

Gross lesions may occur throughout the small and large intestines, but are usually most severe over Peyer's patches in small intestine, and in the cecum, large colon and related lymph nodes (Fig. 1.175A). Mucosal lesions consist of irregular ulcers up to 1–2 cm in diameter, often covered by purulent or necrotic debris (Fig. 1.175B). Edema of the wall of the gut may be severe. Mesenteric or colonic lymph nodes are often massively enlarged by edema and by caseous or purulent foci that may obliterate the structure of the node. Occasionally, massively enlarged abscessed lymph nodes are found without evidence of concurrent enteritis.

Microscopically, infection seems to occur by penetration of the specialized epithelium over Peyer's patches or intestinal lymphoid follicles. An initial neutrophilic response occurs and erosions of the epithelium develop subsequently. Macrophages and neutrophils accumulate in the lamina propria. The macrophages contain aggregates of *R. equi* but do not destroy them. Later, necrosis of lymphoid follicles occurs, and deep ulcers develop that contain masses of neutrophils, macrophages, and multinuclear giant cells. Pyogranulomatous lymphangitis and mesenteric lymphadenitis characterize the chronic enteric disease.

Enterococcus sp. enteritis

Small gram-positive cocci identified as *Enterococcus durans*, found in the environment and the gut of various species, have occasionally been associated with diarrhea in suckling pigs, puppies, foals, calves, and suckling rats. The organisms from rats have been described, on genetic grounds, as *E. ratti*, whereas those from piglets have been described as *E. villorum* or *E. porcini*, which may be synonyms.

These bacteria adhere to the microvillus surface of enterocytes by fine filamentous pili. In tissue section, they form a layer of small cocci crowded on the entire surface of epithelial cells, from the tips to the base of villi. There may be mild-to-moderate villus atrophy and some desquamating enterocytes. Malabsorption associated with reduced brush border enzyme activity may explain diarrhea. Although in spontaneous cases in piglets, *Enterococcus* is frequently associated with other pathogens, the organism isolated from foals produced diarrhea when inoculated alone into gnotobiotic pigs.

Bacteroides fragilis-associated diarrhea

Bacteroides fragilis is a nonspore-forming obligate anaerobe that is part of the normal enteric flora. Some enterotoxin-secreting strains have been associated with diarrhea in piglets, calves, lambs, foals, and humans. This enterotoxin is a *protease*, and probably damages the zonula adherens at the tight junction between enterocytes. Enterotoxigenic strains or cell-free culture filtrates cause secretion in ligated lamb or calf intestinal loops, and bacterial inocula cause diarrhea when administered orally to gnotobiotic piglets.

Bacteria do not adhere to the surface. Surface enterocytes round up and exfoliate, with villus attenuation and crypt elongation and hyperplasia. Infiltration of neutrophils is common. Damage may be seen in both small and large intestines. Ultrastructurally, affected cells lose their intercellular interdigitations, microvilli are shortened or absent, and the terminal web is disrupted.

Anaerobiospirillum ileocolitis

In **cats**, ileocolitis has been associated with small spiral gram-negative bacteria, probably of the genus ***Anaerobiospirillum***. Cats may be asymptomatic, lethargic, and anorexic, or have vomiting and diarrhea. Microscopically, exfoliated epithelial cells and neutrophils are in dilated crypts in the ileum and colon, and bacteria stained with silver can be found in the lumen of crypts, in goblet cells, and sometimes in the lamina propria. Septicemia may occur, and renal failure has been associated.

Enteritis due to Chlamydiaceae

Members of the family Chlamydiaceae are *obligate intracellular parasites*. Two genera are recognized on the basis of molecular genetics: *Chlamydia* and *Chlamydophila*. Among the three species in the former genus, only ***Chlamydia suis*** in pigs is associated with enteritis, while only one of the six species in the latter genus, ***Chlamydophila pecorum***, is associated with enteritis, in calves. Other syndromes associated with Chlamydiaceae in domestic animals include respiratory disease, polyarthritis, conjunctivitis, abortion, and encephalomyelitis, discussed in appropriate chapters elsewhere in these volumes.

The intestinal tract is the natural habitat for *C. pecorum*. Most infections are probably inapparent, but the intestine may be an important portal of entry in the development of systemic infections leading to hepatitis, arthritis, encephalitis, and pneumonia in ruminants. Enteritis may accompany or presage these diseases, and occasionally *C. pecorum* causes severe enteric disease in calves.

Following oral infection, *C. pecorum* infects mainly the enterocytes on the tips of ileal villi. These cells are in the G_1 phase of the cell cycle, which is required by *Chlamydophila* for multiplication. *C. pecorum* also infects other cells, including goblet cells, enterochromaffin cells, and macrophages, and the latter cells may transport the organisms systemically prior to being destroyed by them.

C. pecorum adsorbs to the brush border of enterocytes and enters the cell by pinocytosis. Following multiplication of organisms in the supranuclear region, the cells degenerate. *Chlamydophila* are released into the gut lumen, and into the lamina propria, where they infect endothelial cells of lacteals, whence they are released and become systemic.

Gastrointestinal disease caused by *Chlamydophila* is usually a problem of **calves** less than 10 days old, but it may affect older calves, and can produce recurrent diarrhea. Watery diarrhea, dehydration, and death are often accompanied by lesions, though not necessarily signs, of hepatitis, interstitial pneumonia, and arthritis. Gross lesions may occur in the abomasum and throughout the intestinal tract but are most consistent and severe in the *terminal ileum*. Mucosal edema, congestion, and petechiae, sometimes with ulceration, are usually observed. Serosal hemorrhages and focal peritonitis may occur. Histologically, *Chlamydophila* in inclusions may be demonstrable with Giemsa, Macchiavello, or immunoperoxidase staining. Central lacteals and capillaries are dilated, and neutrophils and monocytes infiltrate the lamina propria. Occasionally, granulomatous inflammation occurs in the intestinal submucosa and extends into the mesentery and to the serosa, producing the peritonitis observed grossly. Crypts in the small and large intestine may be dilated, lined by flattened epithelium, and contain inflammatory exudate.

C. suis has been recognized in the intestinal mucosa of **swine**, with approximately equal frequency in diarrheic and nondiarrheic animals. After experimental inoculation of *C. suis* into gnotobiotic piglets, there was necrosis and exfoliation of enterocytes on the apical half of villi, resulting in mild-to-severe villus atrophy in the distal jejunum and ileum, with moderate diarrhea. Lymphangitis and perilymphangitis were also evident in affected gut. In weanling pigs, similar lesions were induced, but no diarrhea.

Potomac horse fever

This condition, also described as *equine monocytic ehrlichiosis* and *equine ehrlichial colitis*, was first defined clinically in 1979, and is characterized by fever, leukopenia, depression, loss of appetite, and diarrhea. It is caused by ***Neorickettsia*** (formerly *Ehrlichia*) ***risticii***, a member of the order Rickettsiales, which are *obligate intracellular bacterial pathogens*. *Neorickettsia* spp. replicate within the phagosome in the host cell, and use trematodes as hosts. Potomac horse fever typically occurs in the summer. It was first described in the Potomac river valley, and is associated with other river valleys in the northeastern USA. The condition is not commonly diagnosed as a cause of death elsewhere, though antibody has been reported from horses in many parts of North America, and in Europe. *N. risticii* in trematode metacercariae found in aquatic insects are probably ingested accidentally while drinking. The definitive hosts of trematode reservoirs are insectivorous bats, which themselves become infected with *N. risticii*.

The disease may be highly variable. Many infected horses seem not to get sick. Others develop severe colic, subcutaneous edema, laminitis, and shock: mortality can be up to 30% in untreated cases. Abortions of pregnant mares have been attributed to *N. risticii* infection.

The incubation period in experimental infections is about 9–14 days, and diarrhea begins 1–3 days after the onset of fever. Not all experimentally infected animals develop disease.

At **necropsy** of spontaneous cases, small vesicles are reported in the oral cavity, and epicardial hemorrhages and pulmonary congestion and hemorrhage, compatible with endotoxemia, are described. These are not reported in experimental cases; nor is laminitis. The lesions of the gastrointestinal tract are the most significant, in both spontaneous and experimental cases. In some animals there may be focal or more extensive erosions in the gastric mucosa, perhaps with some overlying fibrinous exudate. Lesions in the small intestine are generally limited to segmental areas of mucosal congestion or hyperemia, with occasional focal ulcers or hemorrhage, and are much less consistent and severe than those in the *cecum and colon*. The content of the large bowel is abnormally fluid, and may have a brown or red-brown color, and foul odor. In the cecum and colon, there may be patches of hyperemia 5–10 cm in diameter, aggregates of small ulcers a few millimeters in diameter, and petechial hemorrhages. Sometimes the mucosa of the entire cecum is widely hyperemic. Ulcers and petechial hemorrhage are more severe and consistent in the right dorsal colon. The small colon is usually unaffected grossly.

Microscopic lesions are most consistent in the large intestine; similar changes may be evident in small bowel. In areas of gross hyperemia, there is marked congestion and superficial hemorrhage in the mucosa. Associated with these lesions are superficial epithelial necrosis, erosion, and fibrin effusion. The mucosal surface is denuded, or perhaps covered by fibrinocellular exudate, and epithelium in the upper half of crypts is attenuated. Deeper parts of crypts are dilated and may contain necrotic epithelium and inflammatory cells. An abnormally intense mixed inflammatory cell population is in the lamina propria, and sometimes, the submucosa. Lymphoid tissue in the gut, mesenteric lymph nodes, and spleen is moderately involuted, compatible with the effects of the stress of systemic illness.

Organisms are not evident in hematoxylin and eosin-stained tissue. They are visible, in colon, and less consistently, in cecum, small colon, and small intestine, with *modified Steiner silver stain*. They appear as small clusters of 10–15 fine brown dots, under 1 μm in diameter, in the apical cytoplasm of epithelial cells deep in crypts, or as more numerous, smaller black structures distributed in the cytoplasm of macrophages in the periglandular lamina propria, or in a few glandular epithelial cells. Ultrastructurally, small dense elementary bodies may be found, alone or in small clusters in vacuoles in the cytoplasm of macrophages, mast cells, and crypt epithelium, or as the morula – aggregates of larger, more open organisms, in the same locations. *N. risticii* can be identified in feces or peripheral blood buffy coat by polymerase chain reaction, providing a more sensitive and specific means of diagnosis.

Mycotic diseases of the gastrointestinal tract

Intestinal phycomycosis and aspergillosis

Mycotic invasion of the wall of the gastrointestinal tract is a common sequel to many diseases and lesions affecting the mucosa, and it may be the precursor to systemic infection. It is generally agreed that one or more of heavy fungal challenge, disruption of the normal flora, a primary local lesion, or lowered host resistance, is required for establishment of mycotic disease in the gut. Spores are probably carried across the mucosa by macrophages in the normal course of events, and only if phagocyte function is compromised, permitting germination, will they establish in the deeper tissues or become disseminated. Neutrophil function seems important in prevention of establishment of mycoses, whereas T-cell-mediated macrophage activity is involved in resolution of lesions.

Organisms associated with alimentary tract mycoses are *Aspergillus*; zygomycetes of the family Mucoraceae, including the genera *Absidia*, *Mucor*, and *Rhizopus*; the aquatic oomycete *Pythium*; and entomophthoracetes such as *Basidiobolus* and *Conidiobolus*. *Candida* spp. may also invade the wall of the alimentary canal; that is considered separately, below, as are enteric manifestations of histoplasmosis.

Aspergillus has relatively uniform narrow (3–6 μm) hyphae with relatively numerous septa; it typically displays acute angled dichotomous branching. **Mucoraceous fungi** are characterized in their invasive mycelial form by broad (6–25 μm), coarse irregular hyphae, with infrequent septation and random branching, sometimes surrounded by an eosinophilic sleeve in tissue sections. ***Pythium* spp.** have relatively narrow (up to 9–10 μm), thick-walled hyphae, with almost parallel walls and occasional septa; they branch at about right angles. In **entomophthoromycosis**, hyphae may vary from 5 to 25 μm in diameter, with thin irregularly parallel walls, infrequent septa, and rare random branching. They are characteristically surrounded by a wide sheath or sleeve of eosinophilic material in tissue section.

Lesions occur anywhere in the gastrointestinal tract, including the forestomachs of ruminants, and in the mesenteric lymph nodes. Clinical signs may be specifically related to the location of lesions (vomition, bloody diarrhea), or be nonspecific (malaise, weight loss), or be absent. Three types of lesion are produced: (1) *hemorrhagic and infarctive*; (2) *caseating*; *and* (3) *granulomatous*.

Mucoraceous fungi and ***Aspergillus*** typically cause *hemorrhagic and infarctive lesions*. Cases in cattle are seen following grain overload, mastitis, "downer cow syndrome," parturition, and subsequent to neonatal infectious bovine rhinotracheitis infection. Mucoraceous fungi frequently complicate Peyer's patch necrosis in cattle with mucosal disease, and are seen along the margins of the abomasal folds in calves with bacterial septicemia, producing mycotic abomasitis. These fungi can be found at any level of the gastrointestinal tract; however, omasum followed by rumen and reticulum are the most common sites. *Aspergillus* tends to be most common in the abomasum. These fungi have a propensity to invade mucosal and submucosal veins, producing *thrombosis and venous infarction*. Characteristically there is mucosal to full-thickness necrosis of the wall, which grossly is edematous and red-black due to venous stasis and hemorrhage. Often there is a relatively mild inflammatory response to the fungi. Spread to the liver and more distant organs via the portal and systemic circulations is not uncommon.

Mycotic ileitis and colitis in cats may occasionally be a sequel to panleukopenia. Intestinal lesions caused by the fungi (often *Aspergillus*) may be hemorrhagic and necrotizing with a prominent cellular response, but sometimes are small, localized, and difficult to find. In the latter cases, lesions of panleukopenia in the intestine and multifocal mycotic emboli in the lung suggest the pathogenesis. The lung appears to be the favored site of dissemination in cats. Mycotic enteritis with dissemination is a rare sequel to *Canine parvovirus 2* enteritis.

The gastrointestinal tract is probably a common portal of entry for many sporadic, disseminated zygomycoses, and aspergillosis, in animals. The presence of fungal hyphae in mesenteric lymph node granulomas of many clinically normal cattle indicates that, contrary to general impressions, *invasion by these agents across the intestinal mucosa does not lead invariably to systemic disease*. Fungi may produce a localized granulomatous lesion in specialized lymphoid tissue of the Peyer's patch or may be carried to the regional lymph node, while the mucosal lesion, if any, heals. In the lymph nodes, a granulomatous response, with giant cells that contain hyphal fragments, often develops; asteroid bodies may form around *Aspergillus* spp. Usually the granulomatous lesions produce little or moderate enlargement of lymph nodes, but sometimes a massive, caseating lymphadenitis results, with adhesions to adjacent structures.

Pythiosis (*oomycosis*), caused by the aquatic oomycete *Pythium insidiosum*, occurs most commonly in tropical and subtropical areas, but on occasion can be found in more temperate climates. It is best recognized as a cause of *cutaneous lesions in horses* (see Vol. 1, Skin and appendages). However, it causes enteric disease in dogs, and, less commonly, horses. There is segmental thickening and ulceration of the stomach and small intestine, with transmural granulomatous inflammation, and sometimes granulomatous peritonitis, with adhesions of the omentum. Obstruction may occur. Lymphovascular channels on the intestinal serosa are thickened, and the mesenteric lymph nodes are greatly enlarged and frequently embedded in a granulomatous mass. Small firm or caseous yellow foci, known as "*leeches*" or "*kunkers*," may be embedded in the firm fibrotic reactive tissue. Segments of bowel may be infarcted. Granulomatous inflammation is evident in the mucosa, and especially the submucosa; it extends along lymphatics transmurally. Granulomas, with a local mixed inflammatory infiltrate, often including eosinophils, may have liquefactive or caseous necrotic centers. Characteristic hyphae are difficult to see with hematoxylin and eosin; they are best exposed, in the areas of necrosis or centers of granulomas, by *silver stains*. Similar lesions are reported in horses with intestinal obstruction.

Entomophthoromycosis involving the gastrointestinal tract has been reported in a few dogs. Ulcerative stomatitis, gastritis, and enteritis are reported, with induration of involved tissues by a granulomatous inflammatory reaction containing the typical hyphae. In horses, entomophthoromycosis due to *Conidiobolus* may involve the lips and pharynx, as well as the nostrils and nasal mucosa.

Definitive **diagnosis** of mycotic lesions requires culture, which may be difficult, and identification of the isolate, which is frequently a specialist activity. If possible, granulomatous lesions of the gut should always be cultured for fungi as well as bacteria, in order to increase the frequency of specific diagnosis. Mycotic lymphadenitis must be differentiated from a mycobacterial, actinomycotic, or nocardial lesion. A presumptive diagnosis may be based on morphologic characteristics of organisms in tissue sections. Immunochemical procedures using specific antibody may add to the confidence of a morphological diagnosis.

Candidiasis

Candida spp. are normal inhabitants of the alimentary tract of animals, existing as *budding yeasts* in association with mucosal surfaces. When there are changes in the mucosae, particularly squamous mucosae, or in the mucosal flora, the yeasts may become invasive; *branching, filamentous pseudohyphae and hyphae largely replace the yeast forms*. Only a few of the almost 200 *Candida* species cause candidiasis; in animals the most important are ***Candida albicans*** and ***C. tropicalis***.

Changes in the mucosal flora usually result from antimicrobial therapy that reduces the numbers of anaerobic bacteria and allows proliferation of *Candida* spp. Environmental and social stress, and treatment with anticancer and anti-inflammatory agents, may also predispose to candidiasis.

Candida spp., especially *C. albicans*, are capable of adhesion to epithelium, and this is important in virulence. Hypha formation is favored by carbohydrates such as sucrose, or polysaccharides that are less readily fermentable than glucose. Glucose is necessary for keratinolysis by the fungus. An endotoxin released during reproduction and death of *Candida* organisms may cause local damage, permit deeper penetration into squamous epithelium, and perhaps promote systemic dissemination.

Candida spp. are occasionally opportunistic invaders of mucosal lesions anywhere in the alimentary tract, but other fungi are more likely to take advantage of this kind of lesion, particularly in older animals. *Candidiasis is mainly a disease of keratinized epithelium in young animals, especially pigs, calves, and foals*. Accumulation of keratin due to anorexia probably contributes to the extensiveness of lesions in all species by increasing the substrate available to the fungus. Systemic infection appears to be associated with activation of virulence factor genes of *Candida* that facilitate dissemination and colonization. Adequate myeloperoxidase activity of leukocytes is important in prevention of dissemination of *Candida* spp. Foci of necrosis with a mainly neutrophilic infiltrate, and containing masses of proliferating organisms, are found in organs such as the spleen, liver, kidney, and heart.

In **pigs**, *Candida* spp. often invade the parakeratotic material that accumulates on the *gastric squamous mucosa*. Apparently these infections are innocuous. "*Thrush*" is candidiasis of the oral cavity; it is occasionally seen in young pigs, especially those raised on artificial diets, or in pigs with intercurrent disease. Lesions may be confined to the tongue, hard palate, or pharynx, but often involve the esophagus and gastric squamous mucosa as well. Rarely the glandular stomach is involved. Grossly the lesions are yellow-white, smooth, or wrinkled plaques more or less covering the mucosa. Histologically, the epithelium is spongy and contains yeasts and abundant hyphae and pockets of neutrophils and bacteria beneath the cornified layer. Congestion of vessels and a few inflammatory cells are present in the mucosal propria. Desquamation of the epithelium may produce small ulcers.

In **calves**, candidiasis occurs following prolonged antimicrobial therapy and in association with rumen putrefaction. Lesions are most often seen in the *ventral sac of the rumen*, but may involve the omasum and reticulum and occasionally the abomasum. Grossly the lesions resemble those of "thrush" in pigs, but the keratin layer tends to be thicker, less diffuse, and light gray. In the omasum, the leaves may be stuck together by the mass of fungus-riddled keratin. *C. glabrata* in the abomasum has been implicated as a cause of diarrhea in calves, especially during winter months. Disseminated candidiasis occurs more often in calves than in pigs, probably because of the relatively prolonged survival of calves with alimentary lesions. Candidiasis in calves must be differentiated from alimentary herpesviral infections.

Gastroesophageal candidiasis in **foals** involves the squamous epithelium and is associated with *ulceration adjacent to the margo plicatus*. Colic and anorexia are seen, and are probably related to the development of the ulcers, which may perforate, causing peritonitis.

In tissues, the presence of oval or round blastospores about 3–6 μm in diameter, which may be budding, mixed with pseudohyphae comprised of chains of elongate yeast-like cells, or with tubular septate hyphae, permits a provisional identification of *Candida* spp. Silver or periodic acid–Schiff stain enhances the organisms in section.

Intestinal histoplasmosis

Histoplasma capsulatum is a *soil organism* of worldwide distribution. The disease, histoplasmosis, is endemic in certain areas, such as the Mississippi and Ohio river valleys of the USA, and in parts of southern Ontario and the Ottawa–St. Lawrence river valleys in Canada. There are sporadic cases elsewhere. It is important in humans and dogs, and occasionally occurs in other species. Infection generally occurs via *inhalation of spores*, and if lesions occur, they are usually confined to the lungs. Dissemination, with hepatic, splenic, and sometimes gastrointestinal lesions, develops in some dogs. It is associated with heavy exposure, young age, and perhaps some degree of host immunocompromise. Infection can also be produced by *ingestion*, and the rare examples of disease confined to the gastrointestinal tract may develop in this manner. Intestinal infection by ingestion of infected sputum is also possible.

Disseminated histoplasmosis is a disease predominantly of young dogs that are usually presented with weight loss, generalized lymphadenopathy, and often diarrhea with blood, and tenesmus. *Intestinal histoplasmosis* is reported as part of disseminated disease in cats, and as an isolated lesion in a horse.

At postmortem there may be hemorrhagic enteritis involving small and large intestine, or granulomatous thickening of the mucosa and intestinal wall with ulceration (Fig. 1.176), or no apparent lesions. Mesenteric lymph nodes are often markedly enlarged. Histologically, lesions, characteristically *transmural granulomatous inflammation*, may occur in stomach and small or large intestine. The nonulcerated areas of the mucosa contain focal to diffuse infiltrations of macrophages laden with *H. capsulatum* organisms within cytoplasmic vacuoles. The mucosa may be grossly thickened by the infiltrate, causing necrosis and ulceration. The cellular reaction may extend through the muscularis to the serosa. Macrophages filled with organisms are particularly prominent in the lymphoid tissue of the gut and the mesenteric nodes. *Periodic acid–Schiff stain* highlights the organisms in tissues. Microscopic diagnosis of gastrointestinal histoplasmosis is not difficult, but grossly the disease must be distinguished from intestinal lymphoma and in the colon, from colitis of other types. Histoplasmosis is discussed in detail in Vol. 3, Hematopoietic system.

Protothecal enterocolitis

Prototheca spp. are *colorless algae* closely related to *Chlorella*. They are ubiquitous in raw and treated sewage and in water, and are found in feces, plant sap, and slime flux of trees. Two species, ***P. zopfii*** and ***P. wickerhamii*** cause disease in animals with both occurring occasionally in the same animal.

Lesions caused by *Prototheca* spp. include *cutaneous* infections of cats and human, *mastitis* in cows, and *disseminated* infections in cattle and dogs. The intestine and the eye are the most commonly involved sites in protothecosis of dogs.

Factors predisposing to the development of intestinal protothecosis are poorly understood. Skin infections are thought to result from traumatic inoculation, and it is possible that in the alimentary tract *Prototheca* is an opportunistic invader of existing mucosal lesions. Cattle, horses, and wild pigs pass *Prototheca* in the feces without apparent clinical disease. The chronicity of the disease and the mild host response are not consistent with a virulent infection. In dogs, Collies seem overrepresented among the cases reported, suggesting breed-related susceptibility or immune compromise.

Chronic, intractable, bloody diarrhea, or passage of blood-stained feces, is a frequent presenting sign, with progressive weight loss. *Hemorrhagic and ulcerative colitis* is a prominent enteric lesion, but changes may also develop in the small intestine. Mesenteric lymph nodes may be enlarged.

The *mild host response to infection* is characteristic of protothecosis; usually only a few lymphocytes and monocytes are present. In early lesions, the extracellular organisms are scattered in the lamina propria, but later they fill the lamina propria and are often packed in cords in the connective tissue of the submucosa. Lacteals are distended, while lymphatics and the sinuses of draining lymph nodes are filled with organisms.

Prototheca in tissue sections range from 5 μm spheres to 9 × 12 μm ovoids, with a refractile capsule, and are positive with *periodic acid–Schiff and silver stains*. The presence of endosporulation with formation of 2–20 sporangiospores within a single sporangium characterizes *Prototheca* spp. and *Chlorella* spp. *Chlorella* contain periodic acid–Schiff-positive cytoplasmic starch granules that are PAS-negative following diastase digestion; *Prototheca* do not contain these granules. Differentiation of the genera by a fluorescent antibody test using formalin-fixed material is also possible.

Gastrointestinal helminthosis

The diagnosis of disease due to gastrointestinal helminths must be made with knowledge of their pathogenic potential and the mechanisms by which it is expressed. *Parasites are much more common than the diseases they cause*, and "**helminthiasis**," *the state of infection*, must be clearly differentiated from "**helminthosis**," *the state of disease*.

Gastrointestinal helminths fall into *five categories*, according to pathogenesis of disease:

1. The first group **resides free in the lumen of the intestine**, competing with the host for nutrients in the gut content. They are generally of low pathogenicity, except for rare massive infections, and are not likely to be lethal, except by obstruction. Some of these worms, in sufficient numbers, may cause subclinical disease such as inefficient growth, or clinical disease in the form of ill-thrift; others are essentially nonpathogenic. The ascarids, adult small strongyles (cyathostomes) of horses, and tapeworms such as *Moniezia* and *Taenia* spp., fall into this group, as may *Physaloptera* in the stomach of carnivores.
2. A second group of helminths, all nematodes, primarily cause **blood loss**. These worms feed on the mucosa, causing bleeding, or they actively suck blood. Anemia, hypoproteinemia, and their sequelae cause production loss, clinical disease, and death. *Haemonchus* in the abomasum, and in the intestine the hookworms of carnivores and ruminants, the large strongyles of horses, and *Oesophagostomum radiatum* in cattle are the main examples.
3. The third group, composed of nematodes and some flukes, mainly causes **protein-losing gastroenteropathy**, usually associated with inappetence and diarrhea. In the abomasum, *Ostertagia* and *Trichostrongylus axei* cause mucous metaplasia and hyperplasia of gastric glands, achlorhydria, and diarrhea. In the small intestine, *Cooperia*, *Nematodirus*, *Strongyloides*, *Trichostrongylus*, and larval paramphistomes in sheep and cattle cause villus atrophy. This may cause malabsorption of nutrients, electrolytes, and water. But probably more important is the loss of endogenous protein into the gut, mainly related to chronic mucosal inflammation. In heavy infestations with *Trichuris* spp., erosion results in loss of absorptive function, and effusion of tissue fluids, or, in severe cases, hemorrhagic exudate.
4. The fourth group causes **physical trauma to the intestinal wall** by burrowing into or inciting inflammatory foci in the submucosa or deeper layers. In the stomach, various species of spirurids embed in the mucosa, or establish in cystic spaces in the submucosa. In the intestine, acanthocephala cause local ulceration by their thorny hold-fast organ; larval stages of equine cyathostomes and *Oesophagostomum* spp. become encapsulated in the submucosa. Protein loss may occur from ulcerated areas, or when larvae emerge from the submucosa. The potential exists for perforation of the stomach or bowel, or for complications due to sepsis of submucosal nodules. Adhesion of inflamed serosal surfaces associated with nodules or perforations may impair motility.
5. Finally, some intestinal helminths, among them a few in the categories above, have **effects at sites distant from the gut**. This is usually the result of migrating larval stages of the worm, either in definitive or intermediate hosts. Larval *Habronema*, ascarids, hookworms, and equine strongyles may cause lesions in a variety of extraintestinal sites in the definitive host. Larval ascarids and taeniid metacestodes may cause lesions or signs due to migration in nonenteric locations in accidental or intermediate hosts.

A **diagnosis of helminthosis** should be reserved for cases where, ideally, three criteria are met: (1) the helminth is present, in numbers consistent with disease; (2) the lesions (if any) typically caused by the agent, are evident; and (3) there is a syndrome compatible with the pathogenic mechanisms known to be associated with the worm.

Abomasal and gastric helminthosis

Ostertagiosis

A complex of related genera and species of trichostrongylid nematodes, including *Ostertagia*, parasitize the *abomasum of ruminants*. The nomenclature of these worms is in a state of flux; for the sake of simplicity, the disease that they cause will be termed ostertagiosis. *Ostertagiosis is probably the most important parasitism in grazing sheep and cattle in temperate climatic zones throughout the world*. It causes subclinical loss in production, and clinical disease characterized by diarrhea, wasting, and, in many cases, death. ***Ostertagia ostertagi*** and the associated *O. lyrata* infect cattle. Sheep and goats are infected by ***Ostertagia*** (*Teladorsagia*) ***circumcincta***. Some cross-infection by these genera occurs between sheep and cattle, but is of minor significance. Other species of *Ostertagia* and related genera, including *Marshallagia*, *Spiculopteragia*, and *Camelostrongylus*, infect wild ruminants, including farmed deer; some may also parasitize the abomasum of cattle, sheep, and goats. Their behavior in general resembles that of *Ostertagia* and *Teladorsagia*.

The life cycle is direct. Third-stage larvae exsheath in the rumen and enter glands in the abomasum, where they undergo two molts. Normally, early fifth-stage larvae emerge to mature on the mucosal surface, beginning 8–12 days after infection in *O. circumcincta* infections in sheep, and about 17–21 days after *O. ostertagi* infection in cattle. However, a proportion of larvae ingested may persist in glands in a hypobiotic state at the early fourth stage, only to resume development and emerge at a future time, perhaps many months hence. The prepatent period is about 3 weeks.

During the course of larval development, the normal architecture of the gastric mucosa is altered by *interstitial inflammation*, and *mucous metaplasia and hyperplasia of the epithelium lining glands*. In sheep infected with *O. circumcincta*, mucous metaplasia and hyperplasia occur in infected and surrounding glands early in infection, reaching a peak about the time of emergence of larvae on to the mucosal surface. In cattle with *O. ostertagi* (Fig. 1.177A), only glands infected with larvae undergo significant mucous change until about the time larvae leave the glands for the surface of the mucosa (Fig. 1.177B). Mucous change then becomes more widespread, involving uninfected glands in the vicinity of those that contained larvae.

In both species, affected glands are lined by mucous neck cells that proliferate, displacing parietal cells. Affected areas of mucosa thicken. In infected glands, in many cases the lining is flattened adjacent to worms (Fig. 1.177C), but is composed of tall columnar mucous cells elsewhere in the gland. The undifferentiated mucous cells lining uninfected glands also eventually differentiate into tall columnar mucous cells. If infection is not heavy, lesions are limited to a radius of a few millimeters around infected or previously infected glands. These form raised nodular pale areas in the mucosa, often with a slightly depressed center. Confluence of these lesions in heavily infected animals leads to the development of *widespread areas of irregularly thickened mucosa with a convoluted surface pattern*, likened to "*Morocco leather*" (Fig. 1.178).

Mucous metaplasia and hyperplasia are accompanied by a mixed population of inflammatory cells in the lamina propria. Lymphocytes, plasma cells, eosinophils, and a few neutrophils are present between glands in the infected abomasum, and globule leukocytes are common in gland epithelium. There may be edema of the lamina propria associated with permeability of proprial vessels. Lymphoid response in local lymph nodes has been characterized as primarily B-cell-oriented, which is a surprising reaction to a nematode parasite.

Mucosal lesions lead to achlorhydria, elevation of plasma pepsinogen levels, and local vascular permeability with loss of plasma protein. Widespread replacement of parietal cells by mucous neck cells results in progressive and massive decline in hydrogen ion secretion, with severe cases having a pH of up to 7 or more. This increased abomasal pH results in elevated levels of gastrin in the circulation. The permeability of the mucosa is also increased, which is reflected in backdiffusion of pepsinogen from the lumen of glands to the propria, and ultimately to the circulation. Intercellular junctions between poorly differentiated mucous neck cells are also permeable to plasma protein in tissue fluids, emanating from the leaky small vessels in the inflamed lamina propria. Significant loss of protein occurs into the lumen of the abomasum.

The cardinal signs of ostertagiosis in sheep and cattle are *loss of appetite, diarrhea, and wasting*. Plasma protein loss into the gastrointestinal tract, in combination with reduced feed intake, seems largely responsible for the weight loss and hypoproteinemia that occur in clinical ostertagiosis, and for loss in productive efficiency that occurs in subclinical disease.

Clinical ostertagiosis occurs under two sets of circumstances. The first, **"type I" disease**, is seen in lambs or calves at pasture during or shortly after a period of high availability of *infective larvae*. It is due to the direct development, from ingested larvae, of large

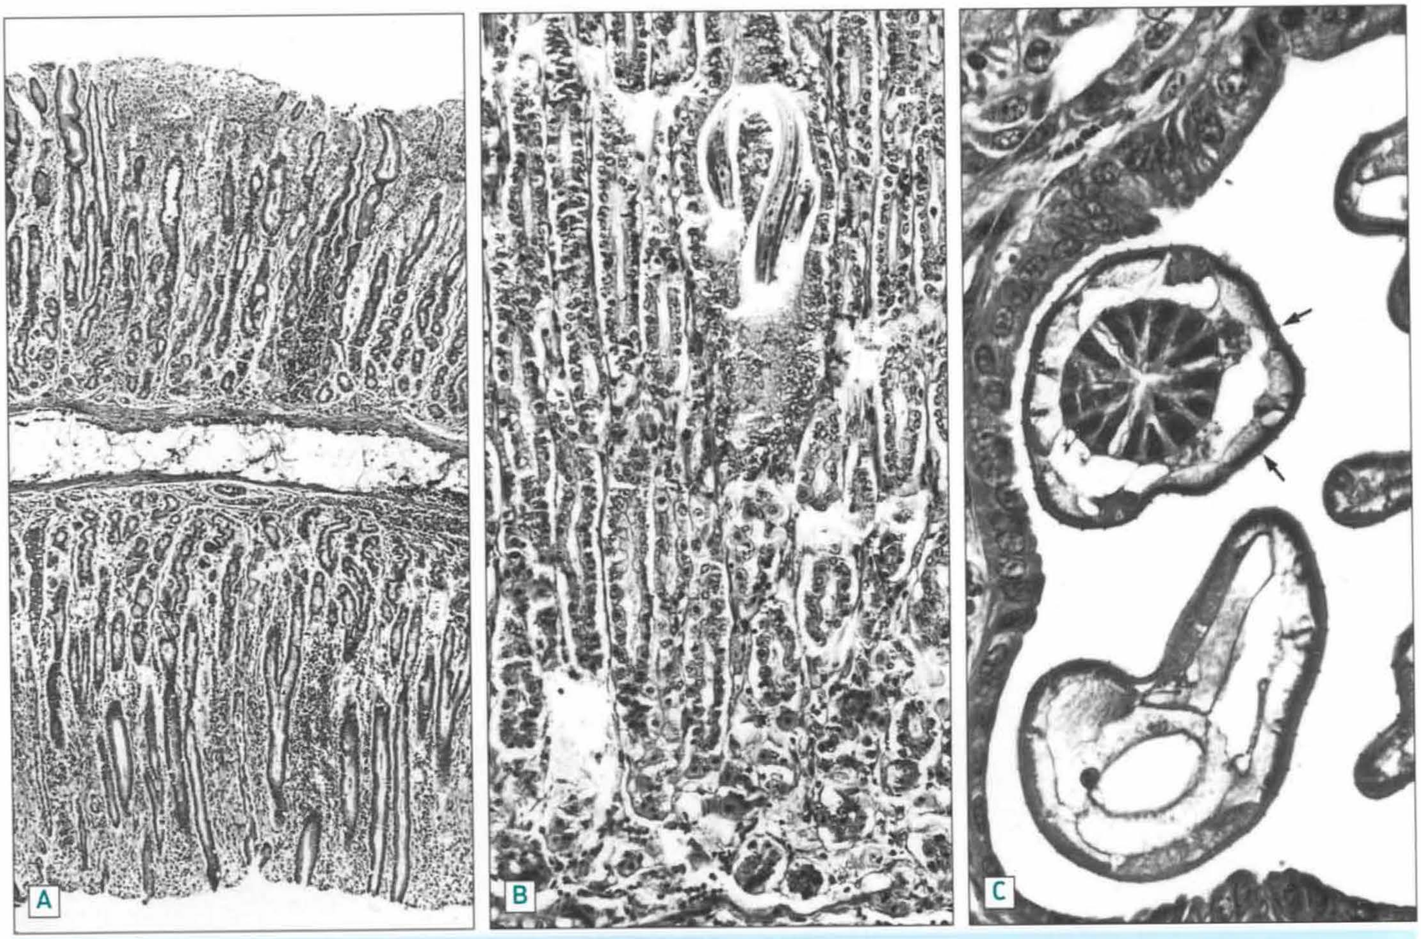

Figure 1.177 Ostertagiosis in the bovine abomasum. **A.** Mucous metaplasia and hyperplasia thickening fundic mucosa on abomasal fold. Moderate inflammatory infiltrate in propria between glands. **B.** Mucous metaplasia and hyperplasia deep in fundic mucosa. Larva in section in gland. **C.** *Ostertagia* in dilated gland lined by cuboidal mucous neck cells. Longitudinal cuticular ridges are visible as fine projections on the nematode (arrows).

numbers of adult worms, over a relatively short period of time. In contrast, **"type II" disease** is due to the synchronous maturation and emergence of large numbers of *hypobiotic larvae* from the mucosa, and it occurs when intake of larvae is likely low or nonexistent. It may occur in yearlings during the winter in the northern hemisphere, or during the dry summer period in Mediterranean climates. Heifers about the time of parturition may succumb, and this syndrome is also occasionally seen in animals experiencing environmental stress of any type.

The **diagnosis** of ostertagiosis is indicated at autopsy by an *abnormally elevated abomasal pH* (>*4.5*), in association with *typical gross lesions* on the mucosa. The adult worms are brown and thread-like, up to 1.5 cm long, but very difficult to see on the mucosa with the unaided eye. *Abomasal contents and washings* should be quantitatively examined for the presence of emergent or adult *Ostertagia* and other nematodes. A *portion of the mucosa should be digested* to permit recovery and quantitation of pre-emergent stages. Significant worm burdens in sheep are in the range of 10 000–50 000 or more. In cattle >40 000–50 000 adult worms may be present, and in outbreaks of type II disease hundreds of thousands of hypobiotic larvae are often detected in the abomasal mucosa. Typically, there is widespread mucous metaplasia and hyperplasia in dilated glands in sections of abomasum. *Ostertagia* are recognized in sections, on the mucosal surface or in glands, by the presence of prominent longitudinal cuticular ridges (synlophe) that project from the surface of worms cut transversely. In some cases, the worm burden may have been lost through attrition or recent treatment, and the diagnosis must be presumptive, based on the characteristic mucosal lesions.

Hemonchosis

Hemonchosis is a common and severe disease in some parts of the world. *Haemonchus* species require a period of minimum warmth and moisture for larval development on pasture. As a result, they tend to be *most important in tropical or temperate climates with hot wet summers*. ***Haemonchus contortus*** infects mainly sheep and goats, whereas ***H. placei*** occurs mainly in cattle. Though *H. contortus* and *H. placei* will infect the heterologous host, the host–parasite relationship appears to be less well adapted, and the species do appear to be genetically distinct. ***Mecistocirrus digitatus*** causes disease very similar to hemonchosis in cattle and sheep in Southeast Asia and Central America.

By exploitation of hypobiosis or retardation of larvae, populations of *H. contortus* are able to persist in the abomasum of the host through periods of climatic adversity, such as excessive cold or dryness. Disease can be expected in animals, especially females, experiencing the synchronous "*spring rise*" or periparturient development and maturation of previously hypobiotic larvae, and in young animals heavily stocked at pasture during periods of optimal larval development and availability.

Haemonchus, commonly called the *large stomach worm, or barber pole worm*, is ~2 cm long. Females give the species its common name by their red color, against which the white ovaries and uterus stand out. The male is a little shorter and uniform deep red. These worms are equipped with a buccal tooth or lancet, and *fourth-stage and adult worms suck blood*. Ingested third-stage larvae enter glands in the abomasum, where they molt to the fourth stage and persist as hypobiotic larvae, or from which they emerge as late fourth-stage larvae to continue development in the lumen. The prepatent period for *H. contortus* in sheep is ~15 days; for *H. placei* in cattle is ~26–28 days; and for *M. digitatus* is ~61–79 days.

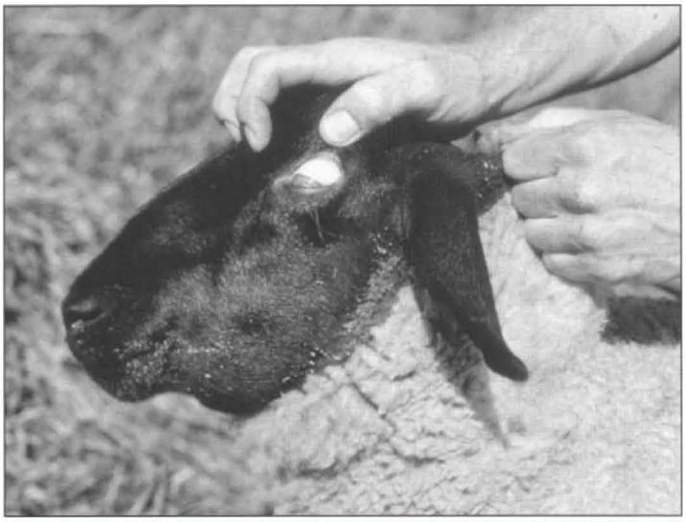

Figure 1.179 Severe **submandibular edema** ("bottle-jaw"), and **anemia**, manifest as conjunctival pallor, in ***Haemonchus contortus* infection** in a sheep.

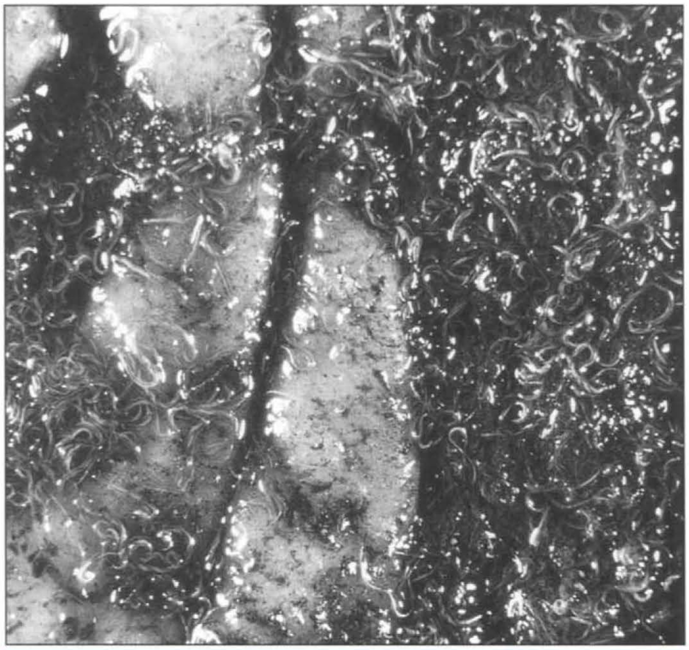

Figure 1.180 ***Haemonchus contortus*** in acid-hematin-tinged abomasal content in a sheep.

Hemonchosis may occur as *peracute or acute disease*, resulting from the maturation or intake of large numbers of larvae. It may cause more insidious *chronic disease*, if worm burdens are lower. The pathogenicity of *Haemonchus* infection, whatever its manifestation, is the result of blood-sucking activity, which causes anemia and hypoproteinemia.

Individual *Haemonchus* worms in sheep cause the loss of about 0.05 mL of blood per day. Of the order of a tenth to a quarter of the erythrocyte volume may be lost per day by heavily infected lambs; the plasma loss is concomitant and may be several hundreds of milliliters. The potential for the *rapid onset of profound anemia and hypoproteinemia* in heavily infected animals is obvious. Such animals succumb quickly, some even before the maturation of the worm burden. Less heavily infected animals may be able to withstand the anemia and hypoproteinemia for a period of time. They compensate by expanding erythropoiesis two- to threefold, and increasing hepatic synthesis of plasma protein. However, they are unable to compensate adequately for the enteric iron loss, despite intestinal reabsorption of a proportion of the excess, and they ultimately succumb some weeks later to *iron-loss anemia*, when iron reserves are depleted. Low-level infections may contribute to subclinical loss of production or ill-thrift through chronic enteric protein and iron loss. Low protein rations compound the effect of infection.

The clinical syndrome may vary somewhat. Some animals are found dead, without the owner observing illness. Others lack exercise tolerance, fall when driven, or are reluctant to stand or move, so weak are they from anemia. Edema of dependent portions, especially the submandibular area or head in grazing animals, is often observed (Fig. 1.179). In primary hemonchosis, there is no diarrhea; diarrhea may occur if intercurrent infection with large numbers of other gastrointestinal helminths occurs.

The **postmortem** appearance of animals with hemonchosis is dominated by the extreme pallor of anemia, apparent on the conjunctiva and throughout the internal tissues. The liver is pale and friable. There is usually edema of subcutaneous tissues and mesenteries, with hydrothorax, hydropericardium and ascites, reflecting the severe hypoproteinemia. The abomasal content is usually fluid, and dark red-brown, due to the presence of blood (Fig. 1.180). The abomasal rugae may be edematous due to hypoproteinemia, and focal areas of hemorrhage are evident over the surface. In animals that are not decomposing, the worms will be evident to the naked eye: if alive, writhing on the mucosal surface; if dead, less obvious and free in the content.

In clinically affected sheep and goats, usually about 1000–12 000 worms are found. The severity of the disease is a function of the number of worms on one hand, and to some extent, the size of the animal on the other. In lambs, 2000–3000 worms is a heavy burden, while in adult sheep and goats, 8000–10 000 are associated with fatal infection.

A high egg count is usually found on fecal flotation, since *Haemonchus* is a prolific egg-layer. However, in peracute prepatent infections, no eggs will be present. In recently treated animals, no worms may be present, and the diagnosis may have to be presumptive. On the other hand, treated animals returned to contaminated pasture may succumb to reinfection within 2–3 weeks. A serologic test targeting a somatic antigen has been developed.

Trichostrongylus axei infection

Trichostrongylus axei infects the *abomasum of cattle, sheep, and goats*, and the *stomach of horses*. It has a direct life cycle: third-stage infective larvae enter tunnels in the epithelium of the foveolae and neck of gastric glands in both fundic and pyloric areas. The worms live throughout their life *partly embedded in intraepithelial tunnels* at about this level of the mucosa. They molt to the fourth stage about a week after being ingested and to the fifth stage by ~2 weeks after infection. The prepatent period is ~3 weeks in calves and sheep, and about 25 days in horses.

Infections with *T. axei* are usually part of a *mixed gastrointestinal helminthosis*. However, in all hosts this species alone is capable of inducing disease, if present in sufficient numbers. After a period of several weeks, *mucous metaplasia and hyperplasia are seen in glands in infected areas of the mucosa*. In severely affected animals, flattening of surface epithelium with desquamation, or erosion of the mucosa, develops, accompanied by effusion of neutrophils, eosinophils, and tissue fluid. Fibroplasia may occur in the superficial propria in eroded areas.

In light infestations there may be no changes visible in the abomasum other than congestion of the mucosa. The gross lesions present in heavy *T. axei* infections reflect the hypertrophy of glands, and superficial erosion. *Circular or irregular raised white plaques of thickened infected mucosa* are present, often with a thick layer of mucus. Erosions or shallow ulcers may be present. In severe infections the entire mucosa appears edematous and congested.

Infection in horses is uncommon and is usually related to sharing pasture with sheep or cattle. In chronically infected horses, white raised plaques (Fig. 1.181) or nodular areas of mucosa are present, covered by tenacious mucus and surrounded by a zone of congestion. Mucosal lesions may be confluent in heavily infected animals, and erosions and superficial ulceration may be encountered. Infection may extend into the proximal duodenum, where polypoid masses of hypertrophic glandular mucosa are occasionally observed. Plasma pepsinogen levels may be elevated.

Achlorhydria develops in heavily infected sheep and cattle, associated with *diarrhea*, particularly in the latter species. Dehydration may prove severe in scouring calves. Plasma pepsinogen and gastrin levels increase, and hypoproteinemia and *wasting* occur. This suggests that the mucous metaplasia in the glands is associated with increased permeability and that plasma protein loss occurs into the gastrointestinal tract.

Though *T. axei* is not common as a primary cause of disease in any species, it should be sought at autopsy of animals with signs of wasting and perhaps diarrhea. The typical gross lesions in the stomach are distinctive in horses. In ruminants, they must be differentiated from those due to *Ostertagia*, with which animals may be intercurrently infected. The worms are very fine, and gastric washes or digestion are required to recover them quantitatively. The *distinctive intraepithelial location* of *T. axei* in section differentiates it from other nematodes inhabiting the abomasum of ruminants and the stomach of horses.

Gastric parasitism in horses

The commonest parasites of the equine stomach are *larvae of bot flies* of the genus ***Gasterophilus***. Though they are not helminths, it is convenient to consider them here. There are six species of the genus, the common ones being ***G. intestinalis***, ***G. nasalis***, and ***G. haemorrhoidalis***, and the uncommon ones being *G. pecorum*, *G. nigricornis*, and *G. inermis*. The ova are deposited on the ends of the coat hairs in the face, intermandibular region, or on the lower body and legs. The eggs hatch spontaneously, or when stimulated by licking. The first-stage larvae penetrate the oral mucosa, molt, emerge, and migrate down the alimentary canal.

Gasterophilus intestinalis usually wander about in tunnels in the superficial mucosa of the cheeks, tongue, or gums for 3–4 weeks before moving to periodontal pockets containing purulent exudate in the gingival sulcus on the lingual aspect of molars, especially in the upper arcade. Here they molt before moving on to the base of the tongue, and to the stomach. This is the most common species, and in the stomach it attaches itself to the squamous mucosa of the cardia to complete its subsequent molts. ***G. nasalis*** first invade the gums, where they may be associated with pockets of purulent exudate in the interdental spaces, then pass to the stomach and settle on the pyloric mucosa and in the first ampulla of the duodenum. Members of any of these species may occasionally be found attached to the pharynx and esophagus but, except for *G. pecorum* that congregates in the pharynx

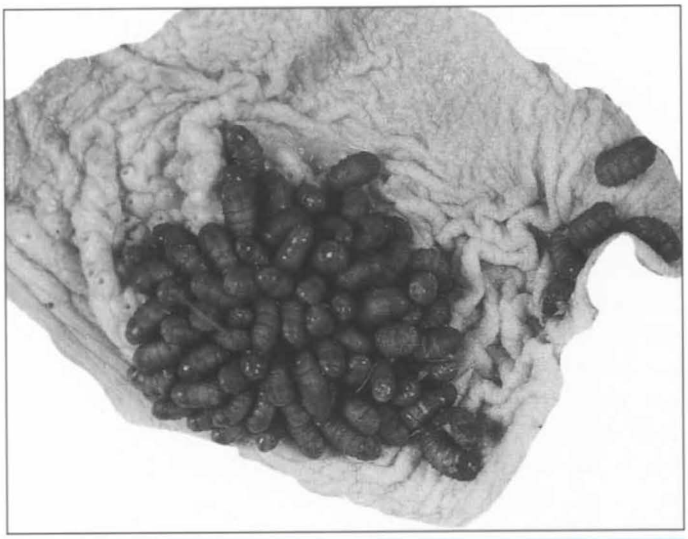

Figure 1.182 ***Gasterophilus* larvae** on gastric mucosa of a horse.

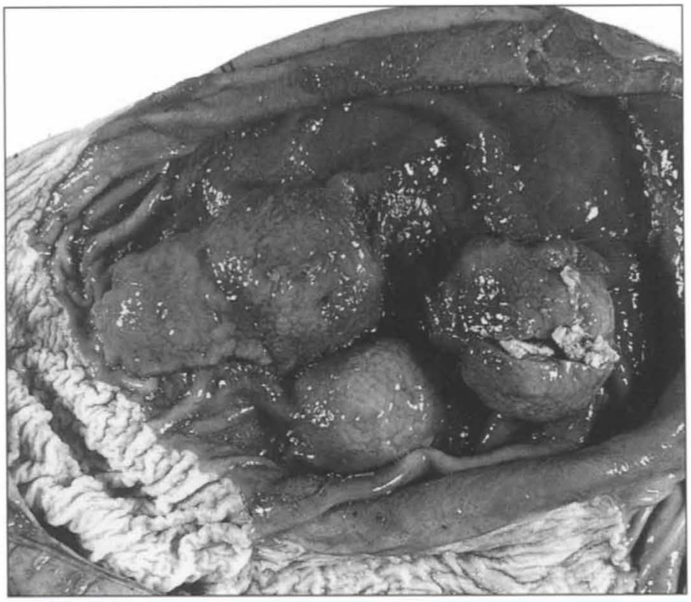

Figure 1.183 Nodules containing ***Draschia megastoma*** in the submucosa of glandular mucosa, near margo plicatus. Purulent content in sectioned nodule.

and causes pharyngitis, these preliminary migrations are uneventful for the host. In the summer following the deposition of the ova, the larvae leave the stomach and pass out in the feces to pupate. Those of *G. pecorum* and *G. haemorrhoidalis* may attach themselves for a short while to the wall of the rectum.

It is generally assumed that the larvae of *Gasterophilus* have little effect on their host. The larvae fasten themselves to the mucosa by chitinous oral hooks and they bore into the mucosa (Fig. 1.182). They apparently subsist on blood, exudate, and detritus, producing focal erosions and ulcerations at the point of contact. These defects in the cardia are surrounded by a narrow rim of hyperplastic squamous epithelium. Usually the number of epithelial defects exceeds the number of larvae, suggesting that they move about on the mucosa.

Severe infestations produce a dense pock-marked appearance of the pars esophagea, with chronic inflammatory thickening. Ulcers may occur in the glandular mucosa and, rarely, a large proportion of the affected pyloric mucosa may be lost. Healing occurs when the larvae migrate on, but may be complicated by secondary bacterial infection. Histologically, the ulcers penetrate the submucosa, which is chronically inflamed. The deep layers of eroded epithelium and the epithelial margins of ulcers in the squamous mucosa become hyperplastic and develop rete pegs. There seems to be no relationship between bot infestations and the development of gastric ulcers in the pars esophagea.

The **spirurid nematodes *Draschia megastoma*, *Habronema majus***, and ***H. muscae*** are also parasitic in the stomach of horses. The adult worms are 1–2 cm in length. The latter two species lie on the mucosal surface and are probably insignificant except possibly for a few erosions and mild gastritis. *D. megastoma* burrows into the submucosa to produce large tumor-like nodules (Fig. 1.183).

H. majus mainly uses *Stomoxys calcitrans* as its intermediate host and the other two species use various muscid flies. The *Habronema* larvae in the feces are swallowed by maggots of the appropriate intermediate host and persist through pupation and maturation of the fly. They leave the host fly via the proboscis when it seeks moisture, for instance, on the lips. Larvae deposited on or in cutaneous wounds, or in the eye, invade the skin or conjunctiva and provoke an intense local reaction, which becomes granulomatous and densely infiltrated with eosinophils (see Vol. 1, Skin and appendages). Occasionally *Draschia* and *Habronema* larvae may be found in the brain, or in the lungs, where they may become encapsulated and mineralize.

The only one of concern in the stomach is *D. megastoma*, which burrows into the submucosa of the fundus, usually within a few centimeters of the margo plicatus. Within the submucosa, the worms provoke a surrounding granulomatous reaction that contains them in a central core of necrotic and cellular detritus, with abundant eosinophils. These lesions form protrusions up to ~5 cm in diameter, with a small fistulous opening to the lumen. The nodules generally produce no clinical disturbance, though they have been considered to lead rarely to abscessation, adhesions of the stomach to the spleen, or perforation when infected with pyogenic bacteria.

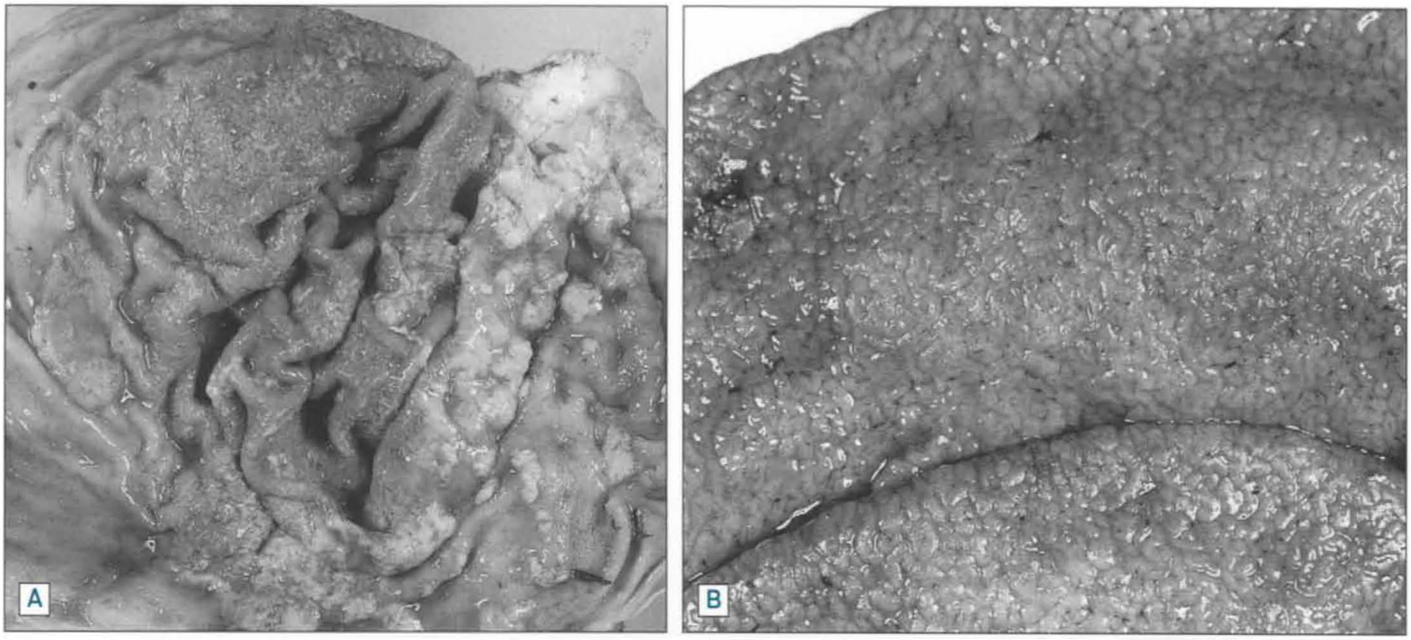
Gastric parasitism in swine

Gastric parasitism is not of great clinical or pathologic importance in swine and is rare in pigs reared in modern total confinement systems.



Ascaris suum, normally inhabiting the small intestine, may migrate or reflux to the stomach after death. *Hyostrongylus rubidus* is probably the most significant parasite of the stomach of swine; it and the various spirurids are more common in pigs allowed to forage. *Ollulanus tricuspis* is reported in pigs. It is more commonly encountered in cats, and is discussed with gastric parasitism in dogs and cats.

Hyostrongylus rubidus is a trichostrongylid nematode with a typical life cycle. Third-stage larvae enter glands in the stomach, especially in the fundic region, where they develop and molt twice. Pre-adult and adult worms emerge on to the gastric mucosa ~18–20 days after ingestion. The lesions produced by *Hyostrongylus* resemble those caused by *Ostertagia* in ruminants. There is *mucous metaplasia and hyperplasia of the lining of infected and neighboring glands*, and dilation of infected glands. The lamina propria in infected mucosa is edematous and infiltrated by lymphocytes, plasma cells, and eosinophils, and lymphoid follicles develop deep in the mucosa. Neutrophils and eosinophils may transmigrate the epithelium into dilated glands, the lining of which may become quite attenuated. There may be extensive erosions.

During the course of development of the worms, the mucous metaplasia and hyperplasia cause the formation of pale nodules in the vicinity of infected glands (Fig. 1.184A). In heavy infections these may become confluent, causing the development of an irregularly thickened convoluted mucosa (Fig. 1.184B), most notable in the fundic area and along the lesser curvature. Adult worms are fine, red, and thread-like in the gastric mucus; they are difficult to see with the naked eye.

Experimental infections of moderate degree do not produce obvious clinical signs or loss of production. However, loss of plasma protein has been documented in heavy *Hyostrongylus* infections. Inappetence, diarrhea, and reduced weight gains and feed efficiency also occur in these circumstances. In the field, hyostrongylosis is mainly associated with the "thin-sow syndrome," in which it seems probable that it may interact with nutritional and metabolic factors.

Spirurid nematodes parasitizing the porcine stomach include *Physocephalus sexalatus*, *Ascarops strongylina*, *A. dentate*, and *Simondsia paradoxa*. *Physocephalus* and *Ascarops* utilize dung beetles as intermediate hosts. ***Ascarops*** and ***Physocephalus*** are common in many parts of the world in swine with access to grazing. Large numbers of worms are required to cause ill-thrift. Worms in affected pigs may be free in the lumen or partly embedded in the mucosa, which may be congested and edematous, or eroded and ulcerated with fibrinous exudate on the surface. There may be chronic interstitial inflammation and fibrosis in the mucosa. ***Simondsia*** is found in swine in Europe, Asia, and Australia. The caudal portion of the female worm is globular, and is embedded in palpable nodules up to 6–8 mm in diameter in the gastric mucosa. *Gnathostoma doloresi* causes gastric ulcers and granulomas in pigs in eastern Asia. *G. hispidum* may cause lesions in the liver, and submucosal nodules in the gastric wall of pigs, similar to those produced by *G. spinigerum* in carnivores.

Gastric parasitism in dogs and cats

Parasites are uncommonly encountered in the stomach of dogs and cats at necropsy and most are incidental findings, or postmortem migrants from the intestine.

Gnathostoma spinigerum occurs in the stomach of dogs and cats, and of a variety of nondomestic carnivores. It is more common in areas with warm climates. The life cycle of this spirurid nematode involves *Cyclops* as an aquatic invertebrate intermediate host, and a variety of fish, amphibian, or reptiles as second intermediate hosts. Ingested third-stage larvae may migrate in the liver, leaving tracks of necrotic debris, which eventually heal by fibrosis. In heavy infections, lesions associated with larval migration may be found elsewhere in the abdominal and pleural cavities, and in the skin. Adults are found in groups of up to 10 in nodules in the gastric submucosa. Nodules are up to ~5 cm in diameter, and open into the gastric lumen. Portions of nematodes may protrude through this opening. The worms lie in a pool of blood-tinged purulent exudate in the lumen of the nodule, the wall of which is comprised of granulation tissue and reactive fibrous stroma. Focal granulomas may center on nematode ova trapped in the connective tissue. Infection with *Gnathostoma* has been considered significant. Illness and death may be associated with disturbance of motility, chronic vomition, and occasional rupture of verminous nodules on to the gastric serosa, leading to peritonitis.

A number of species of ***Physaloptera***, including *P. praeputialis* (cat), *P. rara* (dogs and wild Canidae and Felidae) and *P. canis* (dog) are found in the stomach of dogs and cats. These nematodes utilize arthropod intermediate hosts and probably some vertebrate transport hosts. The adult worms, which may be mistaken for small ascarids, are found in the stomach, where they may be free in the lumen. More commonly they are attached as individuals or in small clusters to the gastric mucosa. Ulcers may be formed, and the cranial end of the worm may be embedded in the submucosa. Hyaline periodic acid–Schiff-positive material surrounds the cranial end of some worms, perhaps anchoring them in the tissue. These nematodes are not highly pathogenic, though heavy burdens may have the potential to cause significant gastric damage and chronic vomition.

Cylicospirura felineus and members of the genus ***Cyathospirura*** may be found in the stomach of domestic and wild felids. *Cylicospirura* are usually found in the submucosal nodules, similar to those formed by *Gnathostoma*, while *Cyathospirura* is usually found free in the lumen, or sometimes associated with *Cylicospirura* in gastric nodules. The pathogenicity of these species is poorly defined, but is likely low.

Ollulanus tricuspis is a small trichostrongyle, ~1 mm long, which inhabits the stomach of cats and swine. It is viviparous, and third-stage larvae developing in the uterus of the female are transmitted in vomitus. As a result, infection is usually not detected by fecal examination, and infection with this species may go unnoticed. In some parts of the world it is common, particularly in cat colonies and cats that roam. Clinical signs and gross lesions due to *O. tricuspis* are uncommon. *Vomition, anorexia, and weight loss* are the signs most frequently associated with infection. The worms lie beneath the mucus on the surface of the stomach, or partly in gastric glands. Infection is associated with increased numbers of lymphoid follicles deep in the gastric mucosa, increased interstitial connective tissue in the mucosa, and numerous globule leukocytes in the gastric epithelium. Heavy infection results in mucous metaplasia and hyperplasia of gastric glands, causing the surface of the stomach to be thrown into thickened convoluted folds, grossly resembling idiopathic hypertrophic gastritis of dogs. Gastric glands are often separated by the heavy reactive fibrous stroma in the mucosa. In gastric biopsies, this suite of microscopic changes in the mucosa should be recognized as characteristic of *Ollulanus* infection, even if worms are not present. *Ollulanus* are characterized in section by the numerous longitudinal cuticular ridges (synlophe) recognized as projections on the surface of sectioned worms.

Intestinal helminth infections

Strongyloides infection

Strongyloides spp. parasitize all species of domestic animals considered here. Ruminants are infected by *S. papillosus*; horses by *S. westeri*; swine mainly by *S. ransomi*; dogs by *S. stercoralis*; and cats by *S. felis*, *S. planiceps* (= *S. catti*), and *S. stercoralis* in the small intestine, and by *S. tumefaciens* in the colon. The parasitic worms are parthenogenetic females, which produce larvae capable of direct infection of the host, or of developing into a free-living generation of males and females. The offspring of the free-living generation then adopt a parasitic existence.

Infection by third-stage larvae takes place by skin penetration, or to a lesser extent by ingestion and probably subsequent penetration of the gastrointestinal mucosa. Larvae attain the bloodstream, and in young animals, break out into pulmonary alveoli. They migrate to the large airways, whence they are carried up the mucociliary escalator to be swallowed, and establish in the small intestine.

Typically infecting the proximal small intestine of all species, *Strongyloides larvae establish in tunnels in the epithelium about the base of villi or in upper crypts*, and they persist in that location (Fig. 1.185). Adult worms are small, only 2–6 mm long, depending on species. In sufficient numbers, they cause villus atrophy, associated with a mixed, but mainly mononuclear inflammatory cell infiltrate into the lamina propria. Cryptal epithelium is hyperplastic. Villi are stumpy or there is subtotal villus atrophy. Surface epithelium is usually low columnar to cuboidal, with an indistinct brush border; it may be squamous, or in some cases, eroded. The nematodes are usually found in tunnels in the surface epithelium, not beneath the basal lamina. Embryonated or larvating ova may be retained in epithelial tunnels, and help to distinguish this nematode in tissue section from *Trichostrongylus*, in hosts in which both species occur.

Strongyloides ransomi is responsible for *diarrhea in suckling piglets* in some parts of the world. Minor local hemorrhage occurs as larvae migrate through the lungs, and thickening of alveolar septa is reported, associated with scattered aggregates of lymphocytes and plasma cells. In the duodenum, villus atrophy is associated with local malabsorption

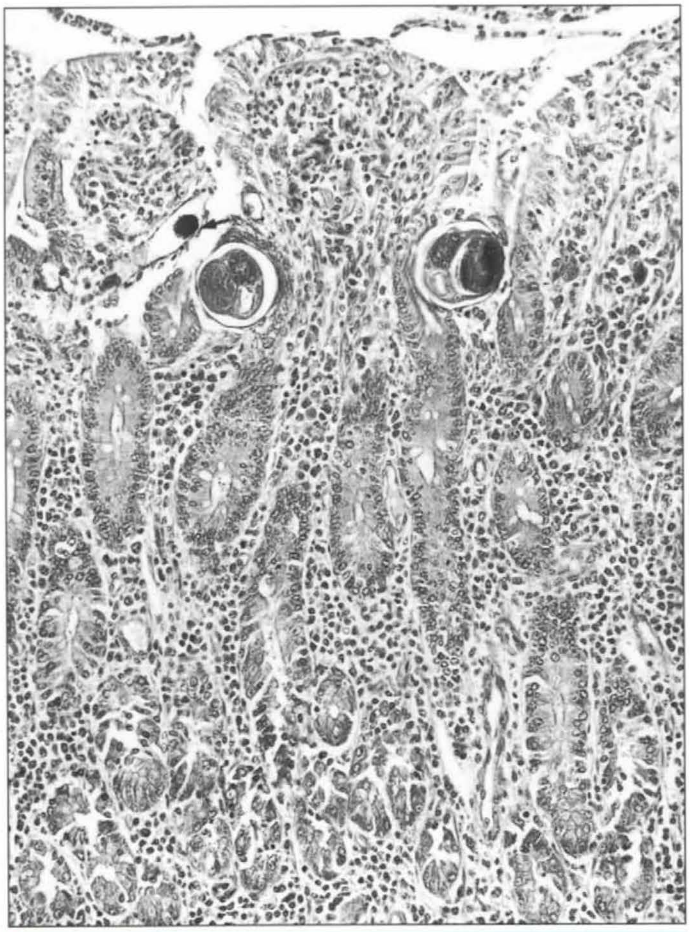

Figure 1.185 ***Strongyloides westeri*** in tunnels at base of a moderately atrophic villus in the intestine of a foal with diarrhea. An ovum is in a tunnel on an adjacent villus (arrow).

of amino acids, and with protein loss into the gut. Diarrhea occurs, presumably the result of malabsorption. Debilitation is the product of anorexia, protein loss into the gut, and nutrient malabsorption. Specific gross lesions other than those associated with diarrhea may be absent. Moderate to severe clinical disease in 3-month-old pigs is associated with 20 000–70 000 worms, most in the cranial 30–40% of the small intestine. Worms are evident in mucosal scrapings at autopsy.

S. westeri commonly infects *foals*. It is associated with diarrhea, occasionally fatal, in some animals under 4–5 months of age (Fig. 1.185). It is claimed that skin lesions by larval penetration may permit entry of *Rhodococcus equi*, which causes lymphadenitis. Millions of larvae are necessary to cause fatal infections experimentally.

S. papillosus may cause diarrhea and, in occasional overwhelming infections, death, in *suckling ruminants*, or young animals being artificially reared. There is also a syndrome of sudden death due to cardiac failure that is associated with heavy infections of *S. papillosus*, the pathogenesis of which is unclear.

S. stercoralis infections are most commonly fatal in *puppies* up to 2–3 months old, often from kennel environments. Affected dogs are wasted and dehydrated with evidence of diarrhea, perhaps blood-tinged, but the intestine may only be congested or unremarkable at autopsy. Severe villus atrophy and heavy mononuclear interstitial infiltrates are evident in the duodenum of affected dogs. Occasionally larvae may be present in granulomas in the lamina propria and submucosa. Focal interstitial pneumonia may be associated with pulmonary migration. There are numerous reports of *S. stercoralis* infecting humans, especially in situations of immunocompromise.

S. felis may cause mild focal granulomatous or eosinophilic interstitial pneumonia in response to lung migration of larvae. In some cases there is local adenomatous hyperplasia of the crypts of Lieberkühn in the vicinity of worms in the small intestine, but no more general lesions. Diarrhea is uncommon.

S. tumefaciens in cats has rarely been associated with chronic diarrhea. It differs from the other species discussed above, in being associated with the formation in the colon of submucosal nodules of proliferative glands, in which the worms are found. It is uncertain whether this is a specific lesion induced by infection, or merely herniation of infected colonic glands into space left by involution of a submucosal lymphoid follicle.

Intestinal trichostrongylosis

Members of the genus *Trichostrongylus* parasitize the *proximal small intestine of ruminants* the world over. They cause significant subclinical inefficiency in production, or clinical disease characterized by *diarrhea, ill-thrift and, in some cases, death*. The most important species infecting sheep and goats are ***T. colubriformis***, ***T. vitrinus***, and ***T. rugatus***; others include *T. longispicularis*, *T. falculatus*, *T. capricola*, and *T. probolurus*. *T. colubriformis* and *T. longispicularis* also parasitize cattle. Though some *T. axei* may be found in the duodenum of cattle and sheep, this species is primarily parasitic in the abomasum.

Trichostrongylosis is most important in zones with a cool climate at some time of the year, but without extreme winters. It is a very important problem in many sheep-grazing areas of New Zealand, Australia, South Africa, South America, and the UK.

The life cycle is direct. Ingested third-stage larvae exsheath in the acid abomasal environment and establish preferentially in the proximal 5–6 meters of the small intestine in sheep. A small proportion of the population settles in the abomasal antral mucosa near the pylorus. The larvae in the intestine enter tunnels above the basal lamina, between enterocytes, mainly at the base of villi, and they persist throughout their life at least partially embedded in the epithelium. Usually, infecting larvae all develop over ~2 weeks into adult worms, with a prepatent period of ~16–18 days.

Experimental infections of all *Trichostrongylus* species studied indicate that the lesions and pathogenesis of disease caused by them are similar, though *T. vitrinus* seems more pathogenic than *T. colubriformis* and *T. rugatus*. Villus atrophy occurs in areas of intestine heavily populated by the worms, and the severity of the lesion within individual animals is correlated with the local density of the worms. The mechanism by which the atrophy occurs has not been investigated. However, in experimental infections, hyperplasia of cryptal epithelium seems to precede the onset of villus atrophy, which may be T-cell mediated.

The established lesion is characterized microscopically by *villus atrophy* that may vary considerably in severity (Fig. 1.186), in association with elongate, dilated, often straight crypts containing many mitotic cells. Goblet cells may be numerous in crypts in some infected animals. In animals with subtotal villus atrophy, the surface epithelium may vary from tall columnar relatively normal-appearing cells, to more domed or cuboidal epithelium lacking a well-defined brush border. Ultrastructurally, such epithelium appears poorly differentiated, containing numerous polyribosomes in the cytoplasm, and with stumpy, sparse, and irregularly oriented microvilli. In animals with subtotal villus atrophy, exfoliating rounded enterocytes are seen, as are focal and probably transient "leaks" of neutrophils and tissue fluids through the epithelial surface. In animals with more severe atrophy, the surface epithelium is flattened between the openings of crypts, and erosions of the mucosa may be evident, from which inflammatory cells and tissue fluid effuse.

The lamina propria in the affected area of intestine is populated by a moderately heavy mixed inflammatory cell population. Lymphocytes and plasma cells are prominent between crypts, with an admixture of eosinophils. Globule leukocytes may be present in the epithelium of crypts and occasionally villi, but this is often not marked in severely affected mucosa. The presence of globule leukocytes is associated with a positive immune response. In the superficial lamina propria, neutrophils often accumulate beneath the epithelium, and in areas of erosion or previous erosion there may be a thin transversely oriented layer of connective tissue. Abnormal permeability of the endothelium of capillaries and venules in heavily infected mucosa has

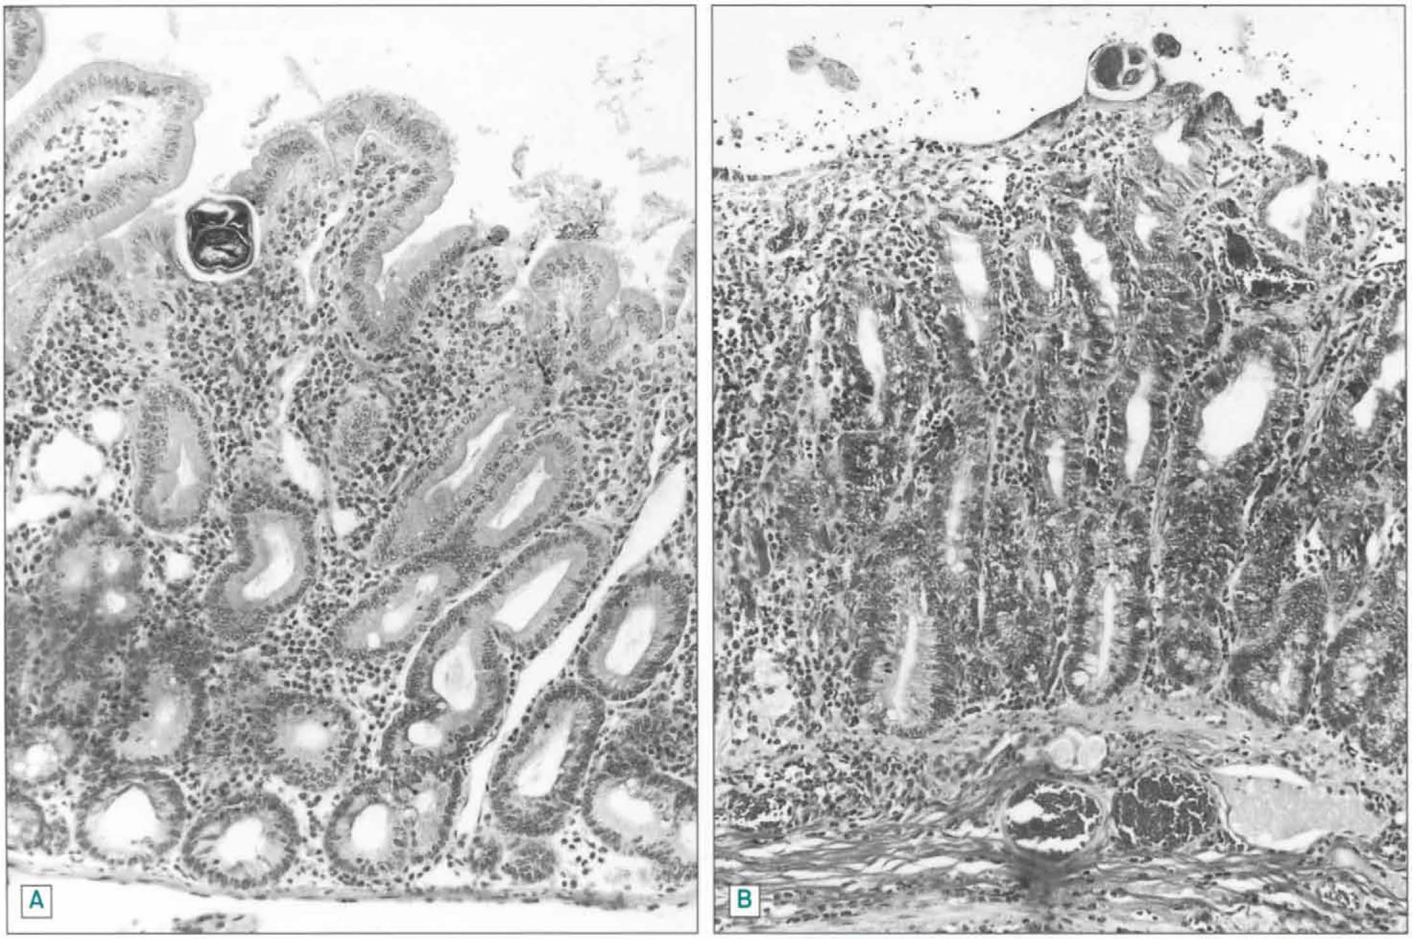

Figure 1.186 Intestinal trichostrongylosis in a sheep. **A.** Subtotal villus atrophy, caused by ***Trichostrongylus colubriformis***. Exfoliation of enterocytes, focal effusion of tissue fluid, dilated crypts, and mononuclear cells in lamina propria. **B.** Severe villus atrophy. Surface epithelium is attenuated or eroded, and crypts are hyperplastic. Nematode in tunnel in surface epithelium.

been demonstrated, and edema of the lamina propria may be evident in these areas.

The disease is marked clinically by depression, inappetence, which may be mild or profound, and by diarrhea and wasting. The cause of the inappetence is unclear. The pathogenesis of the diarrhea is uncertain. It is associated with the period when inappetence and gastric dysfunction occur. Though local malabsorption of nutrients, and presumably electrolytes and water, occurs in the duodenum, it seems unlikely that the absorptive capacity of the remaining small intestine and large bowel would be overwhelmed.

Weight loss or reduced productive efficiency is not related to nutrient malabsorption, since net absorption of nutrients over the length of the small intestine does not seem to be severely affected. Rather, the interaction of reduced feed consumption with increased loss of endogenous nitrogen into the gut seems to be responsible. There is considerable effusion of plasma protein into the intestine of infected animals, and this, coupled with exfoliation of epithelium that appears to be turning over at an increased rate, is the source of *protein loss*. In trichostrongylosis, compensation for increased catabolism of plasma protein and mucosal epithelial protein is at the expense of anabolic processes elsewhere in the body. Wool and muscle growth are hindered. Osteoporosis may occur.

Animals succumbing to trichostrongylosis are usually cachectic and dehydrated. Dark-green scoured feces will be on the skin or wool of the escutcheon or breech. There may be serous atrophy of internal fat depots, and marked atrophy of skeletal muscle. The subcutis is tacky. There may be edema of the mesentery and perhaps serous effusion into the body cavities, associated with hypoproteinemia, if dehydration is not severe. Mesenteric lymph nodes are enlarged and wet. The intestines are flaccid and the small bowel contains thin fluid green content, which in the duodenum may appear somewhat mucoid. The large intestine may contain similar fluid or pasty green, foul-smelling feces.

The mucosa of the duodenum in the freshly killed animal may be glistening and pink, but in spontaneous mortalities with superimposed postmortem change, it will be unremarkable. The proximal third of the small intestine (~5–7 meters) contains the bulk of the population of *Trichostrongylus*. A worm count on the small bowel usually reveals 15 000–80 000 *Trichostrongylus* in severe clinical infections. Subclinical or mild disease may be associated with fewer worms. The *diagnosis* is based on recovery of substantial populations of *Trichostrongylus* spp. in association with the clinicopathologic syndrome and villus atrophy. Mixed infections with other genera are common.

Nematodirus and *Cooperia* infection

Nematodirus species infect the *proximal third of the small intestine of ruminants*. The most important species are *N. helvetianus*, which infects cattle; *N. spathiger*, *N. filicollis*, and *N. abnormalis*, which infect sheep, goats, and cattle; and *N. battus*, a parasite mainly of sheep, which will cause disease in calves.

The life cycle is direct. However, hatching of infective larvae of *N. battus* and *N. filicollis* from the egg is delayed. Eggs of *N. battus* deposited on the ground in one year hatch the next spring, following a period of conditioning by cold over winter. The epizootiologic pattern is that of infection of a susceptible lamb crop during one year by larvae produced by the previous year's lambs. Under these conditions, with many infective larvae, parasitic enteritis dominated by *Nematodirus* may occur. The larvae of *N. spathiger* and *N. helvetinus* are not delayed in hatching, and their epizootiologic pattern resembles that of *Trichostrongylus* spp. in grazing animals. They often form part of a mixed population of worms in parasitic gastroenteritis in grazing lambs and calves. The disease may occur in yarded calves as well as animals at pasture.

Third-stage larvae enter the deeper layers of the mucosa, perhaps entering crypts. Larvae emerge at the fourth or fifth stage to take up residence coiled among the villi, with their caudal ends protruding toward the lumen. They do not normally penetrate the epithelium.

The presence of large numbers of some *Nematodirus* species is associated with the development of villus atrophy, which is usually moderate in comparison with that induced by *Strongyloides* or *Trichostrongylus*. Villi are stumpy, bifurcate, perhaps fused, or ridge-like surface alterations that may replace the normal villus structures. Crypts may appear elongate and dilated.

Surface enterocytes may be domed, with loss of the prominent brush border, and irregular nuclear polarity. Ultrastructurally, such cells appear poorly differentiated and have irregular, deformed microvilli. Biochemical studies reveal reduction in levels of mucosal alkaline phosphatase and disaccharidases, which correlate with the severity of diarrhea in affected sheep.

The pathogenesis of the villus atrophy has not been determined, but it may be related to the development of an immune response to the nematodes in the lumen. A moderate mixed inflammatory response with substantial numbers of lymphocytes, plasma cells, and eosinophils is evident in the lamina propria. The presence of such an infiltrate, and moderate shortening of villi associated with poorly differentiated surface enterocytes, is consistent with the postulated induction of villus atrophy by cell-mediated immune activity in the lamina propria.

Lambs and calves with nematodirosis develop *severe dark-green diarrhea*, which stains the escutcheon or the breech of lambs. Affected animals may become inappetent, scour, and waste for several weeks before recovering, or they may die acutely. Disease is presumably mainly related to malabsorption and loss of appetite. At necropsy, other than the changes associated with dehydration and cachexia, findings are limited to fluid mucoid content in the upper small intestine, and soft or fluid feces in the colon. The mucosa of the duodenum is usually unremarkable or perhaps hyperemic with excess mucus on the surface. Clinical disease is associated with populations of ~10 000–50 000 or more *Nematodirus*.

Cooperia infect the *upper small intestine of ruminants*. The important species include *C. curticei*, mainly in sheep and goats, and *C. pectinata*, *C. punctata*, and *C. oncophora*, mainly in cattle. The latter is regarded as the least pathogenic of the three. Though both sheep and cattle may suffer from mixed burdens of helminths containing or dominated by populations of *Cooperia*, this species seems to be more significant in cattle, especially in cool temperate regions.

Cooperia has a typical trichostrongylid life cycle, but larvae do have the capacity to undergo hypobiosis to carry the population through periods of regular climatic adversity. The normal prepatent period is ~16–20 days. Like *Nematodirus*, *Cooperia* do not tunnel in the epithelium, but rather brace or coil themselves among villi to maintain their place in the intestine. In light infections, the worms are concentrated in the proximal third of the small intestine. Heavier infections, perhaps because they are associated with villus atrophy and therefore loss of the substrate against which to brace, are more evenly distributed down the intestine.

Heavy burdens of *Cooperia* in calves, >70 000–80 000 nematodes, may be associated with *inappetence, reduced weight gain, or weight loss and diarrhea*, with protein-losing enteropathy in experimental infections. The associated atrophy of villi is concomitant with reductions in the brush-border enzymes. The syndrome is typical of intestinal helminthosis and the diagnosis is confirmed by finding large numbers of the fine, coiled *Cooperia* in the small intestine.

Hookworm infection

Members of the Ancylostomatidae infect dogs, cats, ruminants, and swine. Hookworms of the genus *Globocephalus* appear to be of little significance in swine. In dogs, *Ancylostoma caninum*, *A. braziliense*, and *A. ceylanicum* occur. The former is most common in tropical, subtropical, and warm temperate zones of Africa, Australia, Asia, and North America, where adequate humidity for larval development occurs. *A. braziliense* occurs in dogs and cats in the tropics and subtropics, while *A. ceylanicum* is found in both species in Sri Lanka and Southeast Asia. *Uncinaria stenocephala* occurs in dogs in cool temperate regions of Europe and North America. *A. tubaeformae* only occurs in the cat.

***Ancylostoma* spp.** are capable of infecting the host by four routes: (1) *orally*, with direct development to adult worms in the intestine; (2) by *skin penetration*, resulting in movement through the bloodstream to the lungs, and thence via the trachea to the pharynx and gut; (3) by the *lactogenic* transmission of third-stage larvae mobilized from dormancy in the skeletal muscle of parturient bitches; and (4) in occasional instances, by prenatal *transplacental* transmission of mobilized larvae. The latter route of transmission does not apparently occur in *A. braziliense* infection. Some larvae of *A. caninum* may become arrested at the third stage in the intestine, to resume development at a later time.

Ancylostoma spp. all usually *inhabit the small intestine*, where they move about the surface, several times a day attaching to feed, then moving on. They penetrate deeply into the mucosa, sometimes to, or through, the muscularis mucosae, taking a plug of tissue into the large buccal capsule. Tissue is lacerated by prominent teeth, and anticoagulant is released, permitting persistent blood flow. Blood-sucking activity begins when larvae enter the adult stage, in *A. caninum* ~8 days after infection. Blood loss is maximal while worms are attaining maturity between 12 and 16 days after infection, and then again during the peak period of egg production after ~3.5 weeks of infection. The prepatent period for *A. caninum* is ~15 days.

Ancylostomosis is the result of persistent blood loss, resulting in anemia and hypoproteinemia. There is considerable variation in the blood-sucking activity, and therefore the pathogenicity, of the members of the genus. *A. caninum* consumes in the range of 0.01–0.2 mL of blood per worm per day. Pups several months old with populations of the order of 300–400 worms may lose 10–30% of their blood volume per day, depending on body weight. *A. tubaeformae* in cats is a significant blood sucker. Experimentally, about 200 worms may cause anemia, weight loss, and mortality in 1.5 kg cats.

The anemia in ancylostomosis is at first normochromic and normocytic. Small size, poor iron reserves, and the low level of iron in bitch's milk make suckling pups with ancylostomosis susceptible to rapid development of the microcytic hypochromic anemia characteristic of iron deficiency.

Acute fatal ancylostomosis occurs most commonly in pups only 2–3 weeks of age, infected via the bitch's milk. Heavy infections acquired by this route may result in death from anemia and hypoproteinemia within a few days of initiation of blood-sucking activity, and before eggs are present in the feces. Anemia may also lead to mortality of pups after a course of longer duration. Percutaneous infection results in disease in older dogs held in runs or kennels under conditions of moisture and temperature conducive to larval development on the ground. Dermatitis due to larval penetration may be observed between the toes or on ventral contact surfaces of the body. Ancylostomosis in older dogs is usually typified by anemia, lack of exercise tolerance, weakness, and emaciation. Feces may be diarrheic, dark red or black, and are often mucoid. The major effect of ancylostomosis is due to increased loss of erythrocytes, iron, and plasma protein.

Animals dying of ancylostomosis are characteristically *extremely pale*. There is often glistening edema of subcutaneous tissues and mesenteries, and serous effusion into body cavities, attributable to hypoproteinemia. In chronic infections, cachexia may be evident. If recent exposure to heavy percutaneous infection has occurred, there may be dermatitis, and numerous focal hemorrhages scattered in the pulmonary parenchyma, reflecting disruption of vessels by larvae breaking out into alveoli. The intestinal content throughout the entire length is mucoid and deep red, from the erythrocytes voided into it by the worms (Fig. 1.187). The latter are visible, ~1–1.5 cm long, translucent, gray or red, depending on when they last consumed blood, dispersed over the mucosa, sometimes into the large intestine. They are often attached to the mucosa, and pinpoint red sites of recent feeding activity may be scattered over the intestinal surface. In a young pup, as few as 20–50 worms may be present in fatal infections, and they may be sufficiently sparsely scattered as to be overlooked, if not sought.

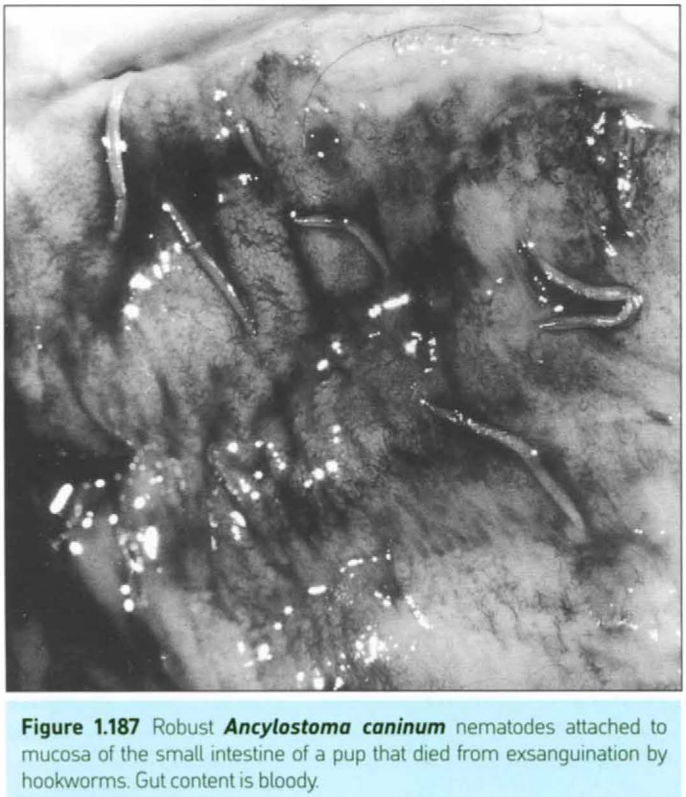

Figure 1.187 Robust ***Ancylostoma caninum*** nematodes attached to mucosa of the small intestine of a pup that died from exsanguination by hookworms. Gut content is bloody.

Uncinaria stenocephala mainly infects by the oral route; percutaneous infection is not efficient, though dermatitis may result; and prenatal and lactogenic transmission appear not to occur. This species sucks little blood and is much less pathogenic than *A. caninum*. However, heavy infections with this species, usually arising in contaminated communal kennel environments, may cause clinical disease and occasional mortality in pups. *Nonspecific lethargy, inappetence, and ill-thrift* are signs of infection, perhaps with diarrhea; anemia does not occur. Disease is associated with burdens of over ~1000 worms. The intestinal mucosa appears thickened, with scattered focal hemorrhages at sites of attachment.

The presence of large numbers of worms is associated with moderate atrophy and thickening of villi. The surface epithelium is irregular. Focal aggregates of mononuclear cells and some neutrophils are in the vicinity of the cranial end of worms embedded deep in the mucosa, a plug of tissue within their buccal cavity. Disease due to *U. stenocephala* may be related to villus atrophy, with protein loss into the gut, and perhaps malabsorption. Hypoproteinemia may be evident, but anemia does not occur. A similar syndrome may be associated with heavy infections of *A. braziliense*, in which hypoproteinemia also occurs.

All of these hookworms, but most especially *A. braziliense,* are associated with the development of cutaneous larva migrans in humans, as larvae can penetrate intact skin. *A. caninum* has been shown to cause eosinophilic enteritis in humans as well.

The **hookworms of ruminants** include: in cattle, *Bunostomum phlebotomum*, and in India and Indonesia, *Agriostomum vryburgi*; in sheep, *B. trigonocephalum* and, in India and Southeast Asia, Africa, and South America, *Gaigeria pachyscelis*. The life cycle of these nematodes is typical of hookworms. *Bunostomum* third-stage larvae infect by the oral or percutaneous routes, while *Gaigeria* only infect across the skin. Eggs and larval stages on the ground are extremely susceptible to desiccation, and hookworm disease in ruminants is most common in tropical or subtropical areas during wet seasons. However, stabled animals in cooler temperate areas may suffer disease resulting from larvae invading the skin from contaminated bedding. Following skin penetration, the usual pattern is seen, with migration of larvae to the lungs, where they molt to the fourth stage, and subsequently pass up the trachea to the digestive tract. Larvae taken in by ingestion spend some time in the deep mucosa of the intestine before emerging to mature in the lumen of the small intestine. The prepatent period of *Bunostomum* is long, ~7–8 weeks. *Gaigeria* larvae migrate via the lungs, and worms begin to lay eggs ~10 weeks after infection.

Both *Bunostomum* and *Gaigeria* cause *hemorrhagic anemia and hypoproteinemia*, especially in animals under a year of age. These species often occur with mixed gastrointestinal helminth burdens, and their effects are at least additive to those of the other worms. As few as 20–30 *Gaigeria* will cause anemia and hypoproteinemia in lambs and kids, though several times that number may be more usual in fatal cases. The size of the animal, the status of its iron reserves, and the plane of nutrition, especially the level of protein, likely influence the pathogenicity of these species.

At autopsy, the lesions expected in anemia and hypoproteinemia are evident. *Bunostomum* are often found in the lower half of the small intestine, while *Gaigeria* tends to be concentrated high in the duodenum. Blood and bite marks may be evident on the mucosa in the infected areas of intestine, but hemorrhage may be occult. The relatively low numbers of worms associated with disease, and their peculiar distribution, dictate that the entire gut be examined and flushed, and a careful search be made for these species in suspect cases.

Oesophagostomum and *Chabertia* infection

Members of the genus ***Oesophagostomum*** infect *sheep, cattle, and swine*. They form *inflammatory nodules in the wall of the intestine*, incited by histotropic larval stages. *Ill-thrift*, *diarrhea*, and, in cattle, *anemia*, can be induced by adult populations in the lumen of the colon.

In **sheep**, two species, *O. columbianum* and *O. venulosum*, are probably most significant; the former is considerably more pathogenic and is particularly important in warm temperate to tropical areas. Third-stage *O. columbianum* penetrate deeply into the lamina propria, or sometimes to the submucosa, mainly in the small intestine, where they normally spend ~1 week. They molt, emerge, and mature in the colon. However, a proportion of fourth-stage larvae enter a second histotropic phase in nodules in the colonic submucosa. Adult worms in the colon may be pathogenic for lambs. Burdens of only a few hundred *O. columbianum* are associated with anorexia, mucoid feces or diarrhea, and ill-thrift.

At necropsy of animals with clinical oesophagostomosis, the carcass is emaciated, the mesenteric lymph nodes are enlarged, and the colonic mucosa is thickened, congested, and covered by a layer of mucus in which the worms are scattered. There is hyperplasia of goblet cells, and the lamina propria contains a heavy mixed inflammatory infiltrate with eosinophils and many immune-active cells. Globule leukocytes are in the epithelium of glands. Nodules caused by histotropic fourth-stage larvae, mainly in the large intestine, are ~0.5–1 cm in diameter and are comprised of a central caseous or mineralized core surrounded by a thin fibrous encapsulating stroma. Microscopically, the nematode (or its remnants) is present among a mass of necrotic debris in which eosinophils are prominent. Giant cells and macrophages may surround the necrotic material. Similar nodules may be found in liver, lungs, mesentery, and mesenteric lymph nodes. Those in the deeper layers of the gut project from the serosal surface, hence the name *"pimply gut."* They may cause adhesion to adjacent loops of gut or to other organs, and rarely may incite intussusception or peritonitis. However, in most cases, nodules are incidental findings at necropsy. *O. venulosum* is a much less significant parasite. It seldom causes significant nodule formation; when it does, the nodules are small and mainly in the cecum and colon.

In **cattle**, two species, *O. radiatum* and *O. venulosum*, occur, the former being the significant parasite. The life cycle is similar to that of *O. columbianum*. The disease caused by *O. radiatum* is characterized by *loss of appetite, reduced productive efficiency, anemia, hypoproteinemia, and diarrhea*. Anemia results from hemorrhage at sites of larval emergence, and from mucosal erosions and discontinuities in the gland lining, associated with maturing and adult populations of worms. Considerable exudation of tissue fluids and plasma protein from colonic lesions, in addition to that due to hemorrhage, contributes to the hypoproteinemia and gastrointestinal protein loss. Reduced growth, or loss in condition, is mainly the product of the interaction between protein effusion into the gut and inappetence. Diarrhea presumably results in part from loss of colonic absorptive capacity.

Oesophagostomosis may be fatal in calves. Animals may be pale from anemia, and edematous from hypoproteinemia. Cases of some duration will be cachectic. Colonic lymph nodes are enlarged. The mucosa of the colon is grossly thickened and folded by edema and increased mixed inflammatory cell infiltrates, including many immune-active cells, in the lamina propria. Colonic submucosal lymphoid follicles are large and active. Pathogenic worm burdens in calves are in the range of ~1000–10 000 *O. radiatum*. Although repeated exposure to infective larvae may result in the accumulation of large numbers of fourth-stage worms in nodules, formation of nodules has little pathogenic significance in cattle.

In **swine**, *O. dentatum*, *O. quadrispinulatum*, and several other species occur in the large intestine; the two mentioned are most widespread. The life cycle is typical of the genus. Third-stage larvae enter the wall of the cecum and colon, where they encyst and molt to the fourth stage, emerging ~1 week later to mature in the lumen. There is some indication that inhibitors of eicosanoid metabolism (indomethacin, acetylsalicylic acid) will suppress migration of these third-stage larvae. The larvae initially lie about the level of the base of the mucosa. They incite a reaction which causes local loss of the muscularis mucosae, so that the nodule formed involves both mucosa and submucosa, and the larvae ultimately reside in the submucosa. The nodules are grossly ~1–20 mm in diameter, umbilicate, and may contain yellow or black cheesy exudate in the center. Once the larvae molt and begin to move to the lumen, an intense influx of eosinophils and neutrophils occurs into the nodules, and a focus of necrotic debris and fibrin lies over the evacuated nodule.

Mucosal and submucosal edema causes thickening of the wall of the large bowel, and contraction of the cecum. Mucosal crypts elongate with increasing worm burdens. Lesions resolve following emergence of larvae.

Oesophagostomosis in swine is a *mild, usually subclinical disease*. Occasional diarrhea, depression in weight gain, and inefficiency of feed conversion may occur, especially during the period of emergence of larvae and maturation of worms in the lumen of the large intestine. Burdens of ~3000–20 000 adult worms are associated with subclinical disease experimentally. The nematodes are ~1–2 cm long, white, and are present in mucus on the surface of the gut, or in luminal content. Massive repeated challenge will cause severe typhlocolitis, but this seems to be purely an experimental phenomenon.

Chabertia ovina, a robust worm ~1–2 cm long, inhabits the *colon of sheep, goats, and cattle*. It is particularly a problem in cooler climatic zones, mainly in sheep. Phylogenetic analysis based on ribosomal DNA sequence data indicates that *C. ovina* is clustered within the Oesophagostominae. The life cycle of *Chabertia* resembles that of *Oesophagostomum*; third-stage larvae encyst in the wall of the small intestine, then emerge to mature in the cecum and colon. Disease in sheep is associated with the presence of mature worms in the colon. Feces are soft, mucoid, and perhaps blood-flecked, and ill-thrift may occur. The adults penetrate to the muscularis mucosae and take a plug of mucosa into the buccal capsule; minor hemorrhage may be related to physical trauma to the mucosa. More significant is loss of plasma protein from the mucosa, associated with numerous focal sites of trauma, and with widespread areas of mononuclear infiltration in the mucosa and submucosa. There is also hyperplasia of goblet cells. Grossly the lesions are characterized by edema of all layers of the wall of infected parts of the colon, and enlargement of colonic lymph nodes. Worms are generally concentrated in the proximal portion of the spiral colon, and the area that they inhabit may have numerous hemorrhagic foci corresponding to sites of former attachment. Pathogenic burdens may be as few as 150 worms and the species must be sought in its usual site of predilection or be missed.

Equine strongylosis

Members of the family Strongylidae are common nematode parasites of the cecum and colon in horses, usually present as mixed infections. The subfamily Strongylinae, or **large strongyles**, includes the important genus *Strongylus* and the less significant genera *Triodontophorus*, *Oesophagodontus*, and *Craterostomum*. Members of this group are *plug feeders or blood suckers*, and *Strongylus* spp. undergo extensive extraintestinal migrations. The subfamily Cyathostominae, or **small strongyles**, includes eight genera of nematodes. Adults of this group *feed mainly on intestinal contents*, and are of little pathogenic significance. However, emergence of *histotropic larval stages* from the gut wall may cause disease.

Large strongyles

Strongylus vulgaris is relatively common, and has been considered the *most significant nematode parasite in horses*. However, infection levels have considerably decreased with the advent of improved anthelmintics. Larval forms cause *endoarteritis* in the mesenteric circulation, resulting in colic and infarction of the large bowel, while the adults cause *anemia and ill-thrift*. Infective third-stage larvae, ingested from pasture, penetrate the mucosa of the small and large intestine, and molt to the fourth stage. They enter the lumina of small arterioles, up which they migrate, on or under the intima, to reach the cranial mesenteric artery within 3 weeks. Three or 4 months later, after molting in that location to the fifth stage, the immature adults return down the mesenteric arteries to the wall of the cecum or colon, where they encapsulate in the subserosa, forming nodules ~5–8 mm in diameter. Returning larvae in nodules are surrounded by necrotic debris, neutrophils, some eosinophils, and macrophages, and the adjacent arteriole may be thrombosed. They eventually break into the lumen of the large bowel, especially cecum and right ventral colon, where they mature in another 1–2 months, ~6–7 months after infection. Some larvae may become trapped and encapsulated in arterioles in the mesentery on their way back to the gut, and remain there to die eventually.

Endoarteritis associated with migration and establishment of larvae in the cranial mesenteric artery and its branches is discussed in Vol. 3, Cardiovascular system, as are the consequences of aberrant migration in the aorta and other arteries. Syndromes associated with aberrant migration include *cerebrospinal nematodiasis* and *aortic-iliac thrombosis*. Lesions of the cranial mesenteric artery and of the cecal and colic arteries may lead to *colic* as a result of reduced perfusion or thromboembolism, or perhaps due to impingement upon autonomic ganglia in the vicinity of the arterial root at the aorta. Though many older horses are infected with adult worms, or have arterial lesions, the complications of colic and infarction caused by this parasite are most common in young horses. An *acute syndrome*, characterized by pyrexia, anorexia, depression and weight loss, diarrhea or constipation, colic, and infarction of intestine occurs in foals infected with large numbers of larvae, but not often in animals previously exposed to infection.

S. edentatus is also common and has a life cycle characterized by extensive larval migration. Third-stage larvae enter the intestinal wall and pass in the portal system to the liver where they incite inflammatory foci. Here they molt to the fourth stage and, ~30 days after infection, begin migrating through the hepatic parenchyma. The foci of inflammatory reaction in the liver are probably related to antigens

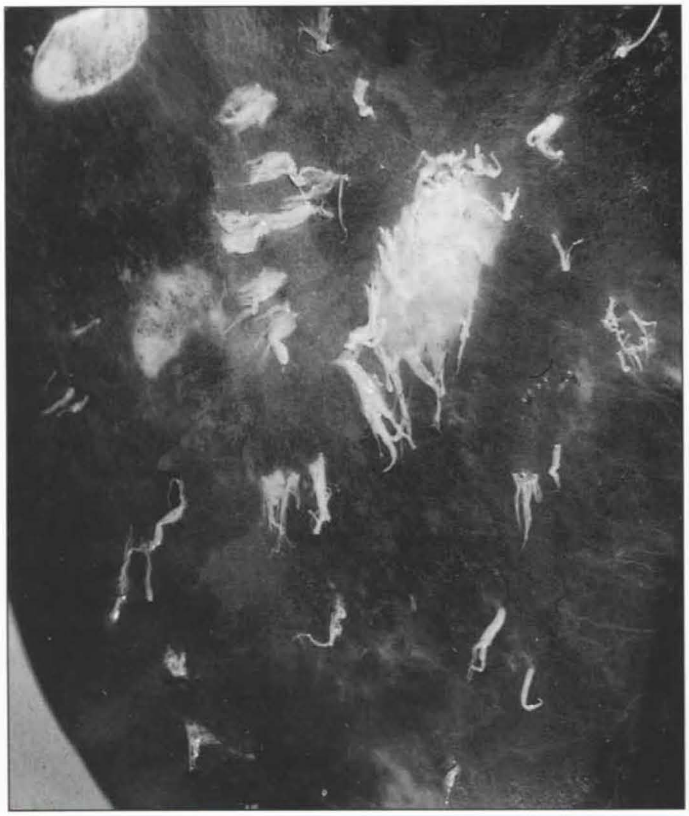

Figure 1.188 Fibrous tags and capsular scars, associated with migration of larval ***Strongylus edentatus***, on the diaphragmatic surface of a horse liver.

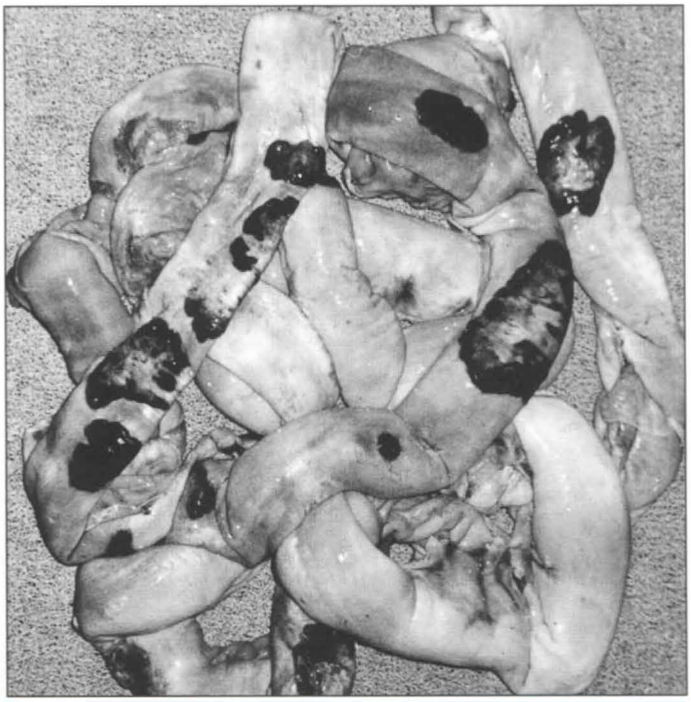

Figure 1.189 Hemomelasma ilei, large subserosal plaques of resolving hemorrhage on the small intestine of a horse, associated with damage caused by migrating larvae of **large strongyles**.

released by migrating and trapped larvae. They consist of a core of necrotic eosinophils, with a surrounding fibrous capsule, a mixture of neutrophils, eosinophils, and mononuclear cells, or recent necrotic foci or tracks infiltrated by neutrophils and a few eosinophils.

By 8–10 weeks after infection, larvae are migrating from the liver via the hepatic ligaments. Hemorrhagic tracks may be produced in the hepatic parenchyma. *Parenchymal scars and tags of fibrous tissue on the hepatic capsule*, especially the diaphragmatic surface (Fig. 1.188), commonly found at autopsy, are the legacy of migrating *S. edentatus*. Those migrating in the hepatorenal ligament enter the retroperitoneal tissue of the flank, where they may be encountered, often associated with local hemorrhage. Larvae in aberrant locations in the omentum, hepatic ligaments, and diaphragm may become encapsulated in eosinophilic granulomas and destroyed. Omental adhesions may also be a sequel to aberrant larval migration. In the flank, larvae persist for several months, molting to the fifth stage before returning from the right flank via the cecal ligament to the cecum and origin of the colon. Here they form nodules and edematous or hemorrhagic plaques in the wall of the gut, eventually perforating to the lumen, where they mature and begin to lay eggs ~10–12 months after infection. Lesions associated with the larval migration of *S. edentatus* are usually incidental findings at autopsy.

S. equinus is less prevalent and abundant than the other two members of the genus. Exsheathed third-stage larvae penetrate to the deeper layers of the wall of the ileum, cecum, and colon, molt to the fourth stage and produce hemorrhagic subserosal nodules, before moving to the liver through the peritoneal cavity. They migrate in the hepatic parenchyma for 6–7 weeks, then leave the liver, probably via the hepatic ligaments, to the pancreas and peritoneal cavity, where they molt to the fifth stage ~4 months after infection. They regain the lumen of the cecum and especially right ventral colon, by an unknown route, probably by direct penetration from the peritoneal cavity or pancreas. Pancreatic damage is usually mild and is mainly manifested by slight periductal infiltration of eosinophils.

Hemomelasma ilei is the term applied to slightly elevated *subserosal hemorrhagic plaques*, up to 1–2 × 3–4 cm in size, usually found along the antimesenteric border of the distal small intestine, or rarely on the large bowel (Fig. 1.189). They are associated with trauma by migrating larvae of *S. edentatus* in particular, but may be caused by larvae of any of the *Strongylus* spp. These lesions are comprised of edema, hemorrhage, and a mixed population of leukocytes, with macrophages ingesting erythrocytes prominent in evolving lesions. Occasionally a fragment of nematode or cuticle, or a migratory track, may be found in section. The lesion may be an incidental finding, and is probably a rare cause of clinical signs of colic.

Adults of all species in the Strongylinae are plug feeders and blood suckers. In sufficient numbers they may cause ill-thrift and anemia, as the result of active hematophagia and blood loss from recent sites of feeding activity. Increased albumin catabolism causing accelerated turnover of the plasma pool, and reduced red cell survival, have been demonstrated in horses infested with relatively low numbers (<100) of *S. vulgaris*. *Triodontophorus tenuicollis*, the most important species of that genus, tends to attach to the mucosa in clusters, usually in the right dorsal colon, causing local congestion and ulceration. *Triodontophorus* may be associated with significant blood loss.

Cyathostomins The **small strongyles**, or cyathostomins, are *essentially nonpathogenic as adults*, despite the fact that tens or many hundreds of thousands may be in the content of the large bowel.

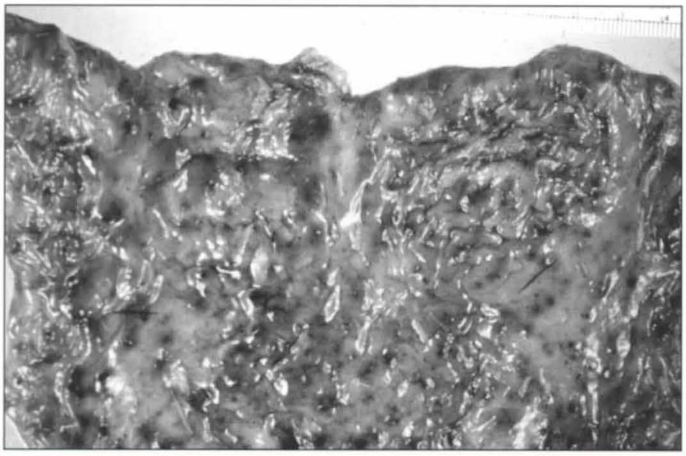

Figure 1.190 Equine colonic mucosa studded with 2–5 mm diameter nodules formed by **larval cyathostomins**, some of which are emerging, others of which have been released by incising nodules. Larvae are red due to nematode, not host, hemoglobin.

The larval stages migrate into the deep mucosa or submucosa of the large bowel (mainly cecum and ventral colon) to molt and develop, before emerging to the lumen to molt again and mature. Adults are mainly found in the dorsal and ventral colon. The third- or fourth-stage larvae may undergo hypobiosis or retarded development, persisting in nodules in the gut wall, only to mature sporadically, or perhaps more synchronously, as the adult population in the lumen turns over or is lost. Emergence of larvae causes rupture of the muscularis mucosae and intense local eosinophilia and edema, followed by infiltration of neutrophils and macrophages.

Mucosal nodules are up to only a few millimeters in diameter, slightly raised red or black, and may be umbilicate. Incision reveals a small translucent gray or red larval nematode. In heavy infections, the mucosa of the cecum and colon may be diffusely pocked by such nodules.

Disease attributable to larval cyathostomins usually occurs in heavily infected horses at the time of turnover of the adult population. It is due to *emergence of large numbers of hypobiotic larvae* over a short period, somewhat analogous to type II ostertagiosis in cattle. This occurs in the late winter, spring, and early summer in northern temperate climates. Cyathostominosis is a disease of horses over a year of age, and little resistance is apparent to repeated infection. Animals develop a syndrome characterized by *diarrhea, ill-thrift, and hypoalbuminemia*. In animals examined at this time, numerous nodules, containing immature cyathostomes or recently ruptured, are present in the mucosa of the cecum and colon (Fig. 1.190). The mucosa and submucosa are edematous and the mucosa congested and many recently emerged fourth-stage or early fifth-stage larvae may be in the gut content. Microscopically, there are numerous encysted cyathostomin larvae within the mucosa.

Ascarid infection

Members of the family Ascarididae are *common and important parasites of swine, horses, dogs, cats, water buffalo, and, to a lesser extent, cattle.* They do not normally occur in sheep and goats. Their importance is related to incidental and sometimes significant lesions caused by *larvae during migration* in the tissues of definitive and accidental hosts, and to the effects of *adult worms* in the small intestine of the definitive host.

Ascaris suum is a large parasite, usually found in the *upper half of the small intestine of swine*; females measure up to 40 cm long. The life cycle is direct. Infective larvae, present in the resistant egg, are released in the intestine and penetrate the mucosa to be carried in the portal blood to the liver. They then pass to the lungs in the blood, and break out of capillaries into alveoli. Third-stage larvae may be found in liver and lung 3–5 days after infection. Larvae move up the respiratory tree to the pharynx, where they are swallowed, arriving in the intestine about a week after infection. Worms mature in the intestine, and begin to lay eggs ~2 months after infection. Small doses of eggs more commonly give rise to patent infections than do large doses. This probably results from excessive loss of migrating larvae due to resistance incited by the antigenic mass of the heavier infections.

Larval migration induces lesions in the liver and lungs (Fig. 1.191). Infections heavy enough to cause clinical signs are rare in swine reared under conditions of good hygiene and husbandry. However, respiratory signs characterized by dyspnea (commonly termed "thumps") may occur in piglets if large numbers of larvae migrate through the lungs. Gross lesions in pigs, associated with pulmonary migration of ascarids, are largely limited to numerous focal hemorrhages scattered over and through the pulmonary parenchyma.

Microscopically there is eosinophilic bronchiolitis. Bronchioles are surrounded by macrophages and eosinophils, and the bronchiolar mucosa is thrown into small folds, the epithelium frequently disorganized or perhaps eroded. The bronchiolar wall is infiltrated by

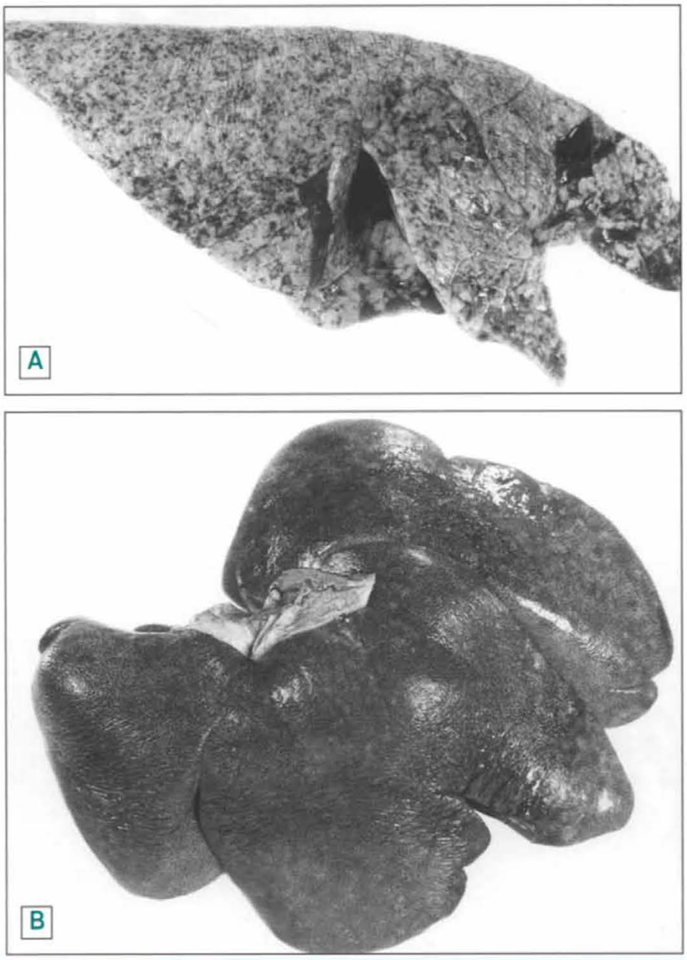

Figure 1.191 Effects of migrating ***Ascaris suum*** larvae in a pig. **A.** Multifocal parenchymal hemorrhages in the lung. **B.** Interstitial hepatitis.

eosinophils that are also present, with necrotic debris, in the lumen. There may also be an eosinophilic and granulomatous vasculitis.

Larvae are usually readily found in section. They may be present in alveoli, alveolar ducts, bronchioles, or bronchi, perhaps surrounded by eosinophils. In more chronic cases, larvae in tissue are in eosinophilic granulomas. The worms may be dead in cases of some standing, and are only recognized as an eosinophilic remnant or some bits of cuticle. Like all larval ascarids of mammals, *A. suum* in the lungs have *lateral alae visible in section.*

Lesions in the liver due to migrating *A. suum*, though not causing clinical disease, do result in considerable economic loss from condemnation at meat inspection. At first exposure to larvae, the lesions are related to mechanical damage caused by the worms, subsequent repair, and hypersensitivity reactions to excretory and secretory products of the larvae. Initially, hemorrhagic tracks are present near portal areas and throughout lobules. They are visible through the capsule as pinpoint red areas, perhaps slightly depressed and surrounded by a narrow pale zone. These lesions collapse and heal by fibrosis, causing scarring that involves most intensely the adjacent portal tracts. However, fibrosis extends diffusely through more distant tracts, emphasizing lobular outlines. There is a heavy eosinophil infiltrate in fibrotic septa, which becomes most obvious beginning ~10–14 days after infection. Granulomatous foci containing giant cells, macrophages, and eosinophils may center on the remnants of larvae trapped and destroyed in the liver.

The inflammatory infiltrates in livers of animals exposed to larval ascarids may become severe and diffuse, and this is reflected in the gross appearance of the liver, which has extensive "*milk spots*," and prominent definition of lobules. The liver is firm, and heavy scars may become confluent, obliterating some lobules and extending out to exaggerate interlobular septa throughout the liver. Where pigs are raised intensively, it is now rare to encounter extreme fibrosis of the liver associated with ascarid migration.

The pathogenicity of adult ascarids in the intestine is poorly defined. Heavy infections may obstruct the gut, being visible as rope-like masses throughout the intestinal wall. Ascarids may occasionally pass to the stomach and be vomited or migrate up the pancreatic or bile ducts. Rarely, intestinal perforation occurs. The presence of ~80–100 worms in 3-month-old swine fed low protein rations may depress feed intake and the efficiency of feed conversion. *A. lumbricoides* in humans interferes with carbohydrate, fat, and protein absorption, and *A. suum* probably has a similar influence. The effects of infection seem to be most apparent in animals on diets marginal in energy, and in quantity and quality of protein.

A. suum also infects animals other than swine. In sheep, and occasionally cattle, immature ascarids may be found in the intestine. Dyspnea and coughing associated with eosinophilic pneumonia, and focal eosinophilic hepatitis, may occur in lambs exposed to *A. suis*; mortality may occur, rarely. Liver lesions in lambs are usually too small to be significant at meat inspection.

In **calves** exposed to yards contaminated by pig feces containing *Ascaris* eggs, *severe acute interstitial pneumonia* may occur. Signs of dyspnea, tachypnea, coughing, and increased expiratory effort are usually first seen ~7–10 days after exposure, when large numbers of larvae are present in the lungs. Deaths may ensue over the following few days, and the lungs are moderately consolidated, light pink to deep red, with alveolar and interstitial emphysema and interlobular edema. Microscopically, there is thickening of alveolar septa, and effusion of fibrin, proteinaceous edema fluid, and macrophages into alveoli. Hemorrhage into alveoli may also occur. Larvae are present in alveoli and bronchioles and provoke acute bronchiolitis. Neutrophils are found around larvae in bronchioles; eosinophils may be present but are not prominent in animals dying acutely. In addition to being usually observed readily in tissue sections, larvae may be recovered from the airways by washing with saline, or from minced lung in saline or digestion fluid, by use of a Baermann apparatus. Tens of thousands to millions of larvae may be present in the lungs of fatal cases.

Parascaris equorum is the *ascarid of horses*. It is widespread and common in young horses; it may contribute to ill-thrift and occasionally causes death by obstruction. *P. equorum* is a large nematode, females being up to 50 cm long. The life cycle resembles that of *A. suum*. Similarly, *hepatic and pulmonary lesions are associated with larval migration*, and coughing may occur at the time larvae are in the lungs, if infections are heavy. The prepatent period is ~10–15 weeks. The lesions in the lungs of foals with migrating *Parascaris* larvae, ~2 weeks after infection, are like those described in swine with *Ascaris*. Animals with resolving pulmonary lesions develop subpleural nodular accumulations of lymphocytes up to 1 cm in diameter, and there may be lymphocytic cuffing of pulmonary vessels.

It is possible to establish heavy infections of *P. equorum* in the intestines of foals a few months old, but not in yearlings, where larvae appear to be killed during hepatopulmonary migration. However, in heavily infected foals, many worms are lost from the intestine prior to patency, suggesting the possibility of an effect of crowding on the population of growing worms. A heavy burden of ascarids in the intestine may reduce weight gains in growing foals. Inappetence occurs but increased plasma protein catabolism or loss into the gut does not. Reduced weight gain may be due to decreased protein intake. Ascarid infection may reduce rate of intestinal transit. Heavy burdens can be associated with obstruction, intussusception or, rarely, perforation of the intestine (Fig. 1.192).

The **ascarids of small animals** are *Toxascaris leonina*, infecting both cats and dogs, and *Toxocara canis* and *T. cati*, infecting the dog and cat respectively. All occur in the *small intestine*, mainly in young animals.

Toxascaris leonina has a life cycle that may be direct, but can involve a paratenic host. In the definitive host, larvae ingested in infective ova enter the wall of the gut, where they remain for several weeks, molting to the fourth stage and emerging to the intestinal lumen to molt again and mature. The prepatent period is ~10–11 weeks.

Toxocara canis has a complex life cycle. Puppies may be infected by ingestion of larvated ova, in which case larvae follow the pathway of hepatopulmonary movement in the bloodstream, and tracheal migration to the pharynx and gut, though some reach other tissues in the circulation. In older dogs most larvae ingested in eggs are disseminated in the circulation to various tissues, where they encyst, rather than undergoing development and tracheal migration. In the pregnant bitch, these larvae are mobilized, crossing the placenta to infect the fetus after day 42 of gestation. In the fetus, they remain in the liver, passing to the lungs after birth. Transmammary transmission of mobilized second-stage larvae also occurs, infecting the neonate via the colostrum. In a wide variety of species, infective larvae are disseminated hematogenously to many organs, where they settle, mainly in muscle. In some abnormal hosts, including humans, a syndrome termed "*visceral larva migrans*" is described, characterized by eosinophilia, general malaise, and perhaps signs related to granulomatous reactions to larvae in the eye, liver, lungs, and brain. Larvae in paratenic hosts eaten by young dogs undergo tracheal migration before maturing in the gut.

T. cati may infect cats directly from the larvated egg, via paratenic hosts, or, in kittens, by the transmammary route from the postparturient queen. Prenatal infection apparently does not occur. Larvae hatching from eggs migrate via the liver, lungs, and trachea, while those taken in from milk or prey do not. Following tracheal migration or ingestion in milk or prey, larvae enter the gastric wall, while fourth-stage larvae are found in the gastric contents, and the wall and lumen of the small intestine. *T. cati* will cause visceral larva migrans in humans, and if ingested as immature worms, will mature in the intestine.

Focal hemorrhages may be found in the lungs of puppies with migrating *T. canis* larvae. Larval *T. canis* are occasionally found in or associated with eosinophilic granulomas in the tissues of pups and older dogs. Inflammatory foci are most commonly seen grossly in the *kidney*, as white elevated spots 1–2 mm in diameter in the cortex beneath the capsule. They may be encountered in section in any organ, and are comprised of a small focus of macrophages, lymphocytes, and plasma cells, with a few eosinophils, and possibly containing a larva. Larvae may be destroyed in such foci, which heal by scarring. Considering the large numbers of larvae that must move through the tissues of dogs, and in many cases be sequestered there, relatively few are encountered incidentally, free or encapsulated in granulomas. Granulomas incited by *T. canis* larvae may be found in the *eye* on ophthalmoscopic examination, and retinitis, postinflammatory retinopathy, and blindness associated with *T. canis* larvae confirm that *ocular larva migrans* is a significant entity in dogs. Occult lesions similar to those occurring in dogs may be found in the tissues of cats infected with *T. canis*, though ocular larva migrans has not been recognized.

T. cati developing in the mucosa of the stomach and intestine may provoke a mild granulomatous response comprised of lymphocytes and a few macrophages about the coiled larva. Larvae free of such a response are also found in the mucosa and submucosa.

Heavy infections of ascarids in puppies and kittens, usually those reared in unhygienic communal environments, may result in *ill-thrift*. The most significant effects are those caused in the stomach and intestine by maturing *T. canis* in young puppies infected prenatally. The animals may develop weakness, lethargy, and vomition that is occasionally fatal. At autopsy the animal appears poorly grown for its age, pot-bellied, and cachectic, and masses of maturing worms are present in the intestine (Fig. 1.193) and perhaps stomach. Sometimes up to 20% of the body weight of young puppies may be accounted for by the worm burden. *T. cati* may be associated with clinical disease, but usually not death, in kittens up to several months of age. Medial hypertrophy of the pulmonary artery in cats has been associated with *T. cati* and *T. canis* infection; whether it is causal is unclear. Disease is rarely attributed to *T. leonina*.

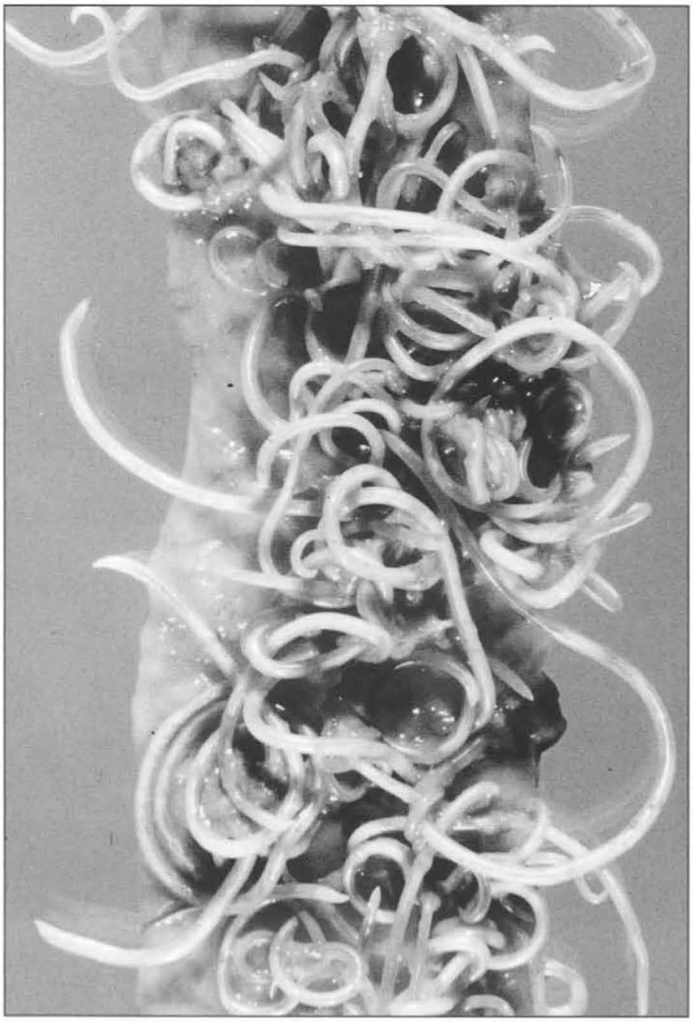

Figure 1.193 Tangled mass of ***Toxocara canis*** in the small intestine of a pup.

Mature *T. cati* are up to ~10 cm long; *T. canis* are up to ~18 cm long. In freshly dead animals, they are often coiled like a spiraled spring. They may maintain their place in the intestine by bracing against the gut wall in this way. The mechanism by which adults of these ascarids in the intestinal lumen impair growth has not been investigated. Ascarids occasionally enter the bile or pancreatic ducts, and many perforate those structures or the intestine.

Toxocara (*Neoascaris*) ***vitulorum*** infects the *small intestine of young calves of domestic cattle*, mainly in the tropics and subtropics, and it is especially significant in water buffalo.

The life cycle involves transmammary transmission of third-stage larvae mobilized from the tissues of the dam within a few days of parturition. The larvae attain the liver of the calf and undergo tracheal migration. Patency occurs within ~1 month of birth, but worms are expelled within a short time, and by ~2–3 months of age, none are present.

Signs of infection include foul-smelling *diarrhea and ill-thrift*. Immature and mature worms both contribute to the signs. Heavily infected calves may die in an emaciated state, with burdens of up to 400–500 worms as much as 30 cm long in the intestine. Occasionally, migration up the bile duct or perforation of the gut may occur.

Trichuris infection

Trichuris species, the **whipworms**, are so called because of their long thin cranial end and shorter stouter caudal portion. They inhabit the *cecum*, and occasionally the *colon*, of all the domestic animals considered here, except the horse. The host–parasite relationships include: in dogs – *T. vulpis*; in cats – *T. campanula* and *T. serrata*; in swine – *T. suis*; in sheep and goats – *T. ovis, T. globulosa, T. skrjabini*; in cattle – *T. discolor* and, less commonly, *T. ovis* and *T. globulosa*.

The life cycle is direct. Larvated ova are resistant to climatic insult, and persist in contaminated environments for several years. Ingestion of larvated eggs leads to release of third-stage larvae, which enter the mucosa of the proximal small intestine for up to 7–10 days, before returning to the lumen and passing on to the cecum, where they establish their adult existence. The prepatent period varies from ~6–7 weeks in the case of *T. suis* to 11–12 weeks for *T. vulpis*. In rare instances, disease may occur during the prepatent period, in which case ova will not be in the feces.

In all species, the cranial end of the worm is embedded at least partially in tunnels within the surface epithelium (Fig. 1.194), but not normally breaching the basal lamina. Light infections apparently cause little morphologic alteration in the mucosa and no disease. While *Trichuris* ingest blood, disease associated with them is not usually related to this activity. A protease produced by *T. globulosa* has been shown to promote degradation of mucosal tissue.

Heavy infection with *Trichuris* is associated with *severe and often hemorrhagic typhlitis or typhlocolitis in all species*. In the **dog**, large populations of worms overflow their normal habitat and infect the mucosa of the ascending, and often more distal, colon, sometimes extending to the rectum. The signs are chronic diarrhea or dysentery, perhaps with some weight loss. The blood and foul odor of the feces are due to hemorrhage and effusion of tissue fluid from the eroded mucosal surface. The mucosa is thickened, red, and edematous. The colonic content is fluid or porridge-like, and brown, tinged pink, or red. Masses of tangled worms are visible on the mucosa (Fig. 1.195). Microscopically the mucosa is widely eroded, or mildly ulcerated, and effusion of inflammatory exudate and blood is evident. Glandular epithelium is hyperplastic. Occasionally, *T. vulpis* infection may be associated with local or regional transmural lesions, with granulomatous foci and fibroplasia in deeper layers of the mucosa. Sometimes ova or worms are in these aberrant locations.

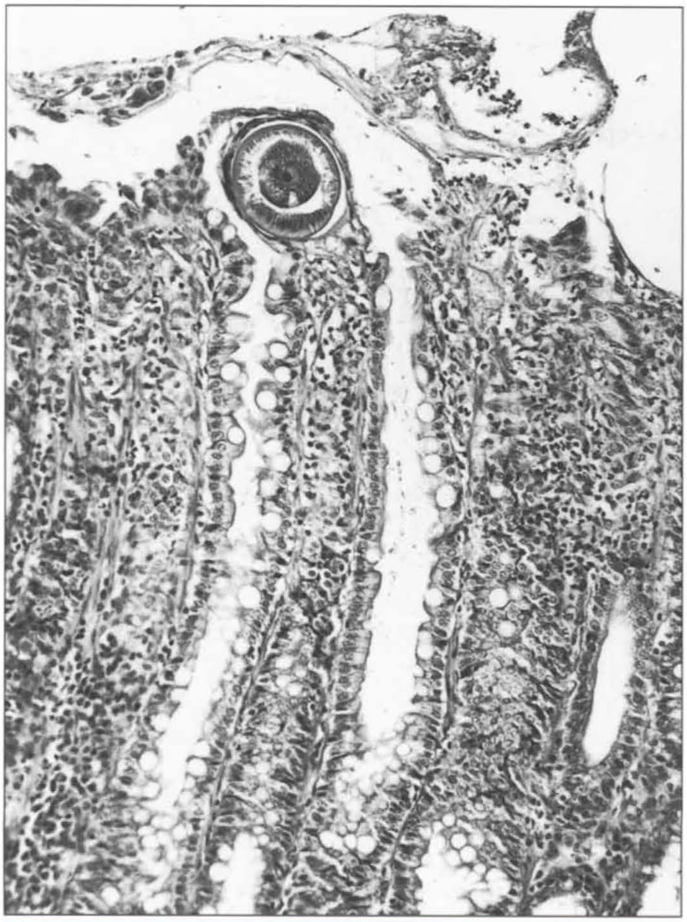

Figure 1.194 Mild erosive colitis in a dog with ***Trichuris vulpis*** infection. Cranial end of nematode is in tunnel in surface epithelium. There is exfoliation of epithelium, and effusion of neutrophils and fibrin from the surface.

Trichuris suis infection in **swine**, if heavy enough, may cause *mucohemorrhagic typhlocolitis* that is associated with anorexia, diarrhea, or dysentery, dehydration, ill-thrift and, in some cases, death. The disease is most common in animals exposed to dirt yards contaminated with infective *Trichuris* ova. The lesion is one of mucosal colitis, resembling that described in the dog. There is thickening of the mucosa with mucus hypersecretion from hypertrophic glands, coupled with erosion of, and effusion from, the mucosal surface. Lesions are more severe in swine with conventional gut flora than in those reared germfree, or free of known enteric pathogens. *T. suis* may suppress mucosal immunity to resident bacteria.

The large bowel in swine with *Trichuris* is thickened and congested, possibly with focal hemorrhages. The surface is glistening with mucus, perhaps with some fibrin exudation. The gross appearance may resemble that found in swine dysentery and the microscopic lesions are similar. However, closer examination reveals the presence

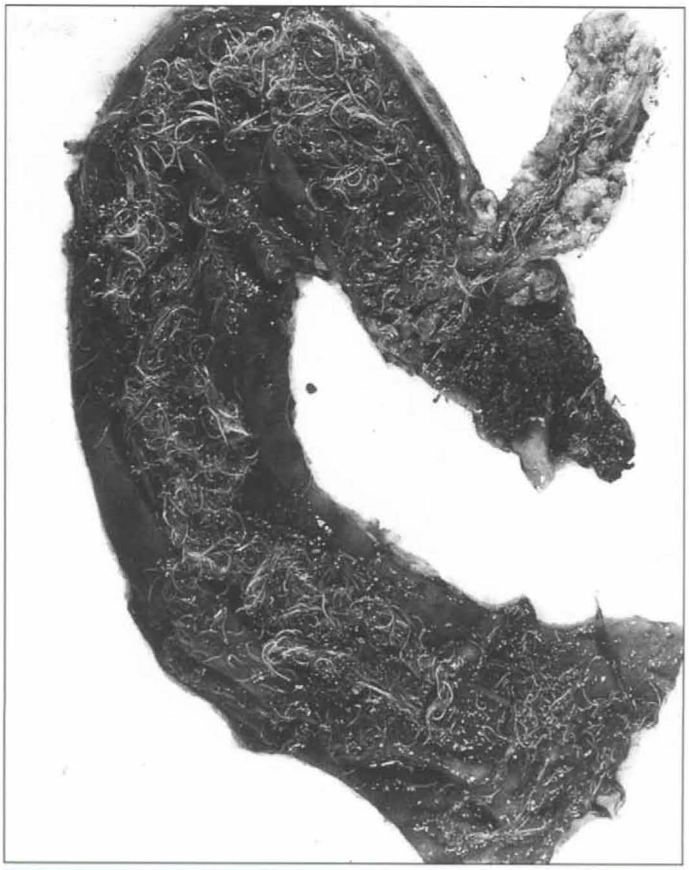

Figure 1.195 Hemorrhagic typhlocolitis in a dog caused by ***Trichuris vulpis***.

of the nematodes over the mucosa. Usually the thicker caudal end of the worms is noted. They may resemble at first glance *Oesophagostomum*, and only on more careful observation is the elongate thread-like cranial end seen.

The signs of the disease appear to be referable to loss of colonic absorptive function, and probably partly due to effusion of protein into the lumen. Erythrocyte loss is a minor component of the pathogenesis.

Trichurosis in **sheep** and **cattle** resembles that described in swine. The disease usually occurs in animals that are concentrated in areas contaminated by ova, and, in one reported case, immunocompromise due to persistent *Bovine viral diarrhea virus* may have predisposed. Affected animals develop chronic diarrhea with brown feces or dysentery, and loss of condition. At autopsy, the lesions are those of cachexia and hypoproteinemia, associated with mucohemorrhagic typhlitis or typhlocolitis.

A **diagnosis** of trichurosis in all species is usually readily made at autopsy. The worms have a characteristic morphology and are usually easily seen on the inflamed mucosal surface. In section, the thin cranial end of the nematodes, embedded in tunnels in the surface epithelium, contains the stichosome esophagus typical of members of the Trichuroidea, and a single bacillary band. The ova may be seen in the body of worms, in the gut lumen, or occasionally in tissue. They are barrel-shaped, have a thick wall and plugs at both poles of the egg. *Capillaria* spp. and their ova may be similar in tissue section, but are not expected in the cecum and colon.

Cestode infection

Adult tapeworms inhabit the gastrointestinal tract, or the ducts of the liver and pancreas, where they are generally of minor significance. They are flattened, segmented colonies of sequentially maturing hermaphroditic reproductive units, or *proglottids*, forming an elongate strobila a few millimeters to many meters long. The Eucestoda are attached to the host by a specialized hold-fast organ, or *scolex*, which usually has four suckers, and perhaps a rostellum, sometimes armed with hooks. The Cotyloda may have elongate muscular grooves (bothridia) on the scolex. Cestodes lack an alimentary tract and absorb nutrients through the specialized absorptive surface or tegument of the proglottids.

Carnivores may be infected by tapeworms that use certain prey species as intermediate hosts. Metacestodes, or larvae, of members of the Taeniidae use as intermediate hosts some species of domestic animals and, accidentally, humans. They may cause disease, result in economic loss due to condemnation of tissues or organs at meat inspection, or have zoonotic significance.

Adult cestodes in tissue section are flattened, with internal organs in a loose parenchymatous matrix, often contain calcareous corpuscles in the outer region, and lack tubular digestive structures. They are segmented and the scolex may be encountered at the cranial end, attached to the intestine.

Ruminants In ruminants, the more common and widely distributed intestinal tapeworms are *Moniezia expansa*, *M. benedeni*, and *Thysaniezia* (*Helictometra*) *giardi*. *Stilesia globipunctata* is found in the small intestine of sheep and goats in Europe, Asia, and Africa, whereas *S. hepatica* occurs in the bile ducts of ruminants in Africa and Asia. *Thysanosoma actinioides* occurs in the small intestine, pancreatic and bile ducts of ruminants in North and South America. *Avitellina* spp. occur in the small intestine of sheep and other ruminants in parts of Europe and Asia. The intermediate hosts of these tapeworms are oribatid mites or psocids (book lice).

Heavy infestations of the small intestine by *Moniezia*, *Thysaniezia*, and *Avitellina* are associated by some with diarrhea and ill-thrift in young lambs and calves. However, the evidence suggests that *Moniezia* is harmless; no effect on production or clinical signs can confidently be assigned to it.

The scolex of *Stilesia globipunctata* may be embedded in mucosal nodules 6–10 mm in diameter in the upper small intestine, with the thread-like strobila streaming into the lumen. There is a chronic inflammatory reaction around the scolex, which is deep in the mucosa, plugs of tissue being grasped by the suckers. Glands in the vicinity are hyperplastic, causing the nodules. The presence of up to 100 of these nodules has been associated with wasting, edema, and diarrhea.

Stilesia hepatica and *Thysanosoma actinioides* may cause mild fibrosis and ectasia of the bile ducts. Worms are often concentrated in the segmented sac-like dilations in the duct. These worms cause economic loss through condemnation of infected livers at meat inspection, and in areas where infection is common, this cost may be very significant.

Horses The cestodes found in horses are *Anoplocephala perfoliata*, which colonizes the proximal cecum, especially at the ileocecal junction, and *A. magna* and *Paranoplocephala mamillana* in the small intestine and occasionally the stomach. The latter worm is small, under 5 cm in length, and is rarely associated with disease or lesions. *A. magna* tends to live in the lower small intestine, where it can attain a length of up to 80 cm, and a width of 2.5 cm. All use oribatid mites as intermediate hosts.

Anoplocephala perfoliata is more commonly associated with lesions, and occasionally with mortality. The risk of spasmodic colic increases with infection intensity. In areas of concentrated mucosal attachment by clusters of up to several hundred of this stumpy species, especially at the ileocecal orifice, erosion and ulceration of the mucosa occur. The depressed surface is often covered by fibrinous exudate, perhaps with some hemorrhage, or a local verrucous granulating mass may project into the lumen. *Ileal impaction* has been strongly associated with *A. perfoliata*. Partial obstruction of the ileocecal orifice may occur rarely, but no clear relationship is established between infection with *A. perfoliata* and the development of ileal muscular hypertrophy. *Ileocecal and cecocecal intussusception*, and, occasionally, perforation of the intestine or cecal rupture, have also been associated with infection by this tapeworm.

Carnivores Dogs may be parasitized by ***Diphyllobothrium*** spp., as may be humans, cats, swine, and many other fish-eating mammals. The adults can be large, attaining lengths of up to 12–15 meters in humans, though those in animals tend to be shorter. The worm is ~2 cm across, and marked centrally by the uterus containing dark eggs, which are operculate. Intermediate stages occur in copepods and fish. The adult worm matures in the intestine of piscivorous mammals. Infection by *Diphyllobothrium* spp. is rarely, if ever, associated with clinical disease in animals.

Spirometra species are, like *Diphyllobothrium*, members of the subclass Cotyloda, and their life cycle is similar. The taxonomy of the genus is difficult, but among recognized species are *S. mansonoides*, infecting dogs, cats, and raccoons in North and South America, *S. mansoni* in dogs and cats in East Asia and South America, and *S. erinacei* found in cats and dogs in Australia and the Far East. Prospective hosts must have the opportunity for predation, since they are infected by the *plerocercoid* or "*sparganum*" found in the body cavity of the second intermediate host, usually an amphibian or reptile, or in another transport host.

Spargana can also occur in carnivores, swine, or even humans, if the procercoid in the first intermediate host, the *Cyclops*, is ingested, usually while drinking. Spargana are white, ribbon-like, but otherwise structureless worms up to several centimeters long. They may be found free or encysted in a thin, noninflammatory fibrous capsule, in the peritoneal cavity and intermuscular or subcutaneous tissue. A chronic inflammatory reaction may occur about dead spargana. The adult worms are nonpathogenic. Plerocercoids are of significance in humans, where they migrate mainly in subcutaneous tissues.

Mesocestoides spp. occasionally infect dogs, as well as other mammals and some birds, in North America, Europe, Asia, and Africa. These members of the subclass Eucestoda have a life cycle involving an insect or mite, and a vertebrate as second intermediate host. In the latter, infective *tetrathyridia*, ~1–2 cm long, flat, narrow, and bearing an invaginated scolex with four suckers, are found in the body cavities, liver, and lung. Tetrathyridia have the capacity for asexual multiplication, resulting in massive infections of intermediate hosts such as amphibia and reptiles, as well as dogs, cats, and other mammals. In the intestine of definitive hosts, *Mesocestoides* adults may also replicate asexually, and heavy infections may occur as a result of this, or from the consumption of large numbers of tetrathyridia in an intermediate host. Animals infected with intestinal *Mesocestoides* may develop diarrhea. Tetrathyridia replicating in the intestine of the dog may also penetrate the gut wall, and proliferate in the peritoneal cavity.

Tetrathyridia in the abdominal cavity of dogs and cats may cause peritoneal effusion (*parasitic ascites*), perhaps with the development of pyogranulomatous peritonitis and adhesions. Tetrathyridia 1–2 mm in diameter are scattered in the thick creamy exudate, along with similarly-sized "white bodies," comprised of necrotic parasite and host cellular debris. Mild infections may be discovered incidentally at necropsy. *Mesocestoides* infection of the abdominal cavity must be differentiated from peritoneal infections by cysticerci of several *Taenia* spp., which occur very rarely in carnivores.

Dipylidium caninum occurs in the dog, cat, fox, and, occasionally, children. It is ubiquitous. The narrow worms, up to 0.5 meters long, have distinctive cucumber-seed-like segments, and are often encountered incidentally in the small intestine at autopsy. They are of no pathologic significance. Cysticercoids develop in fleas and perhaps in the dog louse *Trichodectes canis*. Infection in the normal definitive hosts, or in accidental ones such as humans, is by ingestion of fleas containing cysticercoids.

Taeniid tapeworms

Taeniid cestodes are the most important tapeworms in domestic animals, not because of the effects of the adult worm in the carnivorous definitive host, but rather due to the *metacestodes*, or larval forms, in intermediate hosts. Single oncospheres hatch from the egg in the upper small intestine, penetrate the epithelium, and are carried in the portal blood to the liver. Some species of metacestodes migrate in the liver, eventually to enter the peritoneal cavity. Others persist to develop in the liver, while still others pass on to the heart, lungs, and systemic circulation, establishing in muscle or a variety of other sites and tissues. Metacestodes may occasionally be found in organs other than the site of predilection.

Taeniid metacestodes assume four basic forms. The **cysticercus** is a fluid-filled, thin-walled, but muscular cyst, into which the scolex and neck of a single larval tapeworm are invaginated. The **strobilicercus** is a modification of this theme; late in larval development the scolex evaginates and is connected to the terminal bladder by a segmented strobila, so that it resembles a tapeworm, several centimeters long. The **coenurus** is a single or loculated fluid-filled cyst, in which up to several hundred nodular invaginated scolices are present in clusters on the inner wall. Each scolex is capable of developing into a single adult cestode in the intestine of the definitive host. The **hydatid cyst** is a uni- or multilocular structure, on the inner germinal membrane of which brood capsules develop. Within the brood capsules, invaginated protoscolices form. Brood capsules may float free in the cyst fluid, where they are termed "*hydatid sand.*" Internal daughter cysts can develop. Release of brood capsules or protoscolices into tissues, as a result of rupture of the hydatid cyst, may lead to development of new cysts. The alveolar hydatid cyst proliferates by budding externally.

Taenia taeniaeformis infects the intestine of domestic cats and some wild felids, and the strobilicercus, ***Cysticercus fasciolaris***, is found in the liver of small rodents. Formation of fibrosarcomas has been associated with chronic inflammation due to *C. fasciolaris*. The adults are up to 60 cm long, have no neck, and caudal segments are somewhat bell-shaped, so that this species is readily differentiated from the other cestodes found in the feline small intestine. Usually, only a few worms are present in the cat, and they are of no consequence.

T. pisiformis is common in the small intestine in dogs and some wild canids, which prey on rabbits and hares. ***C. pisiformis*** migrates in the liver of the intermediate host, causing hemorrhagic tracks that are infiltrated by a mixed inflammatory reaction, and ultimately heal by scarring. The pea-size cysticerci encyst in a thin, noninflammatory fibrous capsule on the mesentery or omentum, or on the ligaments of the bladder. Occasionally, cysticerci persist beneath the hepatic capsule. Burdens of up to 20–30 worms, sometimes more, may be present in the intestine of the dog.

T. hydatigena infects the dog, and the metacestode, ***C. tenuicollis***, the long-necked bladder worm, or false hydatid, is found in the peritoneal cavity of sheep, cattle, and swine, and occasionally other species. Immature cysticerci in the liver migrate through the parenchyma for several weeks as they develop, before emerging to encyst on the peritoneum anywhere in the abdominal cavity. The immature cysticerci are less than 1 cm long, ovoid, and translucent. They cause tortuous hemorrhagic tracks similar to those produced by immature liver flukes, and if large numbers are present, they may cause a syndrome of depression and icterus identical to acute fascioliasis.

Heavily infected livers, with 4000–5000 actively migrating cysticerci, are mottled due to the subcapsular and parenchymal hemorrhagic foci and tracks. Cysticerci up to 6–8 mm long may be present beneath or breaching the capsule by about 3 weeks after infection. Rarely, animals may exsanguinate into the abdominal cavity, or the hepatic necrosis may predispose to the development of black disease or bacillary hemoglobinuria.

Cysticerci trapped in the liver may persist in a fibrous capsule, or be destroyed in a cystic eosinophilic granuloma that may mineralize; this is common on the diaphragmatic surface where the falciform ligament is attached. Usually, the intensity of infection is low, and a few, but occasionally scores of cysticerci – delicate translucent fluctuant fluid-filled cysts up to 5 cm or more in diameter – are contained in individual thin, noninflammatory fibrous capsules scattered on the peritoneal serosa. When a cyst degenerates, it is destroyed by a granulomatous reaction and the fibrotic mass may mineralize. Hepatic migration by *C. tenuicollis* may, at any stage, cause condemnation of lamb and pig liver at meat inspection.

T. ovis infects the intestine of the dog, while the metacestode, ***C. ovis***, is in the muscle of sheep, where it causes cysticercosis, or "*sheep measles.*" Cysticercosis of muscle caused by *C. ovis*; by *C. bovis* in cattle; and by *C. cellulosae* in swine and other species, including dogs, is considered in Vol. 1, Muscle and tendon. The adult stages of the latter two cysticerci, *T. saginata* and *T. solium* respectively, occur in the small intestine of humans.

T. multiceps occurs in the intestine of dogs and wild canids but the metacestode, ***Coenurus cerebralis***, develops in the brain and spinal cord of sheep and other ungulates, and, rarely, in humans. In the goat, coenuri may also occur in other organs, beneath the skin and intramuscularly. The migration of small metacestodes in the central nervous system may cause tortuous red or yellow-gray tracks in the brain due to traumatic hemorrhage and malacia, and nervous signs or death may occur at this stage. More commonly, signs of central nervous system disease, termed "sturdy" or "gid," do not develop until coenuri, up to 4–5 cm in diameter, have developed more fully, 4–8 months after infection. Cysts may be present at any level and depth in the brain and spinal cord, and projecting into the cerebral ventricles, but they are most common near the surface of the parietal cortex in the cerebrum. They cause increased intracranial pressure, hydrocephalus, necrosis of adjacent brain, and sometimes lysis, perhaps extending to perforation, of the overlying cranial bone. Coenuri developing in the spinal cord may cause paresis or paralysis.

T. serialis infects dogs and foxes throughout the world. The larval coenurus is found in the subcutaneous and intermuscular connective tissue of lagomorphs. Cerebral coenurosis has been reported in cats.

Histologically, cysticerci and coenuri are recognized as generally cystic structures with an eosinophilic outer layer or tegument, which may appear fibrillar or almost ciliate on the outermost surface. Beneath the tegumental cells a less cellular area, which may contain calcareous corpuscles, gives way to a web-like, lightly cellular matrix, and the central open fluid-filled portion of the cyst. No internal organs are seen. Muscular inverted scolices, with suckers, and (in all but *C. bovis*) hooks on the rostellum, may be encountered in favorable sections, extending into the center of the metacestode. Size and shape of hooks may assist in a specific diagnosis, if they are fully developed. Immature migrating metacestodes lack organized scolices. Other sources should be consulted for details on the taxonomy and specific identification of adult and larval taeniid tapeworms.

Echinococcus spp. tapeworms occur in the small intestine of a number of species of carnivores, predominantly canids. In enzootic areas, the distinctive metacestodes, or *hydatid cysts*, are commonly found in normal or accidental intermediate hosts. Humans may accidentally become infected with the metacestode, and echinococcosis or hydatidosis is a significant public health problem where carnivores shedding *Echinococcus* eggs come in close contact with humans.

The species are *E. granulosus, E. multilocularis, E. oligarthus*, and *E. vogeli*. The latter two involve sylvatic cycles in Central and South America, with felids and canids as definitive hosts respectively, and rodents as intermediate hosts in which polycystic hydatidosis occurs; *E. vogeli* may infect humans. The other two species may use domestic animals as definitive hosts, and will be considered further here.

E. granulosus uses the dog and some other canids as the definitive host. The most widespread strain or genotype uses a *sheep–dog cycle*, and has been disseminated wherever there is pastoral husbandry of sheep. It is significant as a potential zoonosis in many parts of Eurasia and the Mediterranean region, some parts of the UK, North America, South America, continental Australia, and Africa. Eradication has been accomplished, or virtually so, in Iceland, New Zealand, and Tasmania. Other cycles affecting domestic animals include horse–; cattle–; camel–; pig–; water buffalo–; goat–, and human–dog. Sylvatic cycles include: in Eurasia and North America, cervid–wolf; in Argentina, hare–fox; in Sri Lanka, deer–jackal; in Australia, macropod–dingo. Not all cycles represent different genotypes.

In the small intestine of the definitive host, protoscolices evaginate and establish between villi and in the crypts of Lieberkühn. The scolex distends the crypt and the epithelium is gripped by the suckers and occasionally eroded, but there is little or no inflammatory response. The worms that develop are short, usually less than 6–7 mm long. They commonly have only 3–5 proglottids, the caudal gravid one making up almost half the length of the worm. Burdens of *E. granulosus* are often heavy, no doubt due to the large numbers of protoscolices ingested at a meal containing one or more hydatid cysts. The heavily infected intestine is carpeted by the tiny white blunt projections, partially obscured between the villi; the worms may resemble lymphangiectasia. Enteric signs are not normally encountered in dogs with intestinal hydatid tapeworms.

Penetration of oncospheres released from eggs in the intestine of the intermediate host takes them into the subepithelial capillaries, or perhaps the lacteal. The majority probably migrate via the liver, some carrying on to the lungs and general circulation. However, those gaining the lacteal may bypass the liver, entering the vena cava with the lymph, and either are filtered out in the pulmonary circulation or are disseminated. *Hydatid cysts occur most commonly in the liver and lung*, with some strain and host species variation in the relative prevalence in these organs. In sheep they may be more common in lungs, while in cattle and horses, the liver is the usual site of establishment. Less commonly in domestic animals, the brain, heart, bone, and subcutaneous tissue may be sites of development of hydatid cysts. A single cyst, or up to several hundreds, may be present, displacing tissue in infected organs. Disease is rarely attributed to hydatidosis in animals, even in those heavily infected. However, strategic location of one or more cysts may lead to heart failure, bloat or central nervous signs. Condemnation of infected organs at meat inspection causes economic loss.

Hydatid cysts are usually spherical, turgid, and fluid-filled. They usually measure 5–10 cm in diameter in domestic animals; rarely, cysts in animals may be larger, but in humans hydatid cysts can become huge. On the other hand, some fertile cysts in equine livers may be as small as 2–3 mm across. The lining of fertile cysts is studded with small granular *brood capsules*, which contain protoscolices; and "hydatid sand," comprised of free brood capsules and protoscolices, is in the fluid. The lining of sterile cysts is smooth. Though the potential exists for development of internal daughter cysts, and rare exogenous budding by herniated cysts, most hydatid cysts in domestic animals are unilocular. However, they may be irregular or distorted in shape due to the variable resistance of parenchyma and portal tracts or bronchi and by the profiles of bone or other resistant tissues.

Microscopically, immature hydatid cysts are surrounded by an infiltrate of mixed inflammatory cells, including giant cells and eosinophils. As they develop, a layer of granulation tissue, which may contain round cells and eosinophils, invests the cyst, and this evolves so that the inner portion of the fibrous capsule is comprised of mature collagenous connective tissue that is relatively acellular. Within this, and in close apposition, is the acellular lamellar hyaline outer layer of the hydatid cyst wall, comprised of a polysaccharide–protein complex, which, with time, may become hundreds of micrometers thick. The cyst is lined by the thin syncytial germinal layer from which the brood capsules form on fine pedicles. If the cyst is ruptured and protoscolices are released into tissue, secondary cysts may form from them.

Hydatid cysts may degenerate. The inner structures collapse, and the mass becomes caseous and may mineralize. Degenerate hydatid cysts grossly may resemble tuberculous lesions or metastatic squamous cell carcinoma.

E. multilocularis has a holarctic distribution, the adults occurring mainly in foxes, and the metacestodes in small rodents, especially voles and lemmings. Dogs and cats may also become infected with the worms in enzootic areas. Though the parasite is principally arctic, the cycle is found in the northern prairie area of North America and in eastern and central Europe, and is moving progressively southward. The mature cestodes in the intestine are similar to, but smaller than, *E. granulosus*. In the intermediate host, the metacestode mainly infects the liver, forming a cystic structure with internal brood capsules and protoscolices; but it is capable of external budding. As a result, racemose proliferative masses of metacestodes infiltrate infected livers. They may metastasize via the bloodstream to the lungs or bone, or implant in the peritoneal cavity. The inflammatory reaction to alveolar hydatids is comprised of macrophages, perhaps giant cells, lymphocytes, and plasma cells in an encapsulating fibrous stroma. The metacestodes are rarely found in domestic animals, but may infect humans who ingest eggs shed by infected carnivores.

Intestinal fluke infection

Trematode infections of the intestine of domestic animals are, on the whole, uncommon. Dogs and cats in many parts of the world may be infected with *Alaria* spp., the second intermediate hosts for which are frogs or other amphibia. *Heterophyes heterophyes, Metagonimus yokagawi, Echinochasmus perfoliatus*, and *Phagicola longa* may infect dogs and cats fed fish that contain metacercariae. The former two occur in the Mediterranean area and the Far East; the latter in Eurasia. *Cryptocotyle* spp., most commonly parasitic in piscivorous birds, may also be found in dogs, cats, and mink fed infected marine fish.

Enteritis is attributed to ***Alaria, Echinochasmus,* and *Cryptocotyle*.** The flukes attach to the mucosa by suckers, and perhaps cause their effects by local irritation, erosion, and ulceration that large numbers of them may induce. Vomiting and ill-thrift have been associated with infection. The production of excessive intestinal mucus and hemorrhagic enteritis have been associated with intestinal fluke infection in small animals. The flukes involved are small, less than 4–5 mm long, and must be sought carefully at autopsy.

Nanophyetus salmincola occurs in the small intestine of dogs, cats, and humans, and in various fish-eating wild mammals and birds in the northwestern USA; Vancouver Island, Canada; and eastern Siberia. Its distribution is determined by that of the snails that are the first intermediate hosts. The second intermediate hosts are fish, especially members of the family Salmonidae. The adult flukes inhabit the small intestine, where they penetrate and attach to the mucosa. Large numbers may cause mucoid or hemorrhagic enteritis. *N. salmincola* transmits *Neorickettsia helminthoeca*, which causes "*salmon poisoning disease*," to canids consuming raw salmon infected with metacercariae. The disease is thought to be restricted to North America. However, similar organisms have been recognized in dogs with lesions compatible with salmon poisoning disease in southern Brazil.

Salmon poisoning disease has an incubation period of about 5–7 days, and is characterized clinically by pyrexia, anorexia, depression, weakness, and weight loss. There may be serous nasal discharge and mucopurulent conjunctivitis. Diarrhea with tenesmus develops; feces are scant yellow and mucoid or watery, often with some blood. The condition is usually fatal; if untreated, only 5–10% of infected dogs recover. They are immune to reinfection.

At necropsy, lesions are most consistently found in the lymphoid tissues. There is *generalized enlargement of lymph nodes*, especially in the abdominal cavity. Enlarged tonsils are everted from their fossae. The thymus is often increased in size in young dogs and the spleen may be swollen and congested. Peyer's patches and other intestinal lymphoid aggregates are elevated above the mucosal surface, and there may be petechial hemorrhages on the mucosa. Lymphoid tissue near the ileocecocolic valve may ulcerate and bleed. Ileocolic intussusception occurs in many cases. The liver of foxes becomes friable, and may rupture, causing hemorrhage into the peritoneal cavity. Focal hemorrhages may be seen in the mucosa of the bladder, and subpleural hemorrhages up to 2 cm in diameter usually occur.

Microscopic changes in lymph nodes include depletion of lymphocytes, focal necrosis with neutrophilic infiltrates, and increased numbers of histiocytes in the cortex and medulla. Similar changes may occur in the thymus, and splenic follicles may undergo necrosis. *Elementary bodies* of the *Neorickettsia* may be demonstrated in the cytoplasm of macrophages in lymphoid tissue, and in other visceral organs, by use of Giemsa or Macchiavello stains, or immunohistochemistry. In the small intestine, the flukes may be present embedded deep in the mucosa, though usually little reaction to them is present.

Lesions of the central nervous system occur in most cases. Leptomeninges may be somewhat opaque, but the lesions are best recognized microscopically. They are composed of macrophage accumulations in the leptomeninges and Virchow–Robin spaces, and focal gliosis in the parenchyma. Meningeal reaction is perhaps most consistent over the cerebellum, and is comprised of mild or moderate perivascular or more diffuse accumulations of histiocytes. Similar cells may cuff small and medium-sized vessels throughout the parenchyma. Focal gliosis is relatively sparsely distributed but seems most common in the brainstem. Elementary bodies are also demonstrable in macrophages in the central nervous system, and the diagnosis is usually made on the basis of this finding in macrophages in lymphoid tissue and/or brain. The organisms can be isolated and grown on primary canine monocyte cultures and in several other cell culture systems, but this is not a routine procedure.

Paramphistome infections in ruminants may cause significant intestinal disease. The adults, of the genera *Paramphistomum, Cotylophoron, Calicophoron, Ceylonocotyle, Gastrothylax, Fischoederius,* and *Carmyerius*, occur in the forestomachs of ruminants in various areas around the world. Infection is most common in warm-temperate to tropical areas. In the rumen, the red pear-shaped adult flukes, with their characteristic cranial and caudal suckers, are considered innocuous, though some papillae may become atrophic and slough (see Fig. 1.36).

When ingested, metacercariae encysted on herbage give rise to immature flukes that inhabit the duodenum, where massive infections may cause severe enteritis. In cattle, water buffalo, and American bison, the species incriminated in disease include *P. cervi*, *P. microbothrium, P. explanatum, Calicophoron calicophorum,* and various species of *Cotylophoron, Gastrothylax,* and *Fischoederius*. In sheep and goats, *P. microbothrium, P. ichikawai, P. cervi, P. explanatum, G. crumenifer, Cotylophoron cotylophorum,* and *F. cobboldi* have been associated with disease. The species involved vary with the host and geographic area.

After ~3–5 weeks in the small intestine, the worms normally migrate forward, through the abomasum, to establish and mature in the reticulorumen. However, if massive infection occurs, growth in the small intestine is retarded, and flukes may persist for months in the duodenum, prolonging the course of disease.

Calves and lambs with intestinal paramphistomosis are depressed and inappetent. Fetid *diarrhea* usually develops within several weeks of infection, and may contain immature flukes. Hypoproteinemia is reflected in submandibular edema in some animals and anemia is reported to occur occasionally. Morbidity and mortality can be substantial, and survivors may suffer considerable loss in condition.

The carcass may be in good or cachectic condition, depending on the duration of the disease, and there may be edema of subcutaneous tissues, abomasal folds, and mesentery, and fluid in the body cavities, due to hypoproteinemia. The proximal small intestine appears congested externally, and immature paramphistomes, deeply penetrating the intestinal wall, may be visible through the serosa. Occasionally, they will perforate the gut and be found free in the abdominal cavity. The mucosal surface of the duodenum is edematous, thickened, corrugated, and covered with mucus. Many immature pink or brown paramphistomes, a few millimeters long, are scattered over the surface and embedded in the mucosa. Most larval paramphistomes are in the first 3 meters of small intestine. In advanced infections, some may be present migrating forward on the abomasal mucosa, or already in the forestomachs.

In section, small larval paramphistomes are found deep in the lamina propria, occasionally in the submucosa, and sometimes in Brunner's glands. Larger immature forms are attached to the surface of the mucosa by a plug of tissue taken into the acetabulum. There is atrophy of villi, elongation of crypts, and possibly erosion or ulceration of the mucosa in heavily infected areas. Heavy infections are associated with fibroplasia. Protein loss into the gut, coupled with loss of appetite, seems to be the most important pathophysiologic consequence.

The other fluke occurring in the intestine of ruminants is *Skjrabinotrema ovis*, associated with catarrhal enteritis in sheep in Eurasia.

In **swine**, the paramphistomes *Gastrodiscoides* and *Gastrodiscus* may be found in the colon, where they are of little significance. *Fasciolopsis buski* and *Artyfechinosomum malayanum* may infect the small intestine of swine, as well as humans. They are of little importance in pigs other than as reservoirs for human infection.

In **horses** in Africa and India, the paramphistomes *Gastrodiscus aegyptiacus* and *Pseudodiscus colinsi* occur in the large bowel. Larvae of the former species have been associated with severe colitis in horses, but they are generally nonpathogenic.

Intestinal schistosomiasis, due mainly to *Schistosoma* spp. in ruminants, and *Heterobilharzia* in dogs, may cause *protein-losing enteropathy*, perhaps associated with granulomatous enteritis in response to deposition of ova in mucosal venules (see Vol. 3, Cardiovascular system). Treatment may precipitate hepatic lesions consisting of granuloma formation around dead parasites as well as periportal fibrosis.

Flukes in tissue section are generally somewhat flattened or globose, with a loose mesenchymal parenchyma in which the internal structures are suspended. The cuticle is eosinophilic, and may be spiny. Muscular oral and acetabular suckers and pharynx may be encountered in sections. Ceca are usually present, and elements of the male and female reproductive systems in these typically hermaphroditic adult worms (excepting the schistosomes) may be seen. The uterus may contain ova with a tan-yellow or brown shell, perhaps with an operculum, and ova are often seen in the intestinal lumen or in tissue. The developing miracidium may be present in ova. Schistosomes are recognized by their intravascular location and sexual dimorphism, the leaf-like male perhaps enveloping the slender cylindrical female within the gynecophoric canal, in section.

Acanthocephalan infections

The Acanthocephala are a phylum of parasitic animals that have an elongate sac-like body, no internal alimentary canal, and use as the hold-fast a spiny protrusible proboscis. The life cycle typically involves obligate development in an intermediate host, usually an arthropod, and perhaps the utilization of a paratenic host to facilitate transmission. The acanthocephala of concern in domestic animals are in the genera *Macracanthorhynchus* and *Oncicola.*

Macracanthorhynchus hirudinaceus is the *thorny-headed worm of swine*, infecting the small intestine. The life cycle involves dung beetles or other Scarabaeidae, and foraging or rooting swine are prone to infection. Males are ~10 cm long, and the females up to 30–40 cm long, slightly pink, curved, and tapering caudally. The proboscis has ~6 rows of hooks, and is used to penetrate deeply into the intestinal wall. It incites a local granulomatous nodule called a "*strawberry mark*," with a purulent focus about the embedded proboscis. The proboscis may penetrate the muscularis, and the nodules around the proboscis, ~1 cm in diameter, may be visible on the serosal surface of the gut as gray or yellow suppurative foci, surrounded by a halo of hyperemic tissue. They occasionally perforate, causing peritonitis. Severely infected pigs may suffer ill-thrift and perhaps anemia, probably related partly to the potential for plasma protein loss and hemorrhage from numerous focal ulcerative lesions.

M. catalinum and *M. ingens* are smaller but similar thorny-headed worms that inhabit the intestine of a variety of wild carnivores, and occasionally the dog.

Oncicola canis occurs in the small intestine of wild carnivores, and occasionally the dog and cat. It rarely causes disease. Intermediate hosts are presumably arthropods, with insectivorous vertebrates acting as paratenic hosts. Up to several hundred worms, 0.5–1.5 cm long and dark gray, may infest the small intestine; usually infections are light. The proboscis is embedded to the subserosal level, and a focal nodular lesion develops about it.

Protistan infections

Coccidiosis

The coccidia are members of the protistan phylum Apicomplexa, intracellular parasites characterized at some stage of the life cycle by a typical "apical complex" of organelles at one end of the organism. Members of the subclass Coccidiasina, which will be considered together under coccidiosis, all have a similar basic life cycle. It begins with infection of a cell, often, but not always, in the intestinal mucosa, by a **sporozoite** released from a **sporocyst** in the lumen of the gut. One or more cycles of asexual division, termed **schizogony or merogony**, follow, and the **merozoites** produced infect other cells, forming another generation of **meronts**, or transforming to sexual stages, termed **gamonts**. Gamonts subsequently develop into nonmotile female **macrogametes**, and motile male forms or **microgametes**. A nonmotile zygote produced by union of micro- and macrogametes forms an **oocyst**. **Sporogony**, production of sporocysts containing infectious sporozoites within the oocyst, may occur in the host, or, more commonly, after the resistant oocysts are passed in feces.

Members of the genus *Eimeria* and *Isospora* are **homoxenous**, with sexual and asexual development taking place in a single host. *Cystoisospora* (former *Isospora* spp. in carnivores) and the genera *Toxoplasma, Sarcocystis, Hammondia, Besnoitia, Frenkelia, Neospora*, and *Caryospora* are all **heteroxenous**, in which case asexual stages occur in an intermediate host. The heteroxenous genera exploit natural prey–predator relationships. In general, sexual development takes place in the intestinal mucosa of a predator, while at least one generation of asexual replication, often several, occurs in the tissues of one or more species of prey.

The *endogenous stages of coccidia are all intracellular*, except, temporarily, the merozoite and microgamete. Mature developmental stages are usually readily recognized; immature forms may not be easily identifiable. **Trophozoites**, small undifferentiated, rounded, basophilic forms with a single nucleus, usually within a parasitophorous vacuole in the host cell, are found at three stages of the life cycle. They occur following invasion by the infective sporozoite, prior to merogony; following invasion by a merozoite, prior to a subsequent generation of merogony; and following invasion by a merozoite, prior to differentiation into a recognizable gamont. Developing meronts are multinucleate. Merogony may involve "**endopolygeny**," multiple fission or apparent "budding" of merozoites from the periphery of the meront or from infoldings of it. A single residual body, surrounded by slightly curved, fusiform, or banana-shaped uninucleate merozoites, or many spherical clusters of merozoites with a central residuum, may be present. A second form of replication, termed "**endodyogeny**," occurs in meronts of many of the heteroxenous coccidia. Two daughter organisms develop within a mother organism, which is destroyed when they are released. The location of a meront, and the number of merozoites it contains, vary with the species and the generation of merogony. A very few, or up to tens or hundreds of thousands of merozoites may be released from a single meront.

Microgamonts mature in two steps. The first involves enlargement of the gamont and proliferation of nuclei. During the second phase, the microgametes differentiate about the periphery of the gamont, which may become deeply folded or fissured by invaginations. Immature microgametocytes during these stages may resemble developing schizonts. However, *fully differentiated microgametes* differ from merozoites in being small, densely basophilic, and comma-shaped, with 2–3 flagella. They may be present in swirling masses, perhaps with some residual bodies, in mature microgametocytes. Macrogametes, the female stage, have a large nucleus with a prominent nucleolus, and with time they usually enlarge to contain refractile eosinophilic "plastic granules" or wall-forming bodies, which give rise to the layers of the oocyst wall. *Mature macrogametes* typically have prominent wall-forming bodies, and contain clear or periodic acid–Schiff-positive amylopectin granules, and a large nucleus and nucleolus.

Fertilization by the microgamete leads to development of the zygote, and subsequent formation of the oocyst wall. The contained *sporont* is spherical, with nucleus and nucleolus, and amylopectin granules in the cytoplasm. Sporulation usually occurs outside the host, but in *Sarcocystis* and *Frenkelia* it occurs in the tissue of the definitive host; in *Caryospora*, sporulated oocysts develop in tissues of the prey host. Sporozoites are enclosed within sporocysts, which in turn are contained by the oocyst wall. Oocysts of most coccidia, or sporocysts of *Sarcocystis* and *Frenkelia*, are passed in the feces.

Coccidia of domestic animals are relatively host-, organ-, and tissue-specific. Asexual stages of *Toxoplasma* and *Neospora* are the obvious exception to this generalization. Species of *Eimeria, Isospora,* and *Cystoisospora* rarely occur in more than one genus of definitive host. Similar coccidia occurring in related genera of hosts, when tested, usually prove incapable of cross-infection.

The economic cost of coccidiosis in the food–animal species is considerable, in terms of mortality, morbidity, subclinical disease, and the cost of prevention and treatment. It is even more so in chickens. In dogs and cats, coccidiosis is a minor problem.

Virulence reflects a number of factors. Among these are the location and type of cell infected by various stages of the organism, the function of infected cells, and the degree of host reaction stimulated by infection.

The effects of infection on the host cell are several, and vary somewhat with the infecting species. Infected cells may be functionally compromised. They may hypertrophy; nuclei may enlarge or a considerable amount of cytoplasm may be displaced; and the outer membrane of infected cells may be highly modified, perhaps to facilitate metabolic exchange. The intercellular relationships may be affected. The rate of movement of infected epithelial cells up villi is altered.

Immunoinflammatory reactions may be incited by coccidial infection. In experimental systems, resistance to coccidial infection is thymus-dependent, and is largely mediated by T-cell-promoted intracellular killing directed mainly against asexual stages in the life cycle.

In mammals, acute inflammatory reactions in intestinal coccidiosis are most commonly associated with heavy infection and destruction of cells by the sexual stages and oocysts, rather than in response to asexual stages. In toxoplasmosis and neosporosis, necrosis and focal acute or chronic inflammatory reactions may be incited by actively replicating asexual stages in many organs. A syndrome characterized by hemorrhage occurs in some species infected with asexual stages of *Sarcocystis*, about the time that merogony occurs in vascular endothelium.

The effects of *intestinal coccidiosis* in mammals vary with the host–parasite system. They are mainly related to malabsorption induced by *villus atrophy*, or to anemia, hypoproteinemia, and dehydration due to exudative enteritis and colitis caused by *epithelial erosion and ulceration.* A *neurotoxin* has been associated with the development of nervous disorders in cattle with coccidiosis. Many species of coccidia appear to have little pathogenic effect under normal circumstances.

Coccidiosis is typically a disease of *intensively managed animals.* It is especially important in naive young animals exposed to a high level of infection. This is predisposed by high contamination rates associated with crowding, yarding, or high stocking rates on pasture. A damp substrate promotes oocyst sporulation and survival, and practices such as feeding on the ground, or the natural propensity of young animals to nibble or perhaps indulge in coprophagy, may promote infection. Although infections may not proceed to patency, chronic ingestion of oocysts may cause an intestinal immune response, villus atrophy, and perhaps ill-thrift, in some situations. Immune reactions may only halt development of, but not kill, endogenous asexual stages. Epizootiologic evidence suggests that under some circumstances there may be relaxation of resistance and resumption of development of the organisms, ultimately expressed in disease. This seems the likely explanation for outbreaks of bovine coccidiosis occurring during midwinter in freezing climates, or in post-parturient stabled dairy cattle.

Coccidiosis caused by members of the genera *Eimeria* and *Isospora* in the various species will be considered further here. The heteroxenous organisms, including *Cystoisospora, Toxoplasma, Neospora,* and *Sarcocystis*, will be considered subsequently, as will *Cryptosporidium*.

Coccidiosis in cattle

Over a dozen species of *Eimeria* parasitize cattle; of these, *Eimeria zuernii* and *E. bovis* are potentially highly pathogenic, while several others, notably *E. ellipsoidalis, E. alabamensis*, and *E. auburnensis*, may cause diarrhea, but probably not death. *Coccidial infection is common*, and it usually comprises several species. Almost half the calves and yearlings in confinement operations shed oocysts, with calves shedding high numbers, while a much smaller proportion of cows shed low numbers of oocysts.

Disease occurs mainly in calves or weaned feeder cattle under ~1 year of age, when one or both of the potentially pathogenic species produce heavy infection. It may occur in animals at pasture or on range, concentrated at water holes, but is most common in animals in feedlots or yards where the level of sanitation is not high. The stress of shipping, cold weather, or intercurrent disease may be associated with outbreaks, which can occur in midwinter when oocyst transmission is expected to be poor. *Bovine parvovirus* infections have been associated with outbreaks of coccidiosis in a dry environment in northern Australia. Reactivation of latent schizonts in tissue may explain coccidiosis in stressed animals, or at a time when transmission is unlikely.

Coccidiosis is characterized by *diarrhea that may progress to dysentery* with mucus, and tenesmus, perhaps causing rectal prolapse. Animals dehydrate, and become hyponatremic and perhaps anemic. Morbidity may be high, but mortality is usually low. The duration of severe disease is ~3–10 days, after which most cases recover, since infection is essentially self-limiting. Some animals develop concurrent nervous signs, including tremors, nystagmus, opisthotonos, and convulsions, and many of these die within a few days.

The signs in bovine coccidiosis due to *E. zuernii* and *E. bovis* occur when the epithelium in the glands of the cecum and colon is infected by second-generation schizonts and gametocytes. In heavily infected animals, disease, and perhaps death, can occur before many oocysts are passed in the feces. The life cycles of both agents are similar, two schizogonous generations preceding gametogony. The first-generation schizont of ***E. bovis*** infects hypertrophic endothelial cells in lacteals on the upper part of villi in the *lower small intestine*, several meters proximal to the ileocecal valve. These schizonts may be large, up to ~300 μm in diameter, and are visible to the naked eye as *pinpoint white nodular foci in the mucosa.* They contain tens of thousands of merozoites, but are invested by only a narrow rim of mononuclear inflammatory cells, unless they degenerate, when a marked local mixed reaction develops, including neutrophils and macrophages. Merozoites released from these schizonts ~14–18 days after infection enter cells deep in cecal and colonic glands. In heavy infections, crypts of Lieberkühn in the terminal ileum may also be infected. Here they produce small second-generation schizonts, which in turn release merozoites, infecting other cells in the gland. Gametogony may begin as early as 15 days after infection, and oocyst production peaks ~19–21 days after infection.

The first-generation schizonts of ***E. zuernii*** may be about the same size as those of *E. bovis*. However, they are most common in the *terminal meter of the ileum* and are located in the lamina propria below the crypt–villus junction, often deep near the muscularis mucosae, rather than in the endothelium of the lacteal. Hence, they are not so readily visible grossly as those of *E. bovis*. The second-generation schizonts and gamonts of *E. zuernii* also occur in glands of the cecum and colon, but not the terminal ileum. The merozoites tend to be somewhat longer (up to 15 μm) and schizonts more numerous and of greater diameter (~14 μm) than those of *E. bovis*. The timing of the development of *E. zuernii* infection is similar to that of *E. bovis*. First-generation schizonts of *E. bovis* occasionally reach the mesenteric lymph node, where they may mature, with no significance.

Animals dying of coccidiosis have fecal staining of the hindquarters, and may be somewhat cachectic and anemic. The gross enteric lesions in severe cases are those of *fibrinohemorrhagic typhlocolitis*, which may extend to the rectum; if *E. bovis* is involved, the terminal ileum may be affected (Fig. 1.196) and perhaps a few schizonts will be visible in ileal villi. The contents of the large bowel are usually abnormally fluid, and may vary from brown to black to overtly bloody, possibly with flecks of mucus or fibrin. The mucosa is edematous, with exaggerated longitudinal and perhaps transverse folds, which may be congested. Submucosal edema is also marked. Fibrin strands or a patchy diphtheritic membrane may be present on the mucosa (Fig. 1.197), and fibrin casts can form. In milder cases, lesions are limited to congestion and edema of the mucosa.

In animals dying at the peak of infection, *virtually all cells lining cecal and colonic glands in many areas are infected by small schizonts, gamonts, or developing oocysts*. Cells infected by *E. bovis* tend to dissociate and project into the lumen of the gland. As cells are disrupted and oocysts are released into the lumen of glands, the remaining glandular epithelium becomes extremely attenuated, or the gland collapses (Fig. 1.198A).

Concurrently, the surface epithelium becomes squamous, or the *mucosa is eroded*, and effusion of fibrin, neutrophils, and hemorrhage occurs from dilated, congested superficial vessels. Oocysts released into the lumen of the colon may be seen in the exudate (Fig. 1.198B). At the same time, the mucosa begins to collapse, and the lamina propria is infiltrated by neutrophils, eosinophils, lymphocytes, macrophages, and plasma cells (Fig. 1.198C). Oocysts trapped in denuded glands in the collapsed mucosa may be surrounded by small giant cells.

If destruction is widespread, and the animal survives sufficiently long, the *mucosa may ulcerate* to the level of the muscularis mucosae, and begin to granulate. In areas where the lesion is patchy, glands that have been relatively spared may become lined with hyperplastic

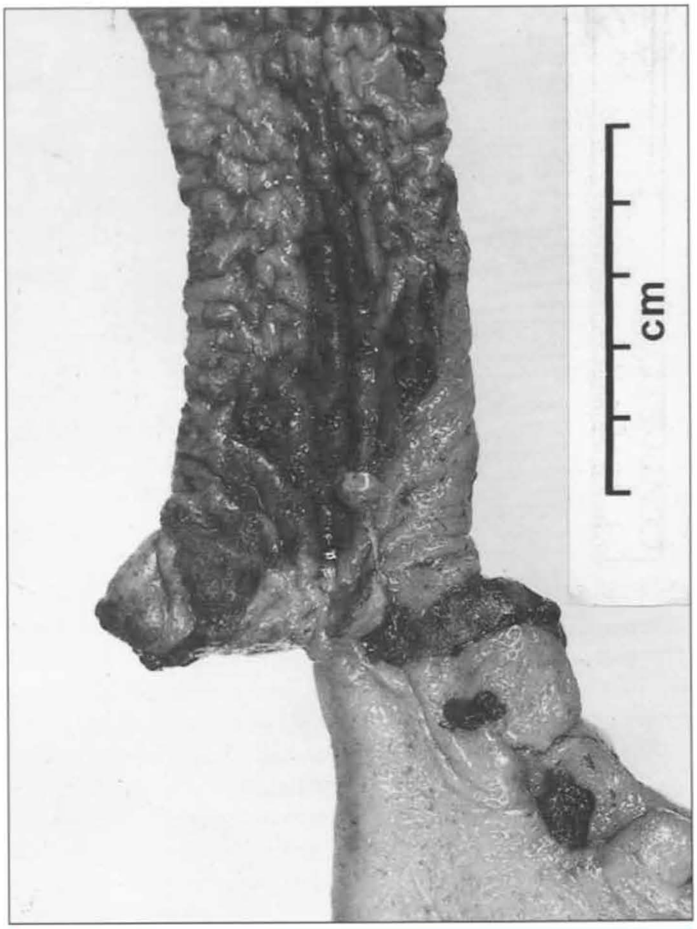

Figure 1.196 Acute enteritis, with mucosal thickening, large and minute ulcerations, and hemorrhages, in **bovine coccidiosis**.

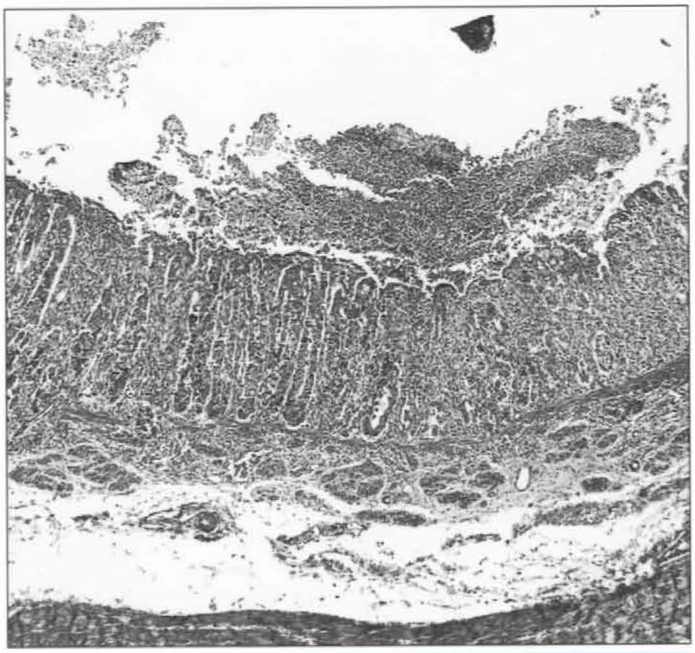

Figure 1.197 Damaged colonic glands and inflammatory exudate, in **bovine coccidiosis**.

epithelium, making an attempt to regenerate the mucosa. Flattened epithelial cells spread from these glands across the denuded surface, beneath the diphtheritic exudate. A few crenated oocysts in small giant cells in the stromal remnants of the mucosa may be all the evidence of coccidiosis found in lesions in animals surviving for 7–10 days.

Malabsorption due to mucosal damage in the cecum and colon, and inflammatory effusion and hemorrhage, explain the enteric signs of coccidiosis. The nervous signs in bovine coccidiosis are not associated with recognized lesions in the brain; they have been related to a neurotoxin found in the blood of affected animals.

The gross lesions of coccidiosis in cattle must be differentiated from those in salmonellosis, bovine viral diarrhea, rinderpest, malignant catarrhal fever, and bovine adenoviral infection, all of which may cause typhlocolitis. Coccidiosis can often be simply confirmed at autopsy by finding large numbers of developing stages in mucosal scrapings. Oocysts of *E. bovis* are ovoid, smooth, and ~28 × 21 μm; those of *E. zuernii* are subspherical to ovoid, smooth and ~18 × 15 μm.

While other coccidia are unlikely to be the primary cause of diarrhea or death in cattle, several have distinctive endogenous stages that may be recognized in tissue section. ***Eimeria auburnensis*** has a giant first-generation schizont that may be confused with those of *E. bovis* and *E. zuernii*. However, they are present usually 6–12 meters cranial to the ileocecal valve and form in the epithelium deep in crypts of Lieberkühn, though this may not be apparent due to plane of section, or following their migration into the lamina propria. Second-generation schizonts and gamonts of *E. auburnensis* develop in the lamina propria in the ileum, small schizonts in villi, and gamonts in the deeper lamina propria. Microgametocytes may be several hundred micrometers across. Oocysts are ~38 × 23 μm.

The other bovine coccidium with gamonts apparently developing in the lamina propria is ***E. bukidnonensis***. Oocysts of this species are large, ~48 × 35 μm and thick-walled, with a micropyle, and have been found in the lamina propria. ***E. alabamensis*** develops in vacuoles within the nucleus of epithelial cells in small intestine and, in heavy infections, the large bowel. Both schizonts and gamonts may be found together within the same nucleus. Gamonts of ***E. kosti*** have been described in the epithelium deep in the abomasal glands. None of these organisms is particularly pathogenic.

Eimeria bareillyi is associated with clinical coccidiosis in water buffalo calves. The serosal vessels in the distal half of the small intestine are congested, and the lumen of the lower small bowel contains creamy or yellow fluid content in which some mucus, fibrin, or blood may be present. Focal to coalescent pale raised plaques or polypoid masses may be present on the mucosa, or the surface may appear granular and necrotic, with petechial hemorrhages. The gross changes are caused by hypertrophy of crypts and villi, upon which virtually every cell is infected with developing gamonts or oocysts. *E. bareillyi* will not cross-transmit to domestic cattle, though *E. ellipsoidalis* and *E. zuernii* of bubaline origin will. *E. zuernii* is pathogenic in water buffalo.

Coccidiosis in sheep and goats

Coccidial infection is universal in sheep and goats, and coccidiosis can be a significant problem in the young of both species. The etiology of coccidiosis in these species is complicated by the morphologic similarity of the coccidia infecting sheep and goats. Assumptions on the potential for cross-infection of coccidia between sheep and goats, and of the species found in each host, have been revised as new taxonomic and biologic information has come to light.

At present, about a dozen species of coccidia are found in each of sheep and goats. Of these, three (*Eimeria pallida, E. caprovina, E. punctata*) may occur in both sheep and goats, though the validity of *E. punctata* as a species is questioned. Eight species pairs of *Eimeria* occur, in which the coccidia look and behave similarly in sheep and goats, but do not cross-infect. Listing the sheep-adapted species of each pair first, these are: *E. ahsata–E. christenseni*; *E. ovinoidalis–E. ninakohlyakimovae*; *E. bakuensis* (=*ovina*)–*E. arloingi*; *E. granulosa–E. jolchijevi*; *E. crandallis–E. hirci*; *E. faurei–E. apsheronica*; *E. parva–E. alijevi*; *E. intricata–E. kocharli*. Two species are unique to sheep, *E. weybridgensis* (formerly *E. arloingi* "B"), and *E. marsica*; in goats, one species, *E. caprina*, is unique. In addition, giant schizonts of an unknown coccidian, termed *Globidium gilruthi*, are seen incidentally as pinpoint white foci in the abomasum of sheep and goats. The taxonomic confusion has been carried over into descriptions of the natural or experimental disease, since many infections were of mixed species, resulted from inocula of poorly defined species of coccidia, or occurred under circumstances where the oocysts associated were not described. However, while the taxonomic picture has changed, the syndromes associated with coccidiosis in sheep and goats have not.

Coccidiosis in these species is a *disease of young animals*. Under conditions of intensive pastoral husbandry or confinement, lambs and kids are exposed to oocysts of many species of coccidia within the first few days of life. Weaned lambs, presumably exposed to only light infections while at range, are also prone to coccidiosis when brought into feedlots. In young suckled animals and those in feedlots, exposed to large numbers of oocysts, signs may occur before oocysts are passed. Suckling lambs, ~5–8 weeks old, reared at pasture at relatively heavy stocking rates, may also develop signs, and occasionally die. Under these conditions, the disease needs to be differentiated from gastrointestinal helminthosis, which may be concurrent.

Outbreaks of coccidiosis in confined lambs and kids are usually acute and characterized by moderate morbidity and low mortality; there is green or yellow watery *diarrhea*, occasionally with blood or mucus. Yarded and grazing animals may also suffer weight loss, or subclinical ill-thrift. Signs are usually associated with lesions in the lower small intestine, caused by *E. ahsata* and *E. bakuensis* in lambs, and their analogues in goats, *E. christenseni* and *E. arloingi*, or with typhlocolitis, caused by *E. ovinoidalis* in sheep, and *E. ninakohlyakimovae* in goats. Some pathogenicity is also ascribed to *E. faurei, E. intricata, E. parva*, and *E. crandallis* in sheep, and presumably to their analogues in goats. Infections may be mixed, and gross and microscopic lesions may reflect this.

E. ovinoidalis in sheep and ***E. ninakohlyakimovae*** in goats presumably have similar endogenous development. In the sheep, giant schizonts up to 300 µm in diameter develop in cells deep in the lamina propria, in the terminal ileum. They release merozoites that enter epithelium in the glands of the cecum and colon, and perhaps distal ileum. Here small second-generation schizonts evolve, and other cells in glands in the same area subsequently become infected by the gametocytes.

These species are considered highly pathogenic and *E. ovinoidalis* is often associated with disease in feedlot lambs. Lesions other than those related to diarrhea, dehydration, and hypoproteinemia are limited to the terminal ileum, and especially the cecum and proximal colon, and are associated with second-generation schizogony and gametogony. Affected areas of gut are edematous and thickened. The most significant microscopic lesions are those in the cecum and colon, which resemble those in cattle due to *E. bovis* and *E. zuernii*. ***E. caprina*** in goats also seems to have pathogenic potential. Like *E. ninakohlyakimovae*, it causes typhlocolitis; the small intestine is not involved.

E. christenseni and *E. arloingi* in goats and their analogues, *E. ahsata* and *E. bakuensis* in sheep, are also associated with serious disease. They seem to have somewhat similar developmental cycles and lesions, though interpretation of the literature is clouded by confusion among these species. Many cases of coccidiosis in lambs attributed to *E. bakuensis* (as *E. arloingi*) may in fact have been due to *E. ahsata*, since the unsporulated oocysts, though of differing sizes, can be confused.

E. christenseni has a developmental cycle that involves giant schizonts up to nearly 300 µm across in the endothelium of the lacteal in villi in the middle small intestine. In heavy infections, every cell in a number of contiguous crypt–villus units may be infected. Though there may be an acute local reaction around ruptured primary schizonts, clinical disease is associated with the subsequent stages of development, diarrhea occurring during the late prepatent and patent periods. Affected intestine may be congested and edematous. Numerous pale white or yellow foci from a few millimeters to up to a centimeter in diameter, often visible from the serosa, are present as slightly raised plaques on the mucosa of the small bowel. These foci are areas of intense infection of cryptal and villus epithelium by gamonts and developing oocysts, and have been dubbed "*oocyst patches.*" There may be some hemorrhage into the intestine but the feces are rarely bloody.

E. arloingi undergoes a development similar to that of *E. christenseni* (Fig. 1.199) and causes similar gross and microscopic lesions in goats, with minor differences. First-generation schizonts are most numerous in the lacteals of villi in the lower jejunum, gamonts are mainly above the host cell nucleus, and the associated grossly visible plaques in the mucosa (Fig. 1.200) may tend to be more distal in the small intestine, and occasionally involve the large bowel. ***E. ahsata*** and ***E. bakuensis*** in sheep are similar.

Nodular polypoid structures, sometimes pedunculate, and about 0.3–1.5 cm in diameter, are encountered in the small intestinal mucosa of sheep and goats, usually as an incidental finding. These masses are comprised of hypertrophic crypt–villus units, in which virtually every epithelial cell is infected by mainly gametocytic stages of coccidia, which, in sheep, are probably *E. bakuensis* and *E. ahsahta.* Adjacent mucosa appears normal and is uninfected. The term "pseudoadenomatous" has been used to describe these polypoid lesions, and the oocyst patches or plaques discussed above in coccidia-infected sheep and goats (Fig. 1.200B). The infected epithelial cells appear somewhat hypertrophic, with eosinophilic cytoplasm and prominent brush borders. Often these coccidia-infected cells do not slough rapidly postmortem, in contrast to their uninfected fellows.

Why masses of infected cells apparently persist in chronically infected animals without clinical disease is unclear. However, the plaques and polyps may be the result of mitogenic stimuli from progamonts, the immature stages in crypt epithelium, which appear to divide by binary fission in synchrony with the infected host cell.

Coccidiosis may also cause ill-thrift and diarrhea in suckling or weanling lambs 5–6 weeks old heavily stocked on pasture. In the UK, ***E. crandallis***, which develops largely in the ileum, and ***E. ovinoidalis*** are mainly associated with this syndrome. ***E. weybridgensis*** (*E. arloingi* "B"), which infects most of the length of the small intestine, may also contribute. The only gross lesion in affected lambs is congestion and thickening of the mucosa of the lower small intestine.

Under some circumstances, probably sudden exposure to large doses of oocysts, ***E. crandallis***, at least, causes *villus atrophy* in infected areas of intestine. Giant first-generation schizonts develop in crypt cells that after infection migrate into the lamina propria. As the infection progresses, villi become stumpy or disappear, and in small bowel

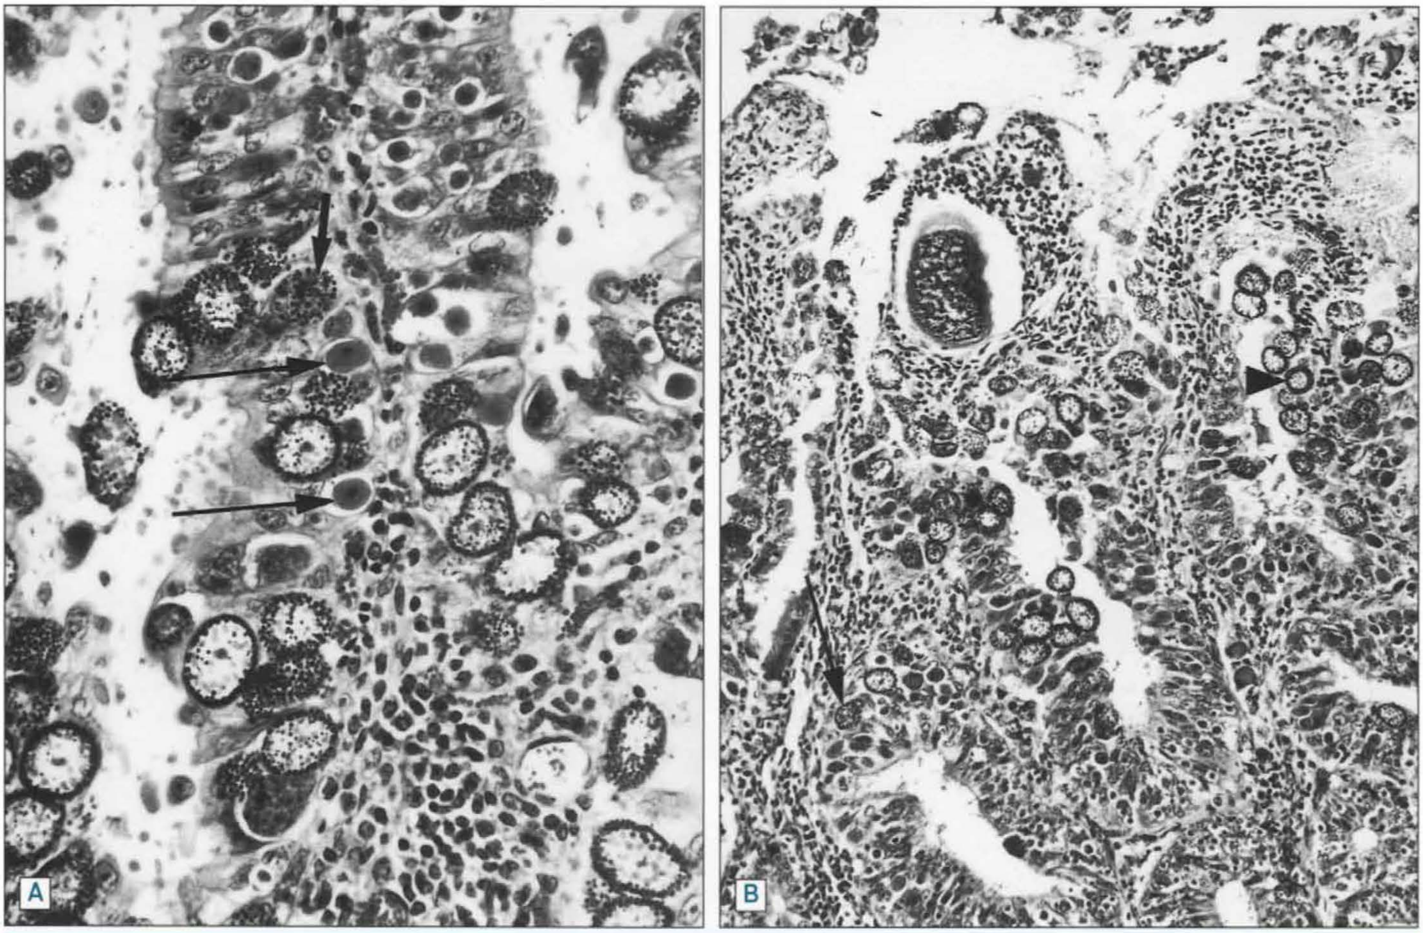

Figure 1.199 Coccidiosis (*Eimeria arloingi*) in a goat. **A.** Undifferentiated gamonts (long arrows), macrogametocytes (short arrow), and microgametocytes infect epithelial cells. **B.** Large schizont in lacteal in the ileum. and cecum, crypts are straight, hypertrophic, and contain proliferative epithelium. Asexual or, more commonly, sexual stages of coccidia are present in epithelium on the surface of the mucosa. In hyperplastic crypts, epithelial cells are infected by progamonts, which seem to be dividing in synchrony with host cells. Masses of macrophages may invest and invade the base of infected crypts, and apoptosis of infected and uninfected cells may occur, resulting in attenuation of surviving crypt epithelium. In heavy infections, there may also be thickening of the cecal mucosa by hyperplastic coccidia-infected cells. Occasionally, areas of small intestine and cecum, in which there has been severe damage to crypts, may become eroded.

Such lesions, if widespread, may cause malabsorption or perhaps protein-losing enteropathy. It is unclear whether atrophy of villi is the result of excess loss of epithelium directly due to the effects of coccidial infection, or whether it is mediated by an immune response.

E. apsheronica in the goat has minor pathogenic potential. Giant schizonts develop in the lamina propria of villi throughout the small intestine and in the cecum: second-generation schizonts are in the epithelium on villi in the small intestine, and in the cecum, but not the colon. Gametocytes have the same distribution. Pale foci in the mucosa, where gametocytes are concentrated, and focal areas of erosion and hemorrhage may occur in heavily infected animals.

Large schizonts are often encountered incidentally in submucosal lymphatics, or in the subcortical or medullary sinusoids of mesenteric lymph nodes in sheep and goats. Sometimes they may be visible grossly in these locations as pinpoint white foci. Occasionally, coccidial gametocytes or oocysts may also develop in intestinal lymphoid aggregates and mesenteric lymph nodes, where they may provoke a mild granulomatous reaction. Stages in lymph nodes probably result from establishment of sporozoites or primary merozoites swept from the lacteal into the lymphatic drainage early in infection. Development in such sites is not uncommon, but aberrant and likely dead-end. The species involved appear mainly to be those considered above, with a giant primary schizont developing in the lacteal.

In coccidiosis, *oocysts are usually numerous in feces*, but this is neither constant in, nor necessarily indicative of, disease. Mucosal scrapings or tissue sections of mucosa containing large numbers of asexual and gametogenous coccidial forms, in association with diarrhea, and perhaps some hemorrhage into the intestine, support the diagnosis, in the absence of other syndromes such as gastrointestinal helminthosis.

Coccidia in horses

The only coccidium of horses reported with any frequency is ***Eimeria leuckarti***, which is found in horses and donkeys the world over. In one survey of foals in Germany, it was found in 100%. It may also occur in older animals. Its reputation for pathogenicity rests largely on the *distinctive large gamonts* found by pathologists in the lamina propria of the small intestine in animals dead of obscure enteric disease. However, implication of *E. leuckarti* in the disease process is rarely, if ever, convincing, and it is encountered incidentally in the intestine of horses dead of other clearly defined conditions. Furthermore, heavy experimental inoculations, producing many gamonts in the gut and heavy oocyst passage, have failed to elicit clinical signs.

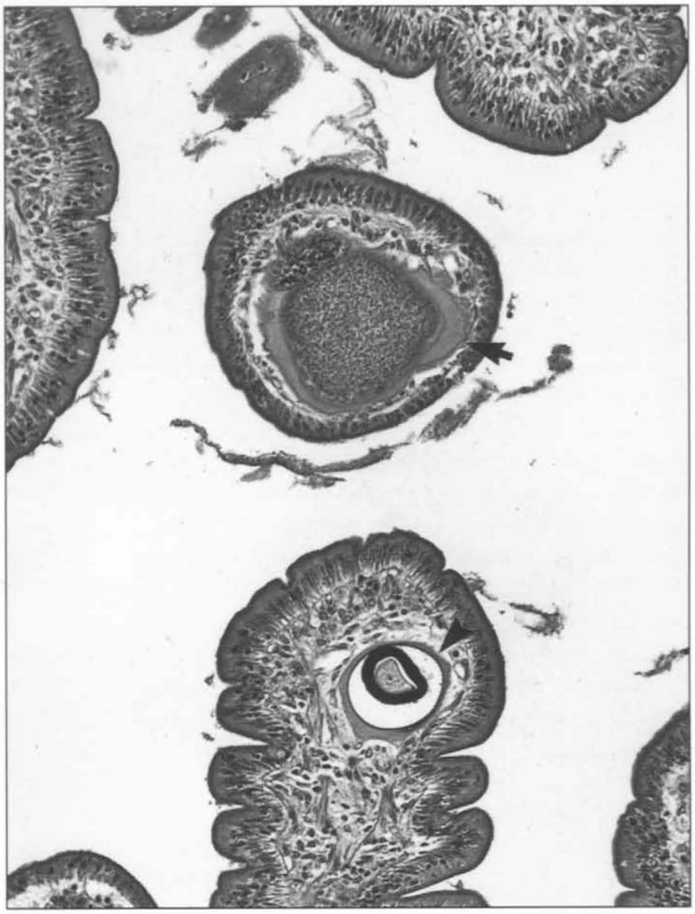

Figure 1.201 Microgametocyte (arrow) and developing oocyst (arrowhead) of ***Eimeria leuckarti*** in lamina propria, in a horse.

The stages present in the lamina propria of villi are giant microgametocytes and macrogametes, developing in markedly hypertrophic host cells, probably of epithelial origin (Fig. 1.201). The microgametocytes are up to ~250 μm in diameter, and when mature they contain swirling masses of microgametes. Immature microgametocytes very much resemble some of the giant schizonts of other species of coccidia, and have frequently been referred to as such; this stimulated the application of the term *Globidium* to the organism. However, the only schizont containing merozoites that has been recognized in horses was very small (12.5 μm in diameter), and in the epithelium of the ileum. The macrogametes have distinctive large eosinophilic or Schiff-positive granules that may be individual or confluent. The host cells are markedly hypertrophic with a fibrillar periphery, and the enlarged nucleus forms a crescent along one side of the parasitophorous vacuole. There is no inflammatory response to the gamonts, and only a mild reaction to degenerate stages in the lamina propria.

Coccidiosis in swine

At least 8–10 species of *Eimeria* are thought to occur in swine, along with a single species of *Isospora*. The latter, ***Isospora suis***, is the most important; it causes *porcine neonatal coccidiosis*, a disease of piglets from ~5–6 days to ~2–3 weeks of age. This disease is recognized in the USA, Canada, the UK, and western Europe; it also occurs in Australia, and probably wherever swine are reared intensively. The condition is most severe in herds where continuous farrowing and total confinement are practiced, and some laboratories report a prevalence of 10–50% among scouring baby pigs. Rapid sporulation (12 hours) and short prepatent period (5 days) promote rapid build-up of infection in a farrowing house.

Porcine neonatal coccidiosis has high morbidity, and usually low but variable mortality. It causes yellow watery diarrhea, dehydration, loss of condition, and death, or at least a temporary check in growth. Some animals may runt severely. Illness usually begins at ~7–10 days of age. Piglets continue to nurse, but may vomit clotted milk. At autopsy, many piglets have the typical appearance of undifferentiated neonatal diarrhea, with no specific gross findings in the gastrointestinal tract other than fluid yellow content. However, the intestine in some animals with coccidiosis may look turgid, rather than flaccid, and in a minority of animals a fibrinous or fibrinonecrotic exudate is present in the lower portion of the small intestine. Occasionally, casts will form.

I. suis replicates in the epithelium on the *distal third of villi* (Fig. 1.202), mainly in the *jejunum and ileum*, though infected cells may be found in the duodenum and colon in a few animals. Piglets usually become infected within the first day or two of life, perhaps by ingestion of the sow's feces. Merogony occurs in vacuoles in the cytoplasm, usually beneath the nucleus of the host cell. Infection of host cells is maximal 4–5 days after infection, and by 5 days, gametogony is evident. Thick- and thin-walled sporulated oocysts have been observed in feces of infected pigs, but either form may cause disease. The onset of lesions and clinical signs corresponds with this period of heavy infection of cells, which undergo lysis. Villi may become markedly atrophic. The surface epithelium that remains is cuboidal to squamous, and infected epithelial cells may be seen degenerating or exfoliating (Fig. 1.203). Erosions may develop at the tips of villi (Fig. 1.204). In the remnant of the villus, neutrophil infiltration, a moderate increase in round cells and eosinophilic proteinaceous material, perhaps collagen, may be present in the lamina propria. Effusion of neutrophils and fibrin from the eroded tips of villi contributes to the fibrinonecrotic membrane seen in some animals, and ulceration can occur. Gram-positive bacilli are often present in the exudate. In animals surviving for a few days, the cryptal epithelium may be markedly hyperplastic.

The severity of the lesions is a function of the size of the inoculum and the age of the pigs. Heavier inocula, within limits, produce more cellular damage and villus atrophy; fibrinonecrotic enteritis indicates ingestion of a large dose of oocysts. However, severe lesions may not be associated with heavy shedding of oocysts, since relatively few gamonts are able to develop in the reduced population of epithelial cells remaining on villi. The severity of lesions and signs is much greater in piglets a few days old in comparison with those 2 weeks of age. This partly relates to the lower rate of replication of epithelium in the crypts of young piglets, and therefore the development of more severe villus atrophy. The smaller size of young piglets also makes them more susceptible to the effects of malabsorption and diarrhea. Animals previously exposed to *I. suis* have relatively strong resistance to challenge.

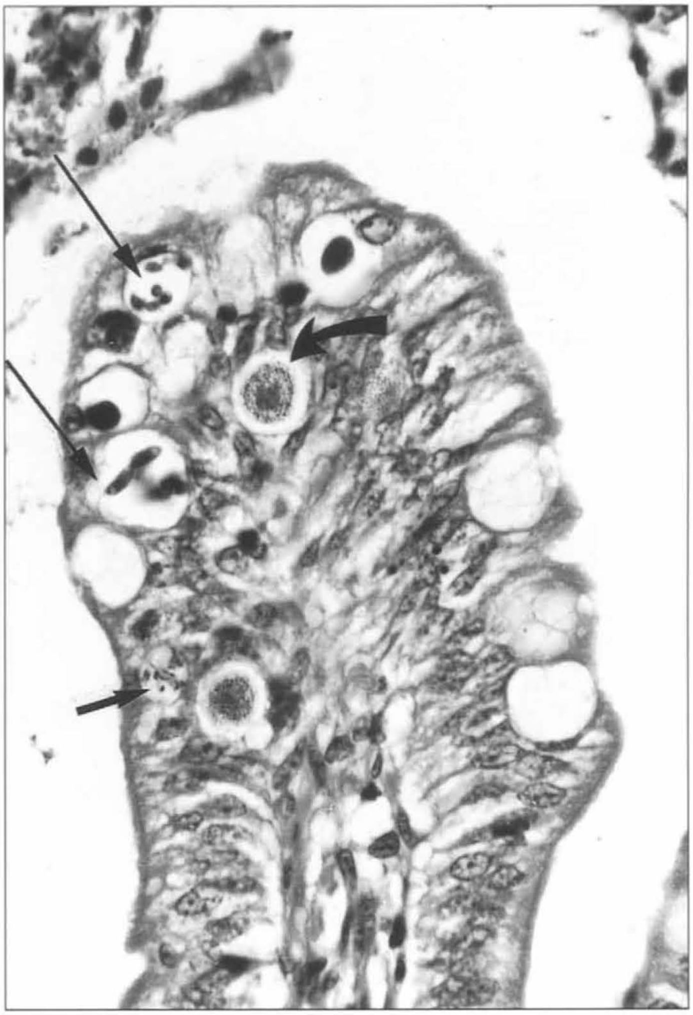

Figure 1.202 Meronts containing merozoites (long arrows), developing oocysts (curved arrow), and a microgametocyte (short arrow) in epithelial cells, in a pig with ***Isospora suis*** infection.

A **diagnosis** of coccidiosis must be considered in scouring neonatal piglets, and is strongly suggested by the presence of *fibrinonecrotic enteritis in the distal small bowel*. Atrophy of villi may be recognized at autopsy using a hand lens or stereomicroscope, or in tissue section. Asexual or sexual stages may be found in smears of mucosal scrapings. The distinctive binucleate type I meronts and pairs of large (12–18 μm in smears, 8–13 μm in sections) type I merozoites may be found in jejunal mucosa in the early phase of diarrheal disease. Multinucleate type II meronts and numerous small type II merozoites are the predominant stage during the clinical phase of disease. In section, these form clusters of 2–16 organisms like bunches of bananas, perhaps with a small residual body, in the parasitophorous vacuole in the enterocyte.

Macro- and microgamonts are present in moderate numbers by day 5 of infection, and a few oocysts may also be seen. Microgametocytes are ~9–16 μm in diameter, and are multinucleate. Oocysts in tissue sections are oval, ~15 × 12 μm, while those

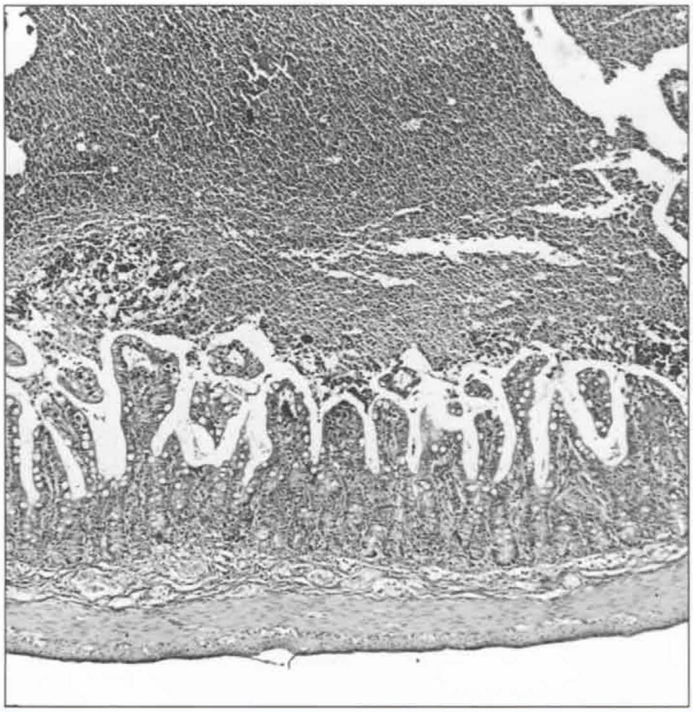

Figure 1.203 Blunting and atrophy of villi in a pig with ***Isospora suis*** infection. Lumen contains massive numbers of exfoliated epithelial cells, inflammatory cells, and coccidial stages, which appear grossly as exudate.

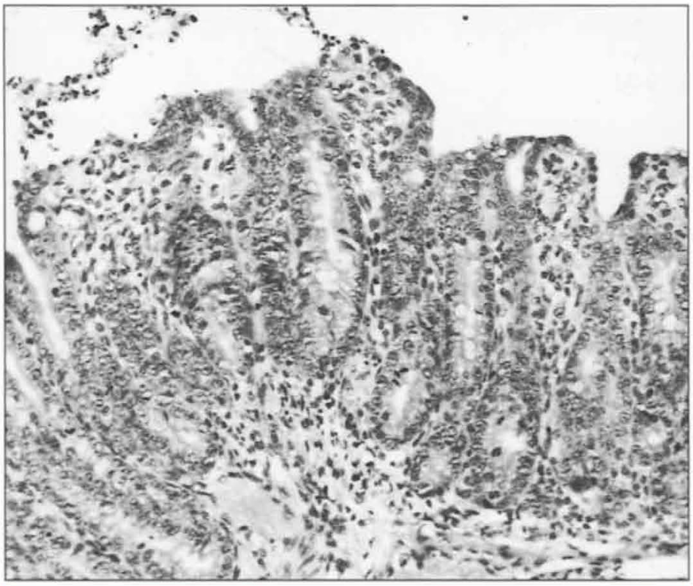

Figure 1.204 ***Isospora suis*** infection. Surface epithelium is severely attenuated, and there is erosion and effusion at tips of villi.

in smears are ~18 × 16 μm. Coccidial stages may be difficult to find in animals that have been ill for several days. Oocysts may not be found in feces, because the infection is not yet patent, the patent period has passed, or the lesions are very severe, reducing the number of oocysts produced.

Coccidiosis in older swine is due to several *Eimeria* species, and is uncommon but speciation can be accomplished. It typically occurs in animals with access to yards or pasture contaminated with oocysts. Weaners and growing pigs are affected. The species considered potentially pathogenic include ***E. scabra, E. debliecki***, and ***E. spinosa***. It is difficult to produce disease in experimentally inoculated pigs; *E. scabra* is probably the most pathogenic. Coccidiosis in swine due to *Eimeria* spp. is usually sporadic, or affects a few pigs in a group. Typically it causes diarrhea of a few days' duration, loss of appetite, and perhaps transient ill-thrift, or, in severe cases, emaciation. Occasionally animals die.

Lesions are usually limited to the lower small intestine, which may be congested or hemorrhagic, though overt blood is rarely found in the feces. Large numbers of schizonts, gamonts, and developing oocysts are in epithelial cells on villi and sometimes in crypts. Atrophy of villi, or erosion and local hemorrhage or inflammatory effusion may be evident, the lamina propria is edematous, and desquamated epithelium and oocysts are in the lumen of the gut. Rarely, heavily infected animals may have lesions in the large intestine. The species involved are diagnosed on the basis of the morphology of oocysts in feces or mucosal scrapings.

Coccidial gamonts and oocysts of a species resembling *E. debliecki* have been found infecting epithelium on the papilliform mucosa of cystic bile ducts in porcine liver. This is probably an aberrant site of development.

Heteroxenous apicomplexan protists

Cystoisospora, Toxoplasma, Neospora, Hammondia, Sarcocystis, Besnoitia, and ***Frenkelia*** comprise this group of protists. All of these heteroxenous members of the Apicomplexa are known to *use carnivores as definitive hosts*, and have one or more generations of merogony in the tissues of various species of prey. *Frenkelia*, which some would place in the genus *Sarcocystis*, as far as is known utilizes only raptorial birds as definitive hosts, and small rodents as intermediate hosts. It will not be considered further.

Coccidiosis in dogs and cats

Although several species of *Eimeria* have been reported from dogs and cats, their status as genuine parasites of these hosts is in doubt. The significant coccidia of dogs and cats are members of the genus *Cystoisospora*, considered here, and of the genera *Toxoplasma, Sarcocystis, Hammondia, Besnoitia,* and *Neospora*, dealt with subsequently. *Caryospora* spp. may occasionally produce dermal coccidiosis in immunosuppressed dogs.

***Cystoisospora* spp.** are characterized by oocysts that are passed unsporulated in feces, and which, when sporulated, have two sporocysts lacking a Stieda body, each with four sporozoites. Following ingestion of sporulated oocysts of heteroxenous species, transport hosts, usually prey species such as mice and other small rodents, but sometimes other hosts, are infected by large sporozoite-like "hypnozoites" in phagocytic cells in lymph nodes and other tissues. These, when ingested by the predator, resume development in the intestine, and lead to asexual and sexual development in the definitive host. Heteroxenous passage is not obligatory, and sporulated oocysts are also directly infective to the definitive host.

In **dogs**, four species of *Cystoisospora* are recognized. Meronts of ***C. canis*** develop in the subepithelial lamina propria of the villi in the distal small intestine and, to a lesser extent, in large bowel. Gamonts occur beneath and within the epithelium of the ileum and large intestine, and the oocyst is the largest among *Cystoisospora* spp. of dogs, being ~38 × 30 μm. The other three are members of the "*C. ohioensis* complex." ***C. ohioensis*** develops exclusively in epithelial cells, mainly in the distal portions of villi along the length of the small bowel, especially in the ileum, and occasionally in the large bowel. It may be the most pathogenic species in dogs. The oocysts of *C. burrowsi*, *C. ohioensis,* and *C. neorivolta* are similar. Original literature should be consulted for details that will permit differentiation of these species in tissue. Endogenous stages of ***C. burrowsi*** occur in epithelial cells, and in the lamina propria of the tips of villi in the distal two-thirds of the small intestine. ***C. neorivolta*** mainly develops in proprial cells beneath the epithelium in the tips of villi in the distal half of the small intestine, and rarely in the cecum and colon. Occasional stages may be in the epithelium. *C. canis* and *C. ohioensis* are known to be heteroxenous. Meronts of an unknown coccidian, probably a *Cystoisospora* sp., have been found in the intrahepatic bile ducts of a dog, associated with severe suppurative cholangiohepatitis.

In **cats**, two *Cystoisospora* spp. occur. Meronts and gamonts of ***C. felis*** develop in epithelium of villi in the small intestine, and occasionally in epithelium in the large bowel. The oocyst is large, ~43 × 33 μm. ***C. rivolta*** also develops in epithelium on villi and in crypts and glands in the small and large intestine. Oocysts are ovoid, ~25 × 23 μm. Subepithelial schizonts and gamonts of an unknown coccidian, possibly a *Cystoisospora* species, have been associated with fatal enteritis in a cat.

Coccidiosis in the dog and cat is largely a clinical entity, *usually nonfatal.* The lesions of coccidiosis in small animals are poorly defined, and care must be taken not to ascribe disease to these organisms simply on the basis of the presence of endogenous stages in the mucosa of animals dead of enteric disease. Rotavirus and coronavirus might be expected to produce similar signs. However genuine cases of fatal coccidiosis do occur, though few are recorded in the literature. Affected animals are young, and usually from environments such as pet shops, animal shelters, or kennels in which standards of sanitation may not be high. There is a history of diarrhea of several days' duration, and the animal is dehydrated. Other than mild hyperemia of the mucosa and excessively fluid content of the small intestine and colon, gross lesions in the gut may not be evident. Microscopically, there may be moderate atrophy of villi, with attenuation of surface enterocytes, and perhaps effusion of acute inflammatory exudate from the tips of some eroded villi. Asexual and sexual stages of coccidia will be evident in moderate to large numbers in the epithelium or lamina propria of villi. In some cases, the large bowel may be infected, with exfoliation of surface epithelium, and accumulation of necrotic debris in some dilated glands.

Toxoplasmosis

Toxoplasma gondii uses members of the Felidae as definitive hosts. It is optionally heteroxenous; cats may be infected directly by ingestion of oocysts, but probably most commonly by ingestion of asexual stages in the tissues of prey species. Cats excrete oocysts 3–10 days after ingesting *bradyzoites*, approximately 13 days after ingesting tachyzoites, and 18 days after ingesting oocysts. The latter occurs with very poor efficiency. Intermediate hosts are infected by oocysts shed in the feces of cats, or by a variety of other routes considered below. Five stages of asexual development are recognized in the intestinal epithelium of cats infected with tissue cysts from intermediate hosts. The gametocytes also develop in epithelium on villi, especially in the *ileum*. In heavy infections, exfoliation of infected epithelium from villi is associated with the development of *villus atrophy*, and occasional spontaneous cases of diarrhea in kittens seem to be caused by *Toxoplasma*-induced atrophy of villi and malabsorption.

In intermediate hosts, and in cats, extraintestinal asexual development occurs in a variety of organs and tissues. Rapidly dividing forms (*tachyzoites*) may by endodyogeny proliferate in cells in many sites for an indefinite number of generations, and are the stage associated with acute toxoplasmosis in cats and other species. Eventually, tachyzoites induce the formation of a cyst wall in a host cell, and divide slowly, forming bradyzoites, which reside in quiescent tissue cysts.

T. gondii, with *Neospora caninum*, is unique among protists in its ability to parasitize a wide range of hosts and tissues. *It is one of the most ubiquitous of organisms*; experimentally, essentially all homeothermic animals can be infected, and natural infections occur in birds, nonhuman primates, rodents, insectivores, herbivores, and carnivores, including domestic species and humans. Serologic surveys indicate that infection is widespread in most species of domestic animals; however, except for abortions in sheep and goats, overt disease is sporadic and rare.

Transmission may occur by a number of different routes. The shedding of oocysts in the feces of cats and wild Felidae has been mentioned earlier. Transplacental infection occurs commonly in sheep and goats and sporadically in swine and humans. Carnivorous animals and humans may become infected by ingesting oocysts from cats, or more commonly from cysts containing bradyzoites in tissues of infected animals, implying that the cycle of infection can be maintained by means of facultative homoxenous transmission, without a definitive host.

Systemic toxoplasmosis occurs most often in young animals, especially immunologically immature neonates and in immunocompromised hosts. Low levels of γ-interferon and the associated inability to activate macrophages are predisposing factors for systemic toxoplasmosis. In dogs, canine distemper, ehrlichiosis, and lymphosarcoma are commonly concomitant with toxoplasmosis. The infection in juveniles may be acquired pre- or postnatally. After ingestion, *Toxoplasma* organisms penetrate the intestinal mucosa. In cats, the enterointestinal cycle and systemic infection occur almost simultaneously. In other animals the tachyzoites are the first stage of infection, after invasion of the lamina propria by sporozoites released from the oocyst, or by bradyzoites released from the tissue cyst digested from food in the intestine.

Dissemination of *Toxoplasma* occurs in lymphocytes, macrophages, granulocytes, and as free forms in plasma. From the intestine the organism may follow two routes. It may spread via the lymphocytes to the regional nodes and from there in the lymph to the bloodstream, or it may pass in the portal circulation to the liver and from there to the systemic circulation. Further dissemination occurs to a wide variety of organs. Tachyzoites actively invade or are phagocytosed by host cells and are surrounded in a parasitophorous vacuole formed of host cell membrane. Tachyzoites proliferate, destroying the host cell, and cell-to-cell transmission may occur within infected organs.

Focal necrosis is common, and appears to be directly related to the rapid replication of tachyzoites. The outcome of infection is determined by a number of factors, including the number and strain of *Toxoplasma* in the infecting dose, and the species, age, and immune status of the host. Lesions in visceral organs are usually evident within 1–2 weeks after oral infection. Variable numbers of tachyzoites are usually found in the vicinity of the necrotic areas.

Specific immunity develops within a few days after infection; the cell-mediated arm is most significant in toxoplasmosis, mediated in large part by interleukin-12. This reduces the severity of infection but usually does not terminate it. Immune animals develop a *chronic or dormant form* of *Toxoplasma* infection that is characterized by the formation of *cysts*, containing bradyzoites. These are mainly located in the brain, skeletal muscle, and myocardium. Cysts may form as early as 1–2 weeks after infection and they may persist for months, possibly years. Intracellular encystment protects the bradyzoites from both cellular and humoral immune mechanisms. *Inflammation is usually not associated with cysts.* When the level of resistance drops below a critical level, for example, due to treatment with immunosuppressive drugs, intercurrent disease, or other factors that depress immunity, particularly decreased levels of γ-interferon, *a chronic infection may become reactivated.* The cysts rupture and cause severe local inflammation. Released bradyzoites rarely survive to infect other cells.

The **clinical signs** of toxoplasmosis vary considerably, depending on the organs affected. The most consistent signs reported are fever, lethargy, anorexia, ocular and nasal discharges, and respiratory distress. Neurological signs include incoordination, circling, tremors, opisthotonos, convulsions, and paresis. Paresis is often associated with radiculitis and myositis. In the dog, signs may coexist with those of canine distemper and are not sufficiently distinctive to allow ready differentiation.

Systemic toxoplasmosis has been reported in most species of domestic animals. The hallmarks are *interstitial pneumonia, focal hepatic necrosis, lymphadenitis, myocarditis, and nonsuppurative meningoencephalitis.* Pulmonary lesions are probably most consistently found, followed by central nervous system lesions. The lesions in the various organs are morphologically similar in most species, varying mainly in degree.

Macroscopic lesions in the lung vary from irregular gray foci of necrosis on the pleural surface to hemorrhagic pneumonia with confluent involvement of the ventral portions. Careful examination of the liver usually reveals either areas of focal necrosis or irregular mottling, and edema of the gallbladder. The spleen is enlarged, as are lymph nodes, which are wet and often red. Pleural, pericardial, and peritoneal effusions occur irregularly. Pale areas may be evident in the myocardium and skeletal muscle. Occasionally, the pancreas is the most severely affected organ, in which case an acute hemorrhagic reaction may involve the entire organ. Yellow, small, superficial intestinal ulcers with a hyperemic border have been reported in piglets. Large pale areas of necrosis may be present in the renal cortices, mainly in goats and kittens.

Microscopically, the early pulmonary lesions are characterized by *diffuse interstitial pneumonia*; the alveolar septa are thickened by a predominantly mononuclear inflammatory cell reaction with a few neutrophils and eosinophils. Macrophages and fibrinous exudate fill the alveoli. Foci of necrosis involving the alveolar septa, bronchiolar epithelial cells, and blood vessels are scattered throughout the lobules. These lesions are soon followed by regenerative changes that are characterized by hyperplasia and hypertrophy of alveolar lining cells, mainly type II pneumocytes: so-called *epithelialization of alveoli.* In some areas this may be so marked as to give the affected areas an adenomatous appearance. Tachyzoites are usually evident in alveolar macrophages and may also be found in bronchiolar epithelial cells and the walls of blood vessels.

In the *liver*, irregular foci of coagulative necrosis are scattered at random throughout the lobules. There is usually little evidence of inflammation associated with the necrotic areas. Variable numbers of tachyzoites may be present in hepatocytes and Kupffer cells, usually at the periphery of the lesions, but often at some distance. If the pancreas is involved, there is extensive peripancreatic fat necrosis, with areas of coagulative necrosis in parenchyma. Numerous tachyzoites are usually evident in both ductal and acinar cells.

Lesions in *lymph nodes* are often associated with infection in the corresponding organ. They are characterized by irregular areas of coagulative necrosis, mainly in the cortex. A moderate inflammatory reaction may be evident at the periphery of the necrotic areas. There may be necrosis and depletion of lymphocytes in the follicles. In more chronic cases, the changes are those of nonspecific hyperplasia of lymphoid cells in cortical and paracortical areas, with a large macrophage population in the medullary sinusoids. Tachyzoites may be seen in phagocytic cells in sinusoids. Similar lesions may occur in the spleen. Necrotic areas are mainly located in the red pulp in this organ.

In the *heart and skeletal muscle*, foci of necrosis and mononuclear cell inflammation may be part of toxoplasmosis. There is often some difficulty in distinguishing between tachyzoites and mineralization of mitochondria in myocytes but, at some distance from areas of acute reaction, inert cysts can usually be identified in healthy fibers.

Brain lesions may vary in appearance. In the most fulminating cases cerebral lesions may be relatively inconspicuous. They consist of nonsuppurative meningoencephalitis with multifocal areas of necrosis and often malacia. There is swelling of endothelial cells, necrosis of vessel walls, and vasculitis. There may be marked perivascular edema and hyperplasia of perithelial cells. Tachyzoites and occasionally cysts may be found in vessel walls and in necrotic areas in both gray and white matter at all levels of the brain. If survival is prolonged, residual cerebral lesions consist of *microglial nodules* along with more extensive hyperplasia of perithelial cells and perivascular fibrosis that tends to make the vessels very obvious. At this stage tachyzoites are rare, and cysts 30 μm in diameter with a wall of amorphous acidophilic material ~0.5 μm thick, located in areas away from the lesions, may be the only form seen. Spinal cord lesions resemble those seen in the brain.

Systemic toxoplasmosis is reported from *cats*, but is certainly seen less commonly in this species than in some others. Lesions are similar to those described for other species. Chronic granulomatous toxoplasmosis may involve the intestine in older cats and produce annular areas of thickening. The mucosa overlying the granulomas may be ulcerated.

The finding of tachyzoites and/or cysts in association with areas of coagulative necrosis in one or more organs is highly suggestive of toxoplasmosis. Often the *Toxoplasma* organisms are difficult to distinguish within the necrotic foci, and immunohistochemical techniques have proved very useful in highlighting their presence. Serological tests are of limited value in the diagnosis of disease associated with *T. gondii* infection.

The placental and fetal lesions associated with *Toxoplasma* infection and abortion are described in Vol. 3, Female genital system, and ocular lesions in Vol. 1, Eye and ear.

Neosporosis

Neospora caninum causes disease in *dogs and ruminants* over much of the world. *Dogs and coyotes are definitive hosts*; cattle, water buffalo, and white-tailed deer can act as intermediate hosts. *Neospora* has been associated with systemic and central nervous system disease in dogs, and with abortion and central nervous system disease in neonatal ruminants. Tachyzoites undergoing endodyogeny, and cysts containing bradyzoites, are found in the tissues of affected animals. Transplacental transmission occurs in ruminants and dogs. Infection may be maintained in lines of cattle in this manner, while some subclinically infected bitches have given birth to successive litters of pups that became affected within the first few months of life. Transmission may also occur by ingestion of infected tissue, as in toxoplasmosis.

Dogs of all ages may be affected, but disease seems most characteristic as *encephalomyelitis, polyradiculoneuritis, and polymyositis* in puppies over ~5 weeks of age, and perhaps involving several animals in a litter. Ascending paralysis, muscle contraction causing hyperextension of the limbs, cervical weakness, and dysphagia may progress to death, or animals will stabilize with caudal paralysis. In adult dogs, there are signs of widespread involvement of the central nervous system, and disseminated disease may be evident, with polymyositis, myocarditis, and dermatitis associated with parasite infection. Though disease may be precipitated or exacerbated by glucocorticoid administration, *Neospora* is regarded as a *primary pathogen*. Circulating levels of γ-interferon may be related to immune resistance.

In acute systemic infections there may be hepatic enlargement with coalescing areas of pallor, related to widespread necrosis of hepatocytes; streaky pallor of muscles due to myonecrosis, mineralization, and nonsuppurative myositis; and pulmonary congestion and edema, due to subacute alveolitis. Tachyzoites are common in affected tissues.

Nonsuppurative encephalomyelitis is associated with the presence of tachyzoites and tissue cysts in neurons and neuropil; the degree of necrosis, gliosis, neovascularization, and demyelination presumably depends to some extent on the duration of the lesion. Retinitis is also reported in association with *Neospora*, as is pyogranulomatous ulcerative dermatitis, occasionally.

In **ruminant abortion**, *Neospora* may be associated with *necrotizing placentitis*, and with *myositis* and *nonsuppurative encephalomyelitis* of the fetus after about 90 days' gestation. While a well-documented etiologic agent of abortion in cattle, the extent of natural *Neospora*-induced abortions in sheep and goats is unknown. Experimentally, sheep and pigs experience placental infection and necrotizing encephalitis in the fetuses. *N. caninum* has also been reported from a case of equine protozoal myelitis.

Tachyzoites are approximately ovoid, ~5–7 μm long, and are found in small groups or large clusters, free in the cytoplasm or in parasitophorous vacuoles in many types of cells throughout the body. Tissue cysts are found in only the brain and spinal cord. They are spherical or slightly elongate, up to ~110 μm in greatest dimension. The cyst wall is ~1–4 μm thick, usually greater than the width of the bradyzoites, which are slender (1.5 × 7 μm), slightly curved, with an obvious nucleus; they stain weakly periodic acid–Schiff-positive.

Neospora must be distinguished from *Toxoplasma* in all species, and from *Sarcocystis* in aborted fetuses. *Neospora* tachyzoites resemble those of *Toxoplasma* in tissue section. Ultrastructurally, *Neospora* tachyzoites have over 11 rhoptries, whereas there are few in *Toxoplasma*. *Toxoplasma* is always found in a membrane-bound vacuole in the cytoplasm; *Neospora* tachyzoites are often not within a parasitophorous vacuole. *Neospora* tissue cysts are relatively uncommonly encountered, especially in acute cases. They are distinguished from *Toxoplasma* by the thicker wall (thinner than 0.5 μm in *Toxoplasma*). Perhaps the most common method of distinction is by immunohistochemistry using specific antibodies, while polymerase chain reaction is also useful. *Sarcocystis* meronts divide by endopolygony in endothelium in domestic animals; they are not in a parasitophorous vacuole; and merozoites lack rhoptries. Sarcocysts in muscle cells are within a parasitophorous vacuole; they have a distinct wall; and they are usually subdivided internally by septa.

Hammondia infection

Hammondia spp. are obligatorily heteroxenous organisms, with the cat (***H. hammondi***) and dog (***H. heydorni***) as definitive hosts. They have also been known as *Toxoplasma hammondi* and *Isospora bahiensis*, respectively. *Toxoplasma*-like oocysts are shed in the feces of the definitive host and are infectious to intermediate hosts, mammals and birds (*H. hammondi*), and ruminants (*H. heydorni*). Here, bradyzoites develop in cysts in striated muscle, which are infective when ingested by the carnivore. Disease is not associated with infection of intermediate hosts; diarrhea may occur in heavily infected dogs.

Dubey JP, et al. Clinical *Toxoplasma gondii*, *Hammondia heydorni*, and *Sarcocystis* spp. infections in dogs. Parasitologia 2003;45:141–146.

Sarcocystis infection

Sarcocystis is comprised of about 200 obligatorily heteroxenous species. Inconspicuous sexual stages occur in the epithelium at the tips of villi in the small intestine, and oocysts sporulate in the subepithelial lamina propria, producing two sporocysts within a thin oocyst wall. Sporocysts containing four sporozoites are shed in feces. These are infective to intermediate hosts, in which three generations of merogony occur in vascular endothelium, and a final cyst containing first *metrocytes* (mother cells), which produce *merozoites* (bradyzoites), is formed in myocytes and occasionally other cells. Ingestion of tissue cysts containing bradyzoites initiates gametogony in the definitive host. There is apparently no resistance to the development of gamonts, and no disease is associated with them in the definitive host.

Many species of *Sarcocystis* are recognized, based on prey–predator cycles. Sporogony of a given species usually occurs in only one or a few genera of carnivores. The number of species capable of acting as intermediate hosts may be narrow or wide, depending on the species of *Sarcocystis*.

Sarcocystis cysts in ovine and, occasionally, bovine muscle may be grossly visible, causing losses at meat inspection. *Eosinophilic myositis* can result from granulomas due to *Sarcocystis* infection of muscle. However, studies have shown that unaffected muscle often harbors more of these organisms than the inflamed portions. *Sarcocystis* infection in cattle (***S. cruzi***), sheep (***S. tenella***), and swine (***S. miescheriana***), and, experimentally, in goats (***S. capracanis***), may cause acute fatal disease characterized by anemia and widespread hemorrhage, which is associated with clotting disorders. As the disease progresses, cattle may develop inappetence, weight loss, reduced milk yield, hyperexcitability, hair loss, and in some animals, nervous signs. Ill-thrift associated with *Sarcocystis* infection may also occur in other species. Both syndromes are initiated during the endothelial phase of the infection. As well, abortion occurs during this phase in some species. Abortion associated with the acute disease is the result of the systemic illness, and the fetus is usually not infected. However, in cattle, some abortions, seen in otherwise clinically normal animals, are associated with meronts of *Sarcocystis* in the placenta and in vascular endothelium of the fetus, especially in the brain, and with nonsuppurative encephalitis. Encephalitis is occasionally associated with *Sarcocystis* infection in sheep, and in horses ***S. neurona*** is the cause of protozoal myeloencephalitis. Details of these syndromes are discussed in Vol. 1, Muscle and tendon; Vol. 3, Female genital system; and Vol. 1, Nervous system.

A *Sarcocystis*-like agent has also been implicated in mortality of Rottweiler dogs with hepatitis, encephalitis, and dermatitis.

Besnoitia infection

Besnoitia spp. are also obligatorily heteroxenous, but the definitive host for many species has not been identified. Some stages of merogony and gametogony occur in the intestine of the only definitive host yet known, the cat, where they are not known to be pathogenic. Oocysts are shed unsporulated, and resemble those of *Toxoplasma* and *Hammondia* when sporulated. Meronts in the intermediate host develop in mesenchymal cells, probably fibroblasts, which become massively hypertrophic, forming cysts containing many clusters of merozoites (bradyzoites) in the host cell cytoplasm. Among domestic animals, cysts of *B. besnoiti* may assume some significance in the skin of cattle and goats (see The Skin and Appendages, Volume 1, Chapter 5), and *Besnoitia* cysts have been reported in association with laryngeal polyps in a horse.

Cryptosporidiosis

Cryptosporidium is a small apicomplexan protist, found on the surface of epithelium in the gastrointestinal, biliary, and respiratory tracts of mammals, birds, reptiles, and fish. Respiratory infection is most significant in birds, and disease in mammals is generally enteric.

Although its taxonomic position in relation to other apicomplexan protists, and its species nomenclature, are in a state of flux, on molecular genetic grounds about 15 morphologically similar species of *Cryptosporidium* are recognized. Five of these occur in domestic animals: (1) ***C. parvum***, small, and initially described in the mouse intestine, but parasitic in cattle, other ruminants, and humans; (2) ***C. andersoni*** in cattle; (3) ***C. suis*** in pigs; (4) ***C. felis*** in cats; and (5) ***C. canis*** in dogs. *C. parvum* is zoonotic, as are *C. suis*, *C. felis*, and *C. canis* to a lesser extent, and disease in humans has been associated with contamination of water sources, food and milk products, as well as close contact with infected animals. However, humans also have a primate-adapted species – ***C. hominis***, and it is probably responsible for the majority of outbreaks of cryptosporidiosis not associated with direct animal contact.

All three stages of the *Cryptosporidium* life cycle – merogony, gametogony, and sporogony – occur extracytoplasmically in a vacuole within the apical region of epithelial cells, protruding above the cell surface (Fig. 1.205). The prepatent period of *C. parvum* in calves is ~7 days and infections usually persist for weeks or, if the animal is immunocompromised, perhaps months. Type I merozoites recycle in a new host cell to produce another meront generation, while type II merozoites differentiate to gamonts. Thin-walled oocysts excyst in the gut of the same host, resulting in autoinfection by the sporozoites released, while thick-walled oocysts are excreted to the external environment and are responsible for transmission to another host. Multiple generations of merogony, and autoinfection by excystment

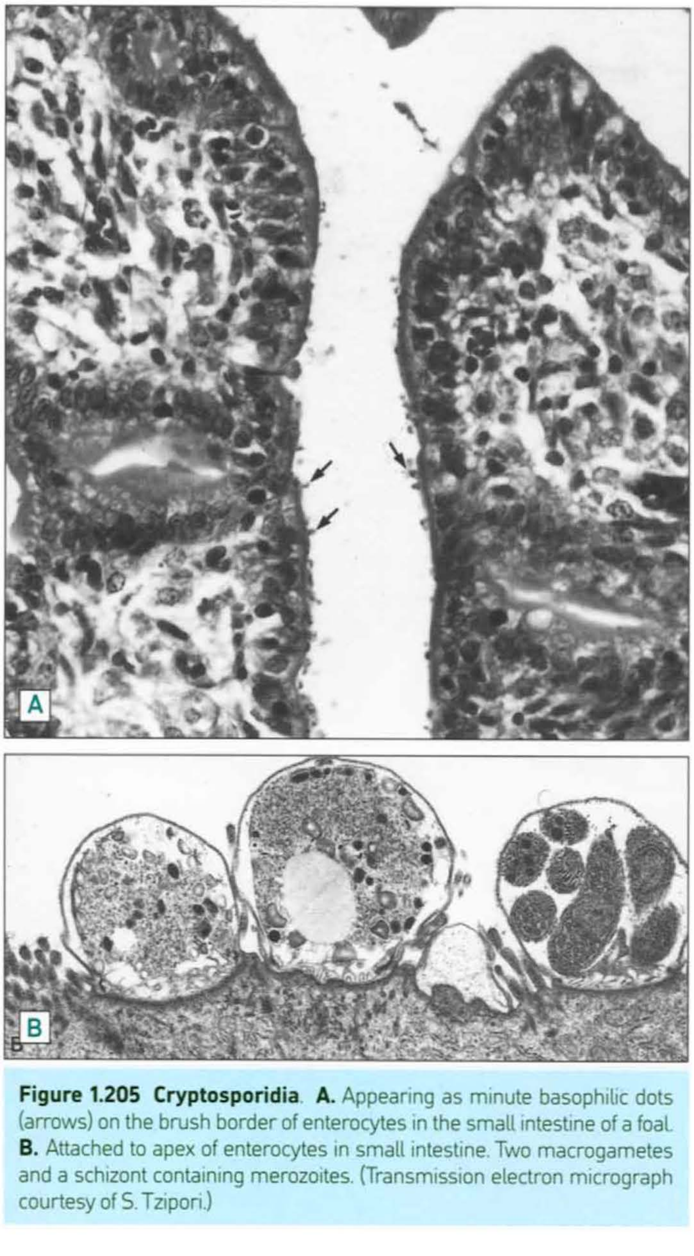

Figure 1.205 Cryptosporidia. A. Appearing as minute basophilic dots (arrows) on the brush border of enterocytes in the small intestine of a foal. **B.** Attached to apex of enterocytes in small intestine. Two macrogametes and a schizont containing merozoites. (Transmission electron micrograph courtesy of S. Tzipori.)

of thin-walled oocysts, result in a large biotic potential and promote heavy colonization of the gut.

The organisms are enclosed within a parasitophorous vacuole formed by apposition of two unit membranes of the host cell, probably caused by inversion of a microvillus by the infecting sporozoite or merozoite. A specialized "feeder" organelle is present at the attachment zone in the base of the vacuole, between the infecting organism and the cytoplasm of the host cell. Developmental stages are small, in most cases ~2–6 μm in diameter. Undifferentiated meronts and gamonts are recognized as small basophilic trophozoites. Mature schizonts contain small falciform merozoites. Macrogamonts are ~5 μm in diameter, and contain small granules. Oocysts in tissue sections are often collapsed into a crescent shape. The various stages may be recognized in wax- or plastic-embedded sections under the light microscope, but are best studied with the electron microscope. Oocysts containing four sporozoites may be demonstrated by fecal flotation, or in fecal smears stained with Giemsa, by a modified Ziehl–Neelsen technique, or with Auramine O or fluorescein-labeled antibody and examined with ultraviolet light.

Cryptosporidia are found in many circumstances, and in some species infection appears to be asymptomatic. Neonates are particularly susceptible to intestinal infections, and this is especially so among ruminants (calves, lambs, kids, red deer calves) infected with *C. parvum*. Diarrhea, anorexia, and depression in calves usually occur between ~1 and 4 weeks of age, and in lambs about 5–14 days old. However, naive calves up to 3 months of age are susceptible to infection and may develop diarrhea.

Cryptosporidial infections are mainly eliminated by cell-mediated immune phenomena, but the humoral arm also contributes. Immunosuppression is contributory to, but not essential for, the development of disease. Heavy infections are reported in Arabian foals with combined immunodeficiency, and cryptosporidiosis has occurred in cats with *Feline leukemia virus* infection, and in dogs with canine distemper. In immunocompromised individuals, organisms may be present at any level of the gastrointestinal tract, from esophagus to colon. Liver, gallbladder, pancreas, and their ducts may also be involved, as may the respiratory tract. Cryptosporidia frequently occur concurrently with enterotoxigenic *Escherichia coli*, rotaviral, or coronaviral infection in neonatal ruminants, but can be primary pathogens.

In all species, *intestinal cryptosporidiosis is associated with villus atrophy of variable severity*, characterized by blunting and some fusion of villi, and by hypertrophy of crypts of Lieberkühn (Fig. 1.206). Surface epithelium is usually cuboidal, rounded, or low columnar, and sometimes exfoliating or forming irregular projections at tips of villi. *Large numbers of cryptosporidia are usually visible in the microvillus border of cells on the villi* (Fig. 1.205A), and not in crypts of Lieberkühn, although occasionally, the reverse is true. Organisms typically are most heavily distributed in the distal half of the small intestine, especially in ileum, though occasionally cryptosporidia may occur in the cecum and colon. Mild proprial infiltrates of neutrophils and mixed mononuclear cells are present, probably attracted by proinflammatory cytokines released from infected epithelium. An increase in intraepithelial T lymphocytes has been documented in the intestine of infected calves.

Diarrhea in cryptosporidiosis is mainly attributable to malabsorption associated with villus atrophy and a population of immature enterocytes; and perhaps to the occupation of a large proportion of the surface area of absorptive cells by the organisms. Release of inflammatory mediators, principally prostaglandins, may stimulate mucosal secretion, and an increase in epithelial cell permeability to macromolecules has been demonstrated in vitro.

Cryptosporidium parvum is most significant in **calves**, as a cause of undifferentiated neonatal diarrhea, in which it must be differentiated particularly from coronaviral and rotaviral infection. Frequently it is concurrent with other agents causing this syndrome; it tends to be most prevalent in animals ~2 weeks old. A similar situation occurs in lambs, though disease does not appear to be as common, or well recognized, in that species. It is a sporadic or minor cause of sometimes fatal diarrhea in other species of ruminants.

Though cryptosporidiosis can be induced experimentally in **piglets**, it is a very rare cause of spontaneous disease in swine. It is only occasionally associated with disease of carnivores, and then often in probably immunocompromised animals. Though infection of **foals** is not uncommon, *Cryptosporidium* has been associated with disease mainly in animals with combined immunodeficiency,

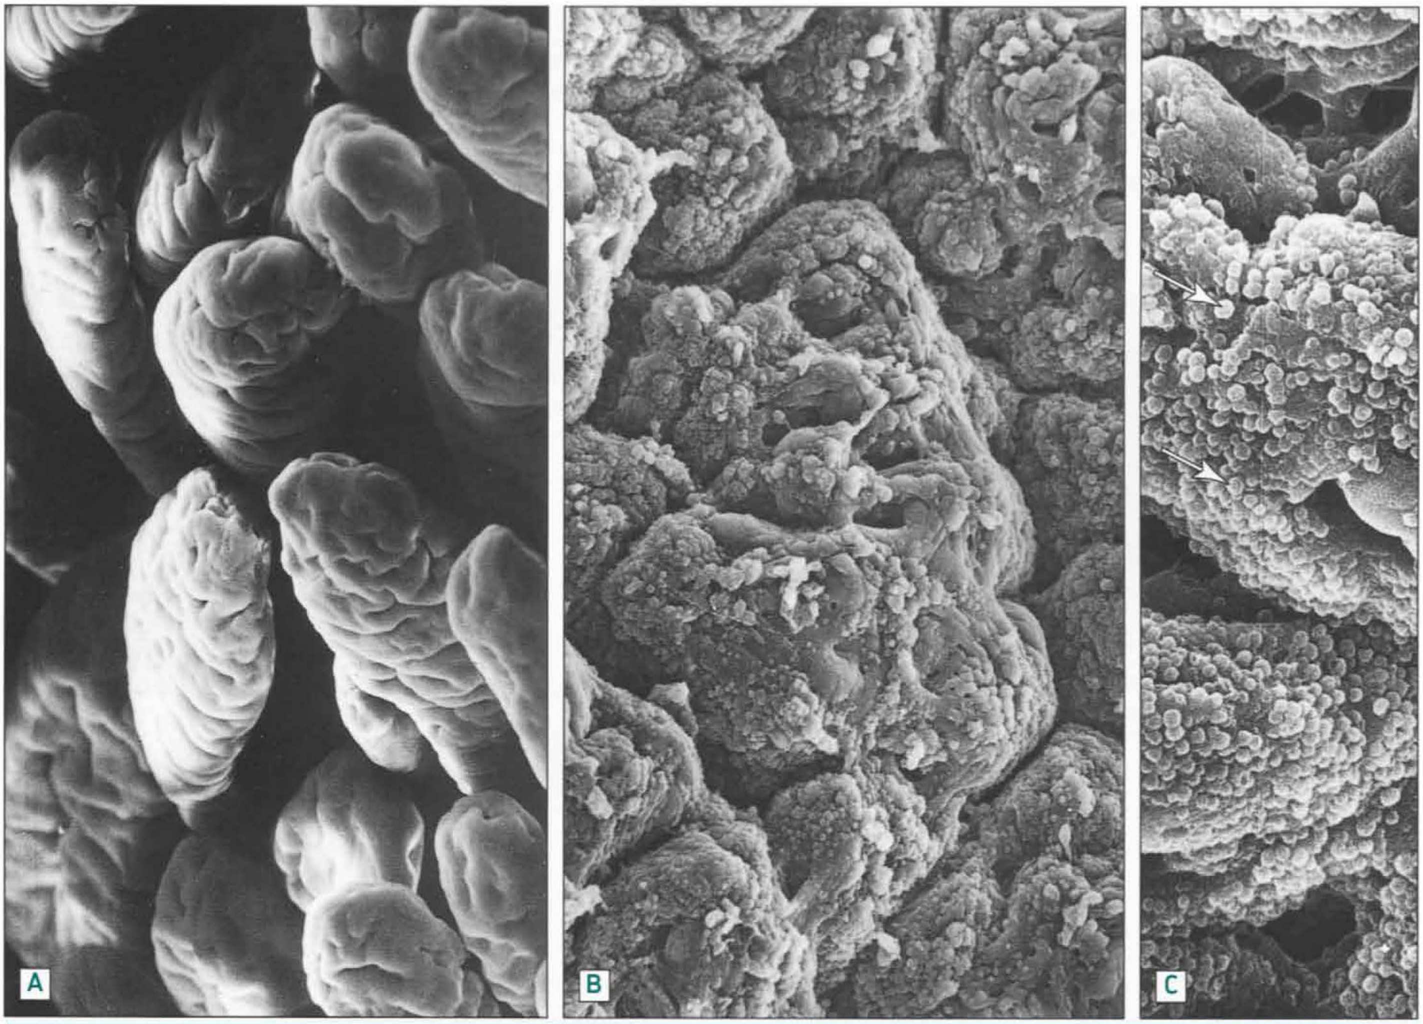

Figure 1.206 Cryptosporidia: scanning electron micrographs. **A.** Normal villi. **B:** Villus atrophy associated with cryptosporidiosis. Cryptosporidia are visible as minute spheres on mucosal surface. **C.** Detail of (**B**) showing cryptosporidia (arrows). (Courtesy of S. Tzipori.)

complicated by adenoviral infection. Disease has not occurred in successful experimental infections in foals, and the role of cryptosporidia in the etiology of neonatal diarrhea in foals is poorly defined, although occasional outbreaks attributable to *C. parvum* may occur.

The diagnosis is based on the presence of large numbers of cryptosporidia in sections of freshly fixed lower small intestine, preferably in association with villus atrophy. Examination of smears of ileal mucosa stained with Giemsa may allow a rapid diagnosis, or permit a diagnosis on tissue from an animal dead for some hours.

C. andersoni, in the *abomasum of weaned calves and older cattle*, is not associated with diarrhea, but plasma pepsinogen levels rise, and weight gains of some growing animals may be adversely affected. There is mucous metaplasia/hyperplasia in the fundic glands, which are dilated, with attenuation of the lining epithelium, on which cryptosporidia are numerous. Infections have been associated with decreased milk production.

Rarely, cryptosporidia are seen in gastric biopsies from **cats**, sometimes associated with mild gastritis. There is some indication that concurrent infection with *Helicobacter felis* will precipitate disease due to cryptosporidia.

Amebiasis

Entamoeba histolytica is the cause of amebiasis in humans, non-human primates, and, rarely, in other species, including dogs and cattle; cats are susceptible to experimental infection. Infection in dogs is sporadic, probably acquired by exposure to cysts in feces from infected humans. Dogs tend not to pass encysted amebae; hence it has been suggested that they present little public health hazard, and are unlikely to support spread from dog to dog. However, under some circumstances, cysts may be shed, and fecal material containing motile trophozoites has been used to transmit infection orally to other dogs.

Amebae are usually nonpathogenic inhabitants of the lumen of the large bowel, but sometimes they cause colitis. The diet and immune status of the host, and virulence attributes of various strains of the organism, seem to influence pathogenicity. Adhesion to mucus by specific lectins, enzymatic degradation of mucus, and lectin-mediated adherence of amebae to host epithelium, are essential steps leading to tissue damage. Cysteine proteinases produced by *E. histolytica* contribute to epithelial cell damage and to induction of inflammation, both of which are involved in initiation of mucosal lesions. Cytolysis is induced by in-contact amebae.

Amebiasis in dogs is associated with diarrheic or mucoid feces, perhaps with some blood, or with dysentery. *Erosive mucosal colitis or ulcerative colitis* occurs in dogs with amebiasis, and disease seems more common or severe in animals with concomitant *Trichuris* or *Ancylostoma* infection.

Early lesions in human amebiasis seem to be diffuse acute mucosal colitis, with focal erosions or ulcerations. Amebae, though scarce, may be found in mucus on the colonic surface, but are most numerous in the fibrinocellular exudate over erosions or superficial ulcers. Ulcers advance as an area of necrosis and predominantly neutrophilic infiltrate, causing loss of glands, and extending for the full depth of the mucosa. Initial lesions consist of tiny erosions of the surface epithelium that evolve to deeper, more extensive ulcers. Established ulcerative amebic colitis classically has a flask-shaped ulcer, the narrow neck through the mucosa, and the broad base in the submucosa. There amebae, and necrosis, expand laterally, apparently less constrained by the architecture of the tissue. Intestinal perforations and intramural abscesses may form.

Amebae may be present, commonly in small clusters, in necrotic debris or in adjacent viable tissue, frequently not involved in an inflammatory reaction. Amebae in tissue, often surrounded by a clear halo, may be spherical or irregular, with extended pseudopodia, and are ~6–50 μm in diameter. The nucleus has a central dense karyosome and peripheral chromatin clumps. The cytoplasm may appear foamy, can contain remnants of erythrocytes in phagolysosomes, and contains glycogen, which makes the cytoplasm periodic acid–Schiff-positive. The lesions of established amebiasis in the colon of dogs resemble those in humans; the early lesions may as well.

Although dissemination of amebae, with abscessation in other organs, especially liver, lung, and brain, is a relatively common complication in humans, it seems rare in dogs. One such case occurred in an animal with canine distemper.

Giardia and other flagellates

Giardia spp. are flagellate protists that inhabit the small intestine of a wide range of vertebrates. The taxonomy of the genus is difficult. It appears that four or five morphologically distinct "species" exist, each with a relatively wide host range within amphibians, birds, rodents, and other mammals. ***Giardia duodenalis*** (= *G. lamblia*) infection is common in humans, and it also occurs in a wide array of mammals. Molecular genetic investigations have identified at least seven genotypes within *G. duodenalis*, several of which (assemblages A, B) infect humans. Hoofed animals are infected by assemblages A and E, the former being potentially zoonotic, dogs by assemblage C, and cats by assemblage F. *Giardia* infection has been associated with disease, with various degrees of credibility, in most of these hosts.

Giardia trophozoites are pyriform in outline, ~10–20 μm long by 5–15 μm wide and 2–4 μm thick, and convex on the dorsal surface. The concave ventral surface is modified by the presence of a

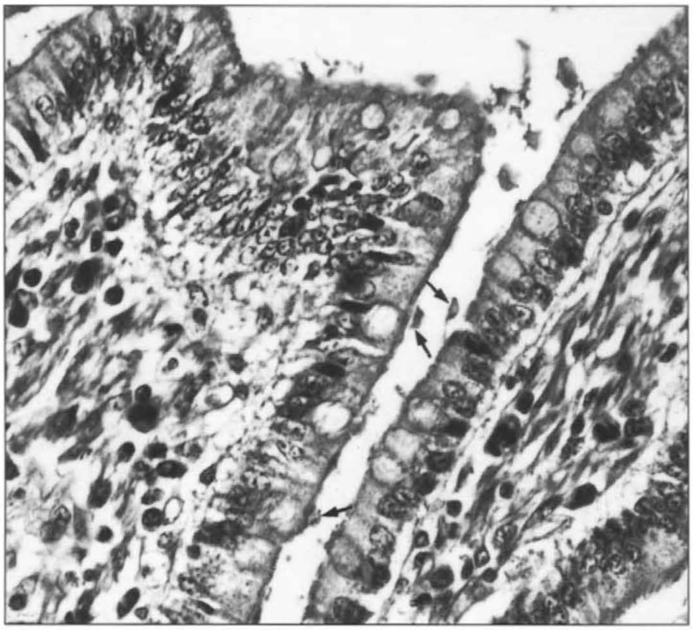

Figure 1.207 ***Giardia lamblia*** (arrows) applied to brush border of enterocytes on villi of a dog.

disk that functions in attachment. Nutrient absorption seems to occur through the dorsal surface. A pair of nuclei, two axonemes, two medial bodies, and four pairs of flagella are present, and the organisms *multiply by binary fission* in the gut lumen. They apply their ventral aspect to the microvillus surface of enterocytes (Fig. 1.207), usually between villi, in folds on the villus surface, or occasionally in crypts of Lieberkühn. *Giardia* has been demonstrated in the mucosa, but this is an unusual and probably aberrant location. Relatively resistant oval cysts are passed in the feces, and transmission is by the fecal–oral route.

The significance of *Giardia* as a pathogen in humans and other species has been controversial, since *asymptomatic infection is the rule*. However, under some circumstances *Giardia* may cause disease. How the host–parasite relationship is modified, and the pathogenesis of the disease, are still unclear.

In *young dogs and cats*, in which giardiosis is most important, though still uncommon, the main sign is intermittent or chronic *diarrhea*, which may persist for several months. The stool is soft, pale, mucoid, and greasy. Though appetite is not usually impaired, there may be a reduced growth rate or weight loss, suggesting malabsorption. A poor hair coat is attributed to deficiency of fat-soluble vitamins. Among animals other than dogs and cats, *Giardia* seems most convincingly to be associated with *enteric signs in neonatal calves*, which may pass soft mucoid feces, and have a reduced growth rate.

Gastrointestinal dysfunction has not been extensively documented in domestic animals. However, in a variety of experimental systems, deficiencies in microvillus-associated digestive enzymes, electrolyte and glucose malabsorption, and microvillus shortening or injury have been documented, though not consistently. Some humans with *Giardia* infection have malabsorption of D-xylose and vitamin B_{12}, with steatorrhea and hypocarotinemia. Excess fecal fat has been found in infected cats, but was not demonstrated in experimentally infected rats. Also, D-xylose malabsorption was not demonstrated in a dog with giardiosis.

Selective deficiencies in some brush border enzymes occur in humans with giardiosis, and in *Giardia*-infected calves. Possibly these are related to the direct effects of *Giardia* on microvilli, which may be deformed adjacent to adherent organisms, or diffusely shortened. *Giardia* may also inhibit the activity of pancreatic lipase, causing fat malabsorption. However, bacterial overgrowth of the small intestine may occur with *Giardia* infection, and associated bile salt deconjugation could explain steatorrhea in giardiosis.

Several mechanisms have been proposed to explain these findings. Although villus atrophy may occur in humans with giardiosis, this mainly occurs in a subgroup of patients with hypogammaglobulinemia. Marked histologic abnormality is not found in many cases of giardiosis in humans, and this also seems to be true for dogs, cats, and calves. In experimental murine giardiosis, infection is associated with hypertrophy of crypts and increased production of cells, combined with an increased rate of movement of enterocytes along villi, with an increased crypt:villus ratio. Deficiencies in brush border form and function may be attributable to incomplete differentiation of enterocytes in this circumstance, or perhaps to damage mediated by mucosal T cells. Intraepithelial lymphocytes are common in infected intestine, and altered epithelial kinetics may be related to cell-mediated immune reactions in the mucosa. Atrophy of villi has been associated with restoration of cell-mediated immune competence in *Giardia*-infected athymic mice, reinforcing the notion that immune phenomena may be involved in the pathogenesis of giardiosis.

Giardiosis is usually *diagnosed clinically* on the basis of typical cysts in fecal flotations, or trophozoites in intestinal aspirates or fecal smears, coupled with remission of clinical signs following therapy, and an inability to identify other potential causes of the signs. A diagnosis is sometimes based on findings in biopsies of small intestine, or at autopsy.

In all species, morphologic changes in the mucosa are not well defined in spontaneous cases of giardiosis. The mucosa may appear normal but there may be equivocal blunting of villi, perhaps associated with a moderate infiltrate of mononuclear cells into the core of the villus, or a heavy population of intraepithelial lymphocytes. *Giardia* should be sought in animals with malabsorption syndromes. They lie between villi, and are usually evident as crescent shapes, applied by their concave surface to the brush border of epithelial cells. In favorable sections through the level of the nuclei, they may appear to have a pair of "eyes." Trophozoites oriented along the plane of section may look as they do in smears, the paired nuclei giving the organism a "face-like" appearance. An abnormal number of bacteria, suggestive of overgrowth, may be present in the mucus and content in the vicinity, in symptomatic animals. A diagnosis of giardiosis should always be reserved for those cases in which no other explanation for the syndrome can be identified. Giardiosis has been associated with colitis in dogs but the association is not clearly causal.

Trichomonads, small flagellate protists that reproduce by binary fission, and are transmitted directly between hosts, are sometimes encountered in the feces of horses, cattle, dogs, and cats with diarrhea. Only in the latter species is there a causal association with disease.

Tritrichomonas foetus is associated with *persistent large-bowel diarrhea*, refractory to treatment, in **cats** under a year of age, and the syndrome has been reproduced experimentally. The microscopic lesions are typical of chronic mucosal colitis, most severe in areas colonized by the organisms. The diagnosis is confirmed in section by detection of pyriform or crescent-shaped organisms, about 5 × 7 µm in size, with a faint nucleus and eosinophilic cytoplasm, applied to the surface epithelium, or in the lumen of colonic glands, usually in large numbers. However, the organisms are present in only a little over half the sections examined from infected cats, and multiple samples may be necessary in order to have a high probability of detecting them. In some cases, trichomonads appear to disrupt the epithelium, attaining the subepithelial lamina propria around crypts, or they are associated with ulceration and foci of necrosis and pyogranulomatous inflammation that are distributed transmurally in affected areas of colon, and in draining lymph nodes.

Balantidium

Balantidium is a large oval protist ~50–60 µm or more long, and ~25–45 µm wide, with a macronucleus and micronucleus, and covered by many cilia arrayed in rows. ***B. coli*** occurs in the large bowel of swine, humans, and nonhuman primates. It is very common in pigs, and many infected humans live in close contact with swine. It has also been reported from several dogs with access to swine yards, as a complication of trichurosis.

Balantidium is normally present as a *commensal* in the lumen of the cecum and colon, but is capable of *opportunistic invasion of tissues injured by other diseases*. On rare occasions, it may be a primary pathogen. In swine, where the organisms are most commonly encountered by veterinary pathologists, *Balantidium* may be found at the leading edge of the crateriform necrotizing or ulcerative lesions of the large intestine that develop secondary to intestinal adenomatosis (Fig. 1.208), swine dysentery, or perhaps salmonellosis. *Balantidium* is recognized in tissue by large size, ovoid shape, the dense curved or kidney-shaped macronucleus, and the presence of cilia (which may be accentuated by silver stains) in rows on the surface.

PERITONEUM AND RETROPERITONEUM

General considerations

The peritoneum lines the abdominal cavity. Peritoneal diseases are commonly secondary to processes in the organs covered by peritoneum or arising in the retroperitoneum. The peritoneal cavity is incompletely divided into compartments by the mesentery, omentum, and ligaments covered by the peritoneum. Its surface area is greater than that of the skin. *The normal peritoneum is a smooth, shiny membrane that is semipermeable to the movement of water and small solute molecules. There is normally just enough fluid present in the cavity to keep it moist.* Peritoneal fluid is clear and watery, but in neonatal pigs and lambs, fluid may contain strands of mucinous coagulum lying on the intact serosal surfaces of abdominal viscera.

Normal peritoneal fluid is in osmotic equilibrium with plasma, but does not contain fibrinogen or other high-molecular-weight proteins, and generally does not clot, except in pigs. The peritoneal cavity has a dynamic circulation driven by intestinal motility and respiratory excursions, which can disperse fluid (and particles) completely throughout the abdominal and pelvic cavities within minutes to hours.

During organogenesis, the coelomic cavity develops and becomes partitioned into pleural, pericardial, and peritoneal cavities. The primary mesentery that develops supports the alimentary tube in the body cavity. Mesentery attached to the dorsal body wall persists as the mesentery in the adult but the mesentery attached to the ventral body wall degenerates, leaving a single abdominal cavity with persisting structures remaining as the gastrohepatic omentum, the falciform ligament, and in horses the nephrosplenic ligament. Sometimes these ligaments are involved in bowel entrapments. Defects in the peritoneal lining, either congenital or acquired, can also lead to entrapments of viscera.

The peritoneum consists of a single serosal lining layer of **mesothelial cells** on a basement membrane and a submesothelial layer of connective tissue, which is inapparent in some places such as over the liver, and abundant in other places such as the mesenteries. The mesothelial cells vary from squamous to low cuboidal with single small round nucleus. Cells bear surface microvilli, more abundant on the visceral than on the fixed parietal surface. Microvilli may have a role in retaining secreted, hyaluronate-based lubricants. Tight junctions and desmosomes are discontinuous in the surface layer, allowing for diffusion across the membrane. Hydraulic forces generally favor net movement of fluid from the vessels in the retroperitoneum into the peritoneal cavity. Mesothelial cells are fragile and will slough after exposure to such mild insults as exposure to air, physiological saline, intestinal dilation, and transient ischemia. However, cells regenerate quickly and, within a few hours, rounded primitive mesenchymal cells differentiate to mesothelium and cover defects in the surface.

Mesothelial cells have high fibrinolytic activity, which normally protects against formation of adhesions. If they are damaged and inflammation is initiated, fibrin effusion and inflammatory cell emigration from subserosal stroma may be rapid and profuse. Transforming growth factor-β is central in these events.

Both parietal and visceral peritoneum are continuously involved in transport of fluid in both directions. Normal fluid contains only traces of protein and secreted macromolecules, such as chondroitin sulfate, that reduce permeability. The electronegativity of the endothelium relative to mesothelium inhibits transfer of plasma proteins from capillaries into the cavity. The net hydraulic forces favor movement of fluid into the cavity. *Several pathways contribute to the drainage of peritoneal fluid.* Direct transfer through stomata in the membrane to subserosal lymphatics is the main mechanism, dominated by transfer into lymphatics of the ventral diaphragm, and thence via the sternal lymph nodes to the right lymphatic duct, or via mediastinal lymph nodes to the thoracic duct. Respiratory diaphragmatic movements assist transfer through the diaphragm to ventral mediastinal lymphatics. Less is taken up through the omentum and abdominal viscera, and drains via visceral lymphatics and lymph nodes to the thoracic duct. There is a lesser contribution to drainage by the pelvic serosa. Transfer of peritoneal fluid through and between mesothelial cells occurs but is minor.

The basement membrane is absent in minute foci, so-called **peritoneal "milk spots,"** pale semitransparent tiny foci that allow transfer of particulate matter from the peritoneal cavity to lymphatics in the mesentery and omentum. Although generally recognized as omental structures, such foci may also be functional on the parietal membranes of peritoneal, pericardial, and pleural cavities and in the mediastinum. *They are nests of macrophages mixed with lesser numbers of lymphocytes* and responsible, in part, for the removal of effete macromolecules and foreign particles from the peritoneal cavity. The presence of adhesion molecules and active cell proliferation in omental milky spots demonstrates that these are active sites for leukocyte migration and supply of peritoneal leukocytes.

The connective tissue that underlies the mesothelium has an ordinary mix of connective tissue cells and may not easily be distinguished from the retroperitoneum, but the cells appear to have alternative potentials in reaction to injury or surface abrasion and may replace differentiated mesothelial cells of the surface.

The **retroperitoneum** is the areolar and adipose connective tissue immediately beneath the peritoneal lining of the abdominal cavity. The concept of retroperitoneum properly includes the lymphatics and draining lymph nodes in addition to connective tissues, blood vessels, nerves, and the fixed and migratory mononuclear cell populations, most significant along the dorsum from the diaphragm to the anus. Its volume is small, except when adipose tissue accumulates, commonly in the dorsal retroperitoneum, around the kidneys, pelvic cavity, omentum, and mesenteries. With emaciation, fat stores of the retroperitoneum undergo *serous atrophy*, similar to those deposits in the subcutaneous tissues, the thorax, and the marrow cavities (Fig. 1.209).

There appear to be no absolute barriers to movement of fluid or exudates within the retroperitoneal space of dogs; it may travel in the fascia around the dorsal and ventral aspects of the sublumbar muscles, to gain access to the fascial planes of the abdominal wall. Suppurative processes of the retroperitoneum of dogs may drain at the flank, by passing along the fascial planes of the abdominal and the iliopsoas muscles, to emerge in the lumbodorsal triangle, cranioventral to the tuber coxae.

Antemortem and postmortem effusions and discoloration in the peritoneal cavity should be distinguished. Fluid accumulates in the peritoneal cavity after death, and this becomes stained with hemoglobin as soon as erythrocytes in the serosal vessels lyse. Such

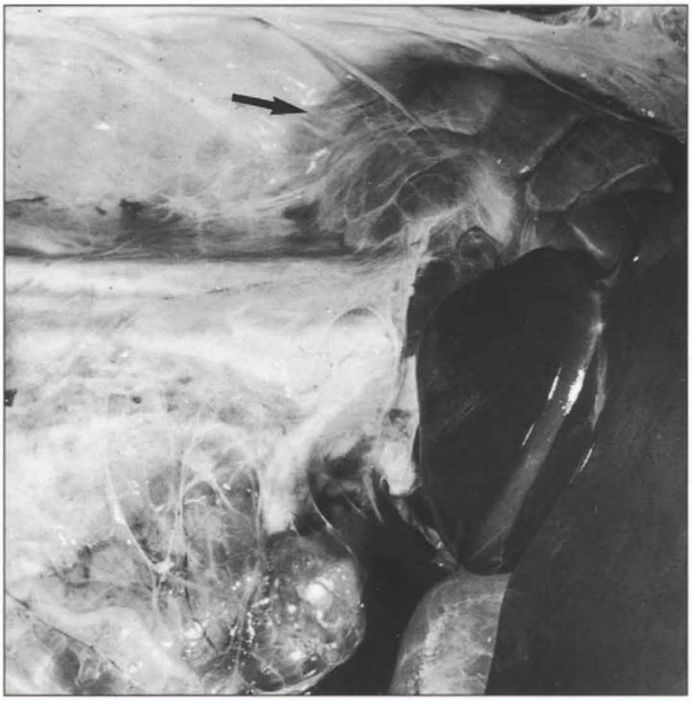

Figure 1.209 Serous atrophy of fat in a calf, resulting from protein-energy malnutrition. Note dark liver (right) and lack of normal perirenal (arrow) and retroperitoneal fat.

fluid does not clot and similar fluid is often also present in other serous cavities. Diffusion of bile pigments through the wall of the gallbladder, the bile ducts, or the duodenum will also stain adjacent viscera.

Anomalies

Congenital abnormalities affecting the peritoneal membranes are associated most frequently with retention of effete embryonic structures or defective partitioning of the coelomic cavity.

A **persistent vitelline or omphalomesenteric duct** *may form a fibrous ligament between the intestine or Meckel's diverticulum and the umbilicus.* The remnant may be partial, not reaching the umbilicus, and may be attached to the mesentery or to a loop of intestine. These structures may become involved in herniation and obstruction or strangulation of the intestine. Persisting ducts may become cystic.

A **mesodiverticular band** is the result of a **persistent vitelline artery**. The band is a fold of mesentery, occasionally carrying a patent vitelline artery in its free edge, that extends from the cranial mesenteric artery, or from a spot partway down the mesenteric veil, to the antimesenteric side of the intestine (to the site of Meckel's diverticulum). The pocket formed between this fold and the normal mesentery *may entrap intestine*; defects may develop in it which permit strangulation of intestinal loops. Occasionally, double (left and right) mesodiverticular bands are present. Rarely, fibrous cords of mesenteric tissue may be found that do not appear to be part of embryonic remnants of vitelline structures.

The **falciform ligament**, which in its free margin may contain the remnant of the umbilical vein as the *round ligament*, varies in size among species and individuals; it is typically largest in young animals. There is potential for entrapment or strangulation of bowel, if a large persistent falciform ligament is perforated.

Partitioning of the coelom to separate the thoracic cavity from the developing gastrointestinal tract begins with the formation of the *septum transversum* from the ventral body wall, eventually forming the ventral part of the diaphragm. The dorsal part of the diaphragm is provided by downgrowth from the dorsal body wall of the paired *pleuroperitoneal and pleuropericardial folds*.

Congenital pleuroperitoneal diaphragmatic hernias are most commonly observed in dogs, but are occasionally observed in herd animals. *They usually involve a defect in the left dorsal quadrant of the diaphragm, presumably from failure of the left pleuroperitoneal fold to fuse with the septum transversum;* the reason for the particular susceptibility for the left side is unknown. The lesion in some breeds of dogs may have an autosomal recessive mode of inheritance. Some congenital pleuroperitoneal defects in small animals may be more extensive, to the point that virtually the entire diaphragm is missing. The margins of the diaphragmatic defect are smooth, and a large mass of abdominal viscera, often including stomach, spleen, liver, small intestine, and omentum, may pass into the thoracic cavity through the opening. Most small animals born with these defects probably die at, or shortly after, birth. In large animals, the lesions may be clinically silent; this is particularly so when only a small nubbin of liver is present in the hernia. The others produce respiratory difficulties, abdominal pain, and bloating if incarceration of herniated viscera occurs.

Peritoneopericardial diaphragmatic hernias *are triangular and ventral, and presumably result from abnormal development of the septum transversum.* They are more common than pleuroperitoneal hernias in small animals, perhaps because the animals live longer. They are sometimes associated with cardiac anomalies, malformations of the sternum and costochondral junctions, or umbilical hernias. Although various portions of the liver, spleen, omentum, and small intestine may herniate into the pericardial sac, these lesions are often clinically silent.

External hernias are the result of abnormal openings in the abdominal wall, which permit passage of the abdominal contents. They may be congenital or acquired. Congenital defects resulting in hernias are of several kinds. They include abnormally increased size of normal opening such as the inguinal canal; persistence of fetal openings as in umbilical hernias; and defects in closure of the abdominal cavity, as in schistosomus reflexus and diaphragmatic hernias.

Reactions of peritoneum to injury

Even minor injuries to peritoneum cause rapid loss of mesothelial cells and exposure of the subserosal tissue. The denuded area is rapidly covered by a deposit of fibrin that includes neutrophils and macrophages. If the cause is removed and the injury is minor, the surface is soon regenerated by flat cells similar to normal mesothelium. Reconstitution of the surface may be delayed if the subsurface tissues are damaged. It appears that the restoration of the surface may not be provided by proliferation and migration of the adjacent mesothelial cells; the experimental evidence favors an origin from multipotent mesenchymal cells lying in the immediate subserosa close to the basement membrane. Unlike other epithelial-like surfaces, in which wounds heal only from the edges, mesothelial healing occurs diffusely across the denuded surface.

Metaplasia of mesothelium is frequently seen in histological specimens. Simple metaplasia also occurs where alterations to surface contours of organs produce clefts or valleys in which fluid movement may slow, and in cases of hydroperitoneum. In these cases, mesothelial cells become cuboidal, columnar, or, if persistent, may produce nodules of hyperplastic mesothelial cells.

Papillary hyperplasia of mesothelium is frequent in some chronic forms of peritonitis, such as those due to actinomycotic infections in dogs and cats, and in organization of subserosal hemorrhages in spleen and intestine.

Traumatic lesions of the abdomen and peritoneum

Physical trauma to the abdomen is common. Among the *sequelae* are hemorrhage, peritoneal sepsis, uremia due to the escape of urine into the abdomen, and dysfunction of traumatized organs.

Blunt trauma to the abdomen, if sufficiently forceful, will result in contusion of abdominal viscera; avulsion of organs from supporting mesenteries or ligaments, and from their vascular supply; and perhaps laceration of the capsule of solid organs such as the liver, spleen, and kidney. Hollow organs, such as the stomach, gallbladder, and urinary bladder, may rupture, releasing their contents into the abdominal cavity. The momentary increase in intra-abdominal pressure resulting from such trauma may cause acquired hernias, forcing viscera through natural apertures such as the inguinal canal, weak points such as the perineum, or through lacerations in the diaphragm, or in the abdominal wall, with eventration.

In abdominal trauma, contusions and perforation or laceration may be evident on the underside of the skin, and in subcutaneous tissues, often in apposition with internal lesions. Animals with a lacerated liver or spleen may be pale from internal hemorrhage. Contusion or laceration of the kidney results in subcapsular, retroperitoneal, or peritoneal hemorrhage. The spleen is contracted in exsanguinated animals. The source of hemorrhage may be subtle slits or crevasses in the capsule of the involved organ, or the laceration may be obvious. Portions of spleen may implant and persist ectopically elsewhere in the abdomen (splenosis), and may be encountered as an incidental finding. Urine in the abdominal cavity, if not suspected, may be mistaken for ascitic fluid. Lacerations of the urinary bladder may be small and difficult to detect, particularly because the bladder contracts as urine is lost through the laceration. If the pregnant uterus is ruptured, fetuses may be free in the abdomen. They will die and cause peritonitis if the dam survives and they are not removed.

Endogenous forces may also result in herniation. The additional weight of intestinal contents in pregnancy, especially when complicated by an event such as hydrops amnios, may cause ventral hernia. Straining to defecate, or at parturition, may also cause herniation; the former is associated with perineal hernias in dogs; the latter, with acquired diaphragmatic hernias in horses. Tympany of the large bowel in horses, or the forestomachs in ruminants, may also cause defects in the abdominal wall or diaphragm. Antemortem lesions must be differentiated from postmortem tears due to bloating of viscera. *The presence of hemorrhage, fibrin deposits, and acute inflammation in torn muscle, or strangulation of herniated gut, is evidence for an antemortem condition.*

Acquired diaphragmatic hernia is usually a sequel to trauma. The diaphragm is weaker than the abdominal wall. If, at the moment of impact to the abdomen, the glottis is open, a very-high-pressure differential may be generated between the abdominal and thoracic sides of the diaphragm, which is relieved by laceration.

In small animals, the diaphragmatic muscle, rather than the tendinous part, tends to tear, but otherwise the location and orientation of the lesion are functions of events at the moment of impact. Almost any of the abdominal viscera may herniate into the thorax through the defect, but liver and small bowel do so most commonly. The lesion may be clinically silent for a considerable period, sometimes years, but sooner or later results in respiratory difficulty, hydrothorax, ascites, chylothorax, gastric tympany, and intestinal obstruction. At surgery or necropsy, acute diaphragmatic laceration is obvious. If chronic, the margin of laceration is usually thickened by fibroplasia and smooth, but rarely there may be adhesion to the viscera. Differentiation of such lesions from congenital hernias is based on the age, clinical history, and any evidence of scarring or adhesions at the margin of the diaphragmatic defect.

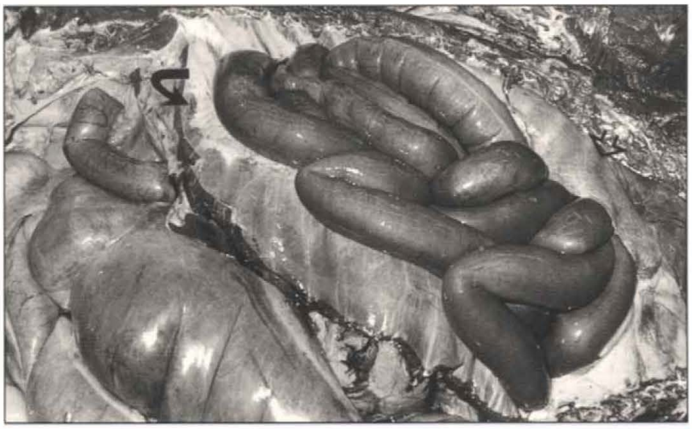

Figure 1.210 Acquired diaphragmatic hernia in a horse. Loops of small intestine have passed through the diaphragmatic laceration into the thoracic cavity, compressing lung (open arrow). Diaphragm (curved arrow).

In horses, acquired lesions usually involve the area where the tendinous portion meets the pars costalis, whereas postmortem laceration of the diaphragm in the horse is most common at the ventral midline, in the xiphoid area (Fig. 1.210). Most horses with acquired diaphragmatic hernias develop abdominal pain, rather than respiratory signs.

Abnormal contents in the peritoneal cavity

Foreign material is commonly found in the peritoneal cavity. Materials of endogenous origin, such as ingesta or urine, indicate an abnormality of another organ. Rupture of the urinary bladder can result in **uroperitoneum**.

Ingesta is frequently found in the peritoneal cavity of horses and cattle, seldom in swine, sheep, and goats, and rarely in dogs and cats. The site of perforation or rupture in the stomach or intestine is usually easy to find, especially when the animal dies before there is time for peritonitis to develop. Once peritonitis has developed and the intestines and mesenteries become adhered together, the primary site of perforation may be very difficult to detect.

Ingesta may leak from any devitalized segment of small or large bowel, as a consequence of impaction with pressure necrosis; or tympany and rupture; or perforation from sharp objects; or ruptured stomach or perforated abomasal ulcer. Cecal rupture in cattle following overload or impaction usually occurs on the medial side of the cecum. **Rectal perforation** will also cause contamination of the abdomen with feces, and these lesions may be hard to find. Rectal perforation is most commonly secondary to *accidental iatrogenic injury*. Most tears occur about 25–30 cm from the anus, in the peritoneal portion of the rectum, on the dorsal aspect. Tears that perforate the muscularis have the potential for contamination of the peritoneal cavity. The less severe of these have an intact serosa, with formation of a subserosal diverticulum, or a fistula into the potential space of the mesorectum. These may result in perineal abscessation or fistulation, pelvic cellulitis, or rectal diverticula, among other complications. Often these eventually perforate the mesorectum, causing gross fecal contamination of the peritoneum.

Pneumoperitoneum commonly arises from perforation of the abdominal wall due to traumatic incidents, from concurrent pneumothorax and diaphragmatic tears, or from leakage of gas and liquid contents from perforations of the gastrointestinal tract. Less commonly, pneumoperitoneum can develop secondary to rupture of the urinary bladder or from the tubular reproductive tract in females.

Postmortem rupture of a viscus must be differentiated from an antemortem lesion. The rumen, stomach, or large bowel of putrefied, bloated carcasses may rupture. Autolysis of the abomasum may release gastric contents in calves and lambs fed milk replacers. The margins of the defect in the viscus are not hemorrhagic, and the peritoneal surfaces are not inflamed.

Hemoperitoneum *is the presence of blood in the peritoneal cavity*. The amount present at death is not necessarily an indication of the volume of bleeding during life, because the blood may be removed quite rapidly via diaphragmatic lymphatics. Blood in the cavity may remain fluid or be partially clotted.

Hemoperitoneum is seen most commonly in the dog and cat as a result of traumatic injury to the liver, spleen, and kidney, and in dogs is also associated with hemangiosarcomas of liver and spleen. Manual efforts at artificial resuscitation, if vigorous, may rupture the liver. Splenic hemangiosarcomas, which bleed into the abdomen, are common in dogs past middle age. Enlarged, tense livers and spleens because of infiltrating leukemic cells, fat, or amyloid are predisposed to rupture. Fine fissures in the capsule of the liver, and hemorrhage, may occur in infectious canine hepatitis.

In several species, *anticoagulant rodenticides*, such as warfarin, may cause hemorrhage that results in unclotted blood in the abdomen. Calves born of cows that have been fed moldy sweet-clover hay bleed from the umbilical vessels into the peritoneal cavity, as well as elsewhere. Manual ablation of a corpus luteum is a source of hemorrhage in cattle. In cattle and horses, laceration of the uterus or rupture of a uterine artery at parturition can result in fatal hemorrhage. In horses, hemoperitoneum may be due to hemorrhage from granulosa-thecal cell tumor of the ovary, and in all species any friable intra-abdominal or retroperitoneal neoplasm may occasionally rupture and bleed if traumatized.

Hemorrhage on or beneath the peritoneum, without free blood in the cavity, may occur in acute bacterial toxemias and in other conditions that interfere with vascular integrity or hemostasis. *Peritoneal hemorrhage must be differentiated from hemorrhagic peritonitis*, which is an important lesion in some diseases. Subserosal hemorrhage and *hemomelasma ilei* occasionally occur on the intestine of the horse, associated with trauma to vessels by migrating strongyles. Rarely, subserosal hematomas may cause intestinal obstruction. Hemorrhage into an omental or mesenteric cyst can cause sudden abdominal enlargement without free blood in the abdomen.

Ascites

Ascites, or hydroperitoneum, is the presence of excess fluid, usually a modified transudate, in the peritoneal cavity. Ascitic fluid is generally watery, clear, or straw-colored, and contains a few leukocytes but may contain numerous desquamated mesothelial cells. The serosal lining is normal and glistening but may become slightly opaque as a result of subserosal edema.

Reduced removal of fluid from the peritoneal cavity *is mainly due to obstruction of the primary route of lymphatic drainage through the diaphragm*. The limited area for direct-to-lymphatic absorption and the small size of the stomata on the diaphragmatic and pelvic serosa explain the ease and rapidity with which peritoneal drainage can be blocked.

Obstruction of diaphragmatic lymphatics as a cause of ascites is illustrated in peritoneal carcinomatosis. Carcinomas may implant extensively on the diaphragm in the region of the lymphatic stomata. Neoplastic cells that are carried to the cranial abdomen by the normal peritoneal fluid circulation can obstruct lymphatic drainage, and may also produce fluid.

Ascites may also develop if there is obstruction to sternal lymphatic flow cranial to the diaphragm. This may occur with sclerosing lymphadenitis or space-occupying lesions in the ventral or cranial mediastinum, and is common in lymphosarcoma of adult cattle.

Overproduction of peritoneal lymph *is mainly related to altered hydrostatic pressure gradients in the hepatic and portal circulation*. The exception is rare **chylous ascites**, which results when the cisterna chyli leak fluid, which has a milky appearance due to the presence of chylomicron fat.

The balance of oncotic and hydrostatic pressure depends on the relative retention of large molecules within the circulation. Vascular injury in the portal circulation allows increased permeability to plasma protein and substantially favors transudation. Small amounts of ascitic fluid may be generated under these circumstances in a variety of systemic illnesses, such as the clostridial intoxications, endotoxemia, acute uremic syndromes in ruminants and pigs, and in the exudative diathesis of animals deficient in vitamin E.

Ascites resulting from overproduction of fluid is usually an expression of hepatic lymphedema. Increased prehepatic portal venous pressure alone does not usually lead to ascites; if present, such fluid is low protein, being derived from intestinal and mesenteric interstitial fluid. Acute portal vein obstruction causes intestinal infarction and death, but not ascites. Slowly developing portal hypertension of prehepatic, hepatic, or hepatic venous origin may cause transient ascites, which resolves with the development of collateral portal–postcaval venous shunts within a few weeks. However, portal hypertension of cardiac origin does not result in portocaval shunts, because the elevation in central venous pressure permits no pressure gradient between the portal and postcaval systems.

The sine qua non of hepatic ascites is that there be increased resistance in the intrahepatic or posthepatic circulation, with edema of the liver. The exception is the increase in portal blood flow caused by hepatic arteriovenous fistulas or anastomoses; in this circumstance, hydrostatic pressure at the level of the hepatic sinusoids is elevated by the arterialization of the portal flow.

The usual conditions causing increased hepatic or posthepatic resistance to blood flow are fibrosis of the liver and congestive heart failure. In diffuse fibrosis, intrahepatic resistance may be compounded by the development of arteriovenous anastomoses in the fibrous septa around nodules; these arterialize the hepatic portal circulation, further elevating hydrostatic pressure.

Additional causes of increased hepatic resistance to blood flow include: primary neoplasms of the liver, especially cholangiocellular carcinomas, which tend to be diffuse and infiltrative; secondary tumors, especially lymphosarcomas, which widely infiltrate the liver; extensive infestation with hydatid cysts; and chronic biliary trematodiasis, or other causes of chronic cholangiohepatitis and portal fibrosis. Tumors or abscesses in or compressing the hepatic vein as it leaves the liver, or obstructions in the caudal vena cava cranial to the entry of the hepatic vein, will cause posthepatic obstruction.

When the liver is congested, there is increased flow of hepatic lymph, which has a high concentration of protein. The bulk of hepatic lymph comes from the space of Disse, which is separated from the sinusoidal lumen only by a fenestrated endothelium that is freely permeable to plasma constituents, including large protein molecules. Hence, the formation of hepatic lymph is not regulated by plasma oncotic pressure, but is sensitive to small changes in hydrostatic pressure in the sinusoids. This accounts for the frequency with which ascites is associated with those diseases that cause increased central and hepatic venous pressure, or increased intrahepatic resistance to blood flow.

If the capacity of the hepatic lymphatics is exceeded, then lymph, high in protein, oozes from the hepatic capsule, presumably from the extensive lymphatic plexus there, and it may spill from the efferent lymphatics that pass from the porta hepatis to the cisterna chyli. In hepatic ascites, these efferent lymphatics become very large, numerous, and thick-walled.

The fluid that enters the peritoneal cavity is continually in flux. *Gross ascites will only develop when the normal high capacity to drain fluid from the abdomen is exceeded by the rate of production, and this requires an increase in renal retention of sodium and water.* The initiating factors causing excess of total body salt and water are uncertain but there are identified contributing factors. These include increase of adrenal medullary hormones, increased sympathetic output leading to reduced natriuresis, and activation of the renin–angiotensin system. Renal factors, including reduced excretion of water and increased reabsorption of sodium, are important in perpetuating the condition. The resultant expansion of plasma volume permits the development of edema and ascites in congestive heart failure, and ascites in hepatic disease. It also further increases hydrostatic pressure in the hepatic sinusoids, driving lymph production to the point that ascitic fluid accumulates. Secondarily, reduced effective vascular volume, associated with sequestration of fluid in ascites, expansion of the splanchnic circulation, and other systemic circulatory events, also causes sodium retention, via the renin–angiotensin pathway, with aldosterone secretion, and by parallel mechanisms. In heart failure, activation of the renin–angiotensin system is expected, due to reduced effective vascular volume.

Hypoproteinemia due to reduced hepatic synthesis may occur in severe liver disease. Normally, oncotic forces are subsidiary to hydrostatic forces at the level of the sinusoid in affecting the formation of lymph. However, in diffuse fibrosis, once advanced capillarization of sinusoids occurs, the free permeability of the hepatic vascular system to the flow of large molecules is reduced. In this circumstance, reduced plasma oncotic pressure due to hypoalbuminemia will promote continued hepatic lymph formation and ascites; it will also promote fluid flux to the peritoneum across the splanchnic capillary bed.

Hypoproteinemia of nonhepatic origin is most commonly associated with protein-losing enteropathy, such as Johne's disease, or with protein-losing nephropathy, as in glomerular amyloidosis or other glomerulopathy. Severe hypoproteinemia will reduce plasma oncotic pressure, promoting edema and permitting transudate to accumulate in serous spaces, including, but not exclusively, in the peritoneal cavity (Fig. 1.211).

Effusion of fluid, sometimes massive, in the peritoneal cavity, thorax, and ventral body wall is part of the postmortem picture in sheep and cattle that die of *urethral obstruction*, and the fluid may have a distinct uriniferous odor. The pathogenesis of this fluid accumulation is uncertain. Although in a few cases there is a rupture of the lower

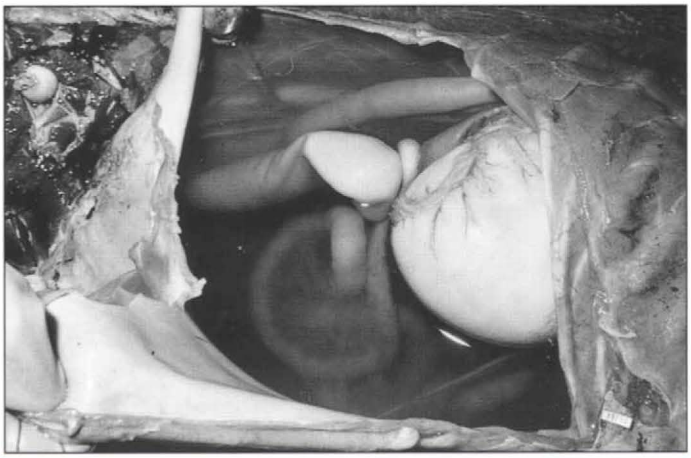

Figure 1.211 Ascites in a dog with profound hypoproteinemia due to enteric protein loss from lymphangiectasia.

urinary tract that might permit leakage, in many cases a rupture cannot be demonstrated. Renal uremia, especially that caused by acute toxic nephrosis, may also be accompanied by massive effusions. It is usually the case with ascites of urinary tract disease that the mesenteries and retroperitoneum also become saturated.

Abdominal fat necrosis

Necrosis of mesenteric or other abdominal or retroperitoneal fat is a common finding at necropsy. The pathogenesis of all cases is poorly understood but there are a number of known causes.

In **pancreatic necrosis,** enzymatic necrosis of fat is always seen, and peripancreatic necrosis of fat may be the initial morphological change. In acute pancreatic necrosis, discrete foci or confluent masses of white necrotic adipose tissue are surrounded by a zone of intense hyperemia with fibrin deposited on the surface. Such lesions may be limited to the peripancreatic fat or be distributed throughout the abdominal cavity. Free droplets of fat can be found floating in the abdominal fluid. Microscopically, the acute lesion is made up of necrotic fat cells containing acidophilic, opaque, amorphous, or lacy substances, or basophilic fibrillar or granular mineralized material. The necrosis is attributed to release of proteolytic and lipolytic enzymes from necrotic acinar pancreas. Degeneration of neutrophils may contribute to the process, as may lipase released from the necrotic adipocytes.

Widespread or isolated **focal necrosis of abdominal fat** is frequently found in sheep, and sometimes in other animals. The necrotic fat is usually only seen at the chronic stage in the form of white small, dry, firm, chalky, or gritty plaques; a flat white color distinguishes the plaque from surrounding fat. There is usually no grossly apparent inflammatory reaction and, microscopically, the lesions resemble the chronic lesion described above with occasional macrophages containing large lipid vacuoles and necrotic debris encapsulated by connective tissue. The pathogenesis of this form of necrosis is unexplained.

Massive fat necrosis in cattle is reported most frequently in Channel Island breeds and occurs in excessively fat cattle. Both sexes are affected, but probably not clinically before the second year of life. The disease has several significant features. Although it is often seen as an incidental finding, it can be fatal, mainly by intestinal obstruction or by complications such as compression of the ureters. There may also be obstruction of the pelvic canal. The hard lumps of fat may be confused with fetal structures, lymphoid tumors, or other masses on abdominal palpation. Clinical signs are most commonly due to *intestinal obstruction* (Fig. 1.212).

The necrosis may occur in any portion of the omental, mesenteric, and retroperitoneal fat, and it is sometimes seen in intermuscular and subcutaneous fat, as well. In the early stage, there is acute inflammation, and the hard necrotic masses are surrounded by a zone of hyperemia; the overlying peritoneum may be necrotic, perhaps with adhesions to adjacent viscera. The masses may vary from small nodules to large solid masses that are encapsulated by fibrous tissue, and which on cut section are firm, dry, and caseous, or sometimes moist, oily, and deep yellow. The surfaces of such masses may be molded to the contours of adjacent organs.

Because of the unusual bulk of the necrotic tissue, and because necrotic fat is sometimes found in abnormal locations, such as under the serosa of the intestine, the condition has been called *lipomatosis*, but the lesions are not hyperplastic or neoplastic.

On microscopic examination the tissue resembles a mixture of acute and chronic fat necrosis with a few neutrophils, lymphocytes, and plasma cells, and many macrophages and giant cells, with some interstitial fibrosis. Elongate clefts and mineral may be present in macrophages and giant cells.

The pathogenesis of this diffuse *lipogranulomatosis* in cattle is not clear, but there is evidence of a dietary cause, somewhat similar to that of steatitis as it occurs in horses, pigs, and other species. Captive deer grazed on endophyte-infested tall fescue pastures may develop lipogranulomatosis with extensive abdominal fat necrosis; the pathogenesis is unclear.

Massive necrosis of abdominal fat is reported in a cat subsequent to trauma. Nodular necrosis of abdominal fat can be an incidental finding in aged dogs and cats.

Steatitis (*yellow-fat disease*) occurs in many species affecting the abdominal and peritoneal fat, along with other adipose tissue. It is associated with diets high in polyunsaturated fat and low in tocopherols, allowing oxidation of fatty acids. Peroxidation of susceptible lipids and membranes creates free radicals that provoke the

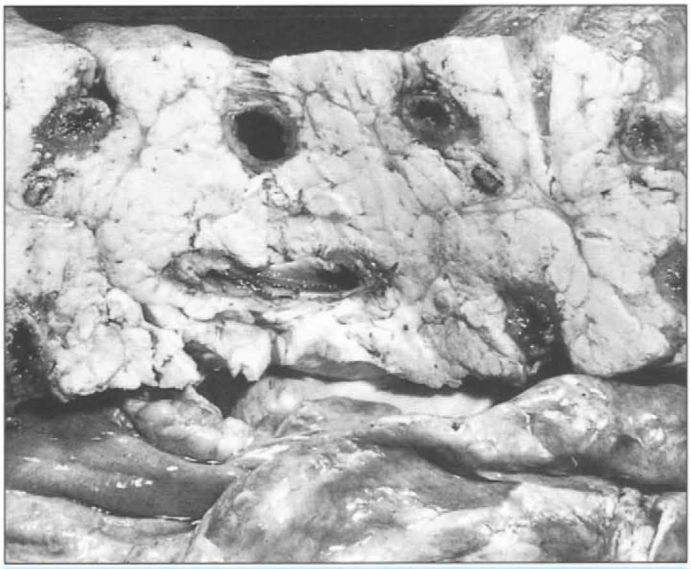

Figure 1.212 Mass of fat enclosing intestinal loops in **abdominal fat necrosis** in a cow.

characteristic inflammatory reaction in response to formation of irritant soaps and the formation of cholesterol deposits and ceroid-lipofuscin (see section on Panniculitis in Vol. 1, Skin and appendages).

Peritonitis

Damage to the serosa of the peritoneal lining associated with inflammation, or **peritonitis**, is very common in the large domestic animals, and less common in dogs and cats. *Peritonitis may be classified as primary or secondary; as acute or chronic; as local or diffuse; as septic or non-septic; and on the basis of the type of exudate, which may be serofibrinous, fibrinopurulent, purulent, hemorrhagic, or granulomatous.* Differences in distribution, type of exudate, and duration of the lesion can be more or less anticipated from the source and the cause. Most cases of peritonitis in domestic animals are secondary; that is, they arise as complications of other events in the abdomen, but primary serositis in systemic infections is of much importance for agricultural livestock. *The causes of peritonitis are numerous and varied*, so only some of the more common and important of them are considered here.

Chemical peritonitis may be induced by a variety of agents. The intraperitoneal instillation of a number of therapeutic agents causes a mild, and usually inconsequential, peritonitis. However, lavage of the abdomen has been associated with serosal damage and formation of adhesions. *Talc*, formerly used as surgical glove powder, and starch, now used for that purpose, may provoke granulomatous peritonitis. Characteristic starch granules may be recognized in phagocytes within granulomas, forming a Maltese cross in polarized light, and with positive periodic acid–Schiff staining. *Barium sulfate* that accidentally spills into the abdomen during contrast studies is highly irritating, causing a potentially fatal hemorrhagic peritonitis, often complicated by intercurrent sepsis. Survivors will have extensive adhesions, and granulomas in which barium is seen in macrophages and giant cells.

The most devastating forms of chemical peritonitis are endogenous, and are caused by *bile and pancreatic enzymes*. The peritonitis caused by bile is intense and, if complicated by sepsis, may be rapidly fatal. There is very little exudate unless the leakage is minor and infected, and then it may become purulent. **Biliary peritonitis** is readily recognized by the typical yellow-green staining. The **peritonitis of pancreatic necrosis** is also acute and is common in dogs. The reaction about the pancreas, particularly its head, is liquefactive and purulent, and the exudate causes the lesser omentum to adhere to the pancreas and the adjacent liver and other organs. This local peritoneal reaction resolves completely if the animal survives, and only very minor adhesions or slight puckering of the mesentery persist, with fibrosis in the pancreas. The peritoneal exudate is usually scant, but is distinctive because, as well as pus, it contains white droplets of fats and soaps released from the adipose tissue by the pancreatic enzymes. Leakage of chyle from intestinal lymphatics often leads to tortuous lymphangitis and granulomatous peritonitis.

Bacterial peritonitis may occur if bacteria reach the peritoneum by direct implantation. This is usually as a result of perforating lesions (Fig. 1.213), from a contaminated "external" surface, either a hollow viscus in the gastrointestinal or urogenital tract, or from the skin. It is most commonly associated with peritoneal contamination by ingesta. In females, the abdominal cavity is open to the exterior through the reproductive tract, and infection may enter the abdomen through the reproductive tract. Endometritis caused by tuberculosis or brucellosis in cows, and brucellosis in sows, may reach the peritoneum through the fallopian tubes. Cystitis and rupture of the bladder may also result in peritonitis.

Bacterial peritonitis is also common as an extension from inflammation localized in an abdominal viscus or the umbilicus, or as a typical part of the syndrome in a number of specific bacteremic diseases. Acute serofibrinous peritonitis may occur by extension through the wall of a gangrenous intestine or uterus prior to rupture; death from toxemia may intervene before rupture occurs. Secondary peritonitis occasionally results by extension from retroperitoneal infection, or in ruminants from omental bursitis. In those cases in which peritonitis develops by direct extension, there is little difficulty in ascertaining its origin, even when the process becomes diffuse.

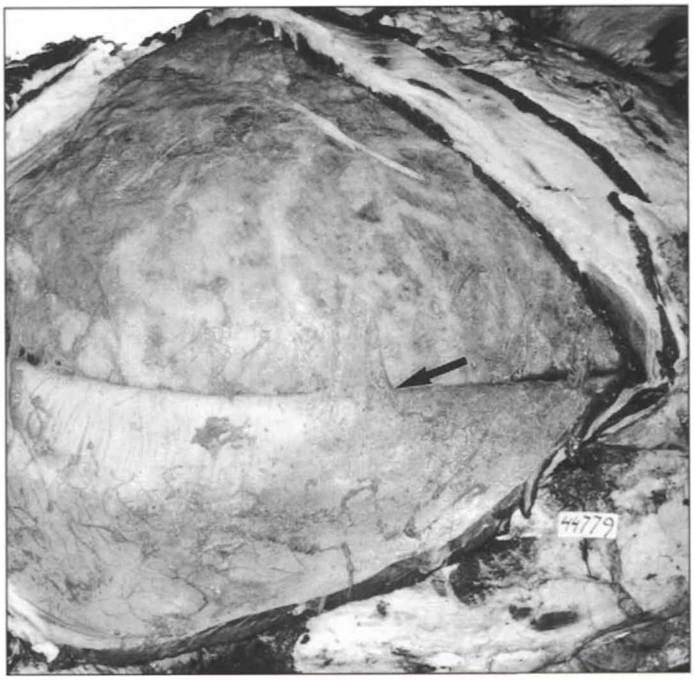

Figure 1.213 Acute diffuse fibrinous peritonitis in a calf as a consequence of perforating abomasal ulcer. A tenacious sheet of fibrin is present between the omentum and the abdominal wall (arrow).

Consequences of peritonitis

The consequences of peritonitis extend from insignificant to catastrophic. Acute generalized peritonitis is a catastrophic sequel in many local diseases of the abdominal cavity, but it may be a relatively insignificant secondary event in generalized infections, though useful to pathologists as part of the suite of lesions used in diagnosis. Obviously, peritonitis does not significantly affect the outcome of an *Escherichia coli* septicemia, or of clostridial infections such as blackleg or braxy.

Within the first few hours of generalized peritonitis, there may be intestinal hypermotility. However, *paralytic ileus*, mediated by autonomic innervation, soon supervenes. The development of ileus has the advantage that exudates are no longer distributed by intestinal movements, but has the disadvantage that fibrinous adhesions develop between loops of intestine, which may, if the animal recovers, produce fibrous adhesions and their sequelae.

The systemic effects of generalized peritonitis are largely related to detrimental effects on cardiovascular function, circulatory homeostasis, and acid–base balance. These are partly the result of sequestration of fluid and plasma proteins in the peritoneal exudate; sequestration of fluid and electrolyte in amotile gut; and loss of intestinal absorptive function. Endotoxin, and exotoxins such as those produced by clostridia, may be absorbed into the circulation, directly through the peritoneum, or via the lymphatic drainage. These cause increased vascular permeability, shock, and other detrimental cardiovascular effects. Death from toxemia may result before obvious peritonitis develops. Sepsis may spread via the lymphatics to the pleura and the sternal or mediastinal nodes, or it will attain the general circulation, causing septicemia.

Not all cases of generalized peritonitis are immediately fatal. Depending on the nature of the exudate, the lesions may resolve completely, be converted to diffuse adhesions, or persist in some localized areas as chronic active or adhesive peritonitis, sometimes with abscessation.

Peritoneal insult, with the initiation of inflammation by mediators released from local mast cells and other mesenchymal elements, results in massive outpouring of fibrinogen and chemotaxis of neutrophils. Tissue thromboplastin polymerizes fibrin. Damage to, or loss of, the peritoneal lining may diminish the fibrinolytic activity of mesothelium and its capacity to produce plasminogen activator; hence, normal fibrinolytic mechanisms are inhibited. Fibrin adheres to the denuded subserosal stroma, which is edematous, congested, or hemorrhagic. The lesion heals by fibroplasia and neovascularization, which extend from the subserosa into the fibrin framework. Mesothelium differentiates from mesenchymal elements in the subserosa. Hence, reconstitution of the mesothelium is not affected by the size of the defect. In uncomplicated situations, peritoneal lesions are debrided by phagocytes; fibroplasia and collagen deposition occur within days, and mesothelial reconstitution is accomplished by 5–8 days after the insult.

If the bridges of fibrin between damaged serosal surfaces persist beyond 3–4 days after the original insult, usually related to failure of fibrinolysis, they become organized by connective tissue, and **fibrous adhesions** form. Contraction of connective tissue as it matures, and in response to tension, may result in close apposition and adhesion of adjacent structures, or stenosis if fibrous bands surround or compress a viscus. The effect is impaired motility, obstruction, or circulatory embarrassment. Fibrous adhesions may remodel and occasionally will separate, but often persist as scars on the serosa.

Formation of adhesions seems to be promoted by ischemia, increasing severity of tissue necrosis, foreign material such as sutures on the serosa, and by sepsis, probably all acting to increase and prolong the inflammatory response. The duration of peritonitis may be a significant question in cases such as iatrogenic rectal perforation, and its assessment requires careful gross and microscopic examination of the serosal surface and the adherent exudates. The proliferation and degree of differentiation of fibroblasts in the exudate and in the edge of any wound, and the presence and degree of differentiation of regenerating mesothelial cells, will give some indication of the age of the lesion. The thickness of granulation tissue over the old serosa may give an indication of the duration of chronic peritonitis.

Peritonitis in horses

Diffuse peritonitis in horses is usually acute and fatal; this is perhaps associated in part with the small omentum, and a poor capacity to wall off contaminated areas. In most cases, clinical peritonitis is caused by rupture or perforation of the stomach or intestine with spillage of contents. Copious purulent peritonitis may be seen in *Rhodococcus equi* infection of foals, which may also cause purulent mesenteric lymphadenitis. Intestinal infection of foals by *Actinobacillus equuli* causes fibrinous mesenteric lymphangitis and peritonitis. *Clostridium perfringens* in foals, and anthrax in older horses, causes acute hemorrhagic enteritis with peritonitis. Peritoneal lavage may cause severe diffuse chemical peritonitis. Seminoperitoneum, due to laceration of the vagina at breeding, is an unusual cause of acute diffuse nonseptic peritonitis; sperm are present in the cytoplasm of neutrophils. Chronic diffuse peritonitis is virtually never recorded in horses, other than rarely with nocardiosis.

Acute or chronic local peritonitis does occasionally occur from surgical or castration wounds with adhesion of colon to inner inguinal area; from other penetration from the skin; and from streptococcal abscesses in the mesentery. It may be secondary to local verminous lesions such as from suppurative gastritis in habronemiasis, or from perforating *Gasterophilus* or *Anoplocephala*. Migrating *Strongylus equinus* or *S. edentatus* larvae cause retroperitoneal lesions in the flank, perirenal fat, and diaphragm; perihepatitis with fibrous tags on the liver capsule; and chronic diffuse thickening and inflammation in the mesentery, omentum, and hepatorenal ligament, with occasional caseous nodules. Large strongyles returning to the gut may cause focal peritoneal lesions on the ileum, cecum, and colon, and migrations of large strongyles in the wall of the small intestine are associated with brown-black subserosal plaques known as **hemomelasma ilei**.

Peritonitis in cattle

Acute diffuse fibrinopurulent peritonitis is common in cattle, and is usually the result of perforation of a viscus, especially the reticulum or uterus. Both may also result in local acute, and then chronic, peritonitis with adhesions. **Traumatic reticuloperitonitis** ("hardware disease") may be part of, or evolve to include, septic reticulopericarditis if the offending foreign body advances far enough. Disordered motility of the forestomachs, manifest clinically as "vagus indigestion," may follow scarring that interferes with esophageal function.

Where tuberculosis and brucellosis remain endemic, spread of infection from the uterine tube will produce granulomatous disease in the ovarian bursa and on adjacent serosa; the lesions of these two diseases are not readily distinguished.

Cattle seem to have a relatively high capacity to localize and wall off septic foci within the peritoneal cavity. Abscesses may develop from such foci. Sometimes these may become quite large; they usually contain creamy pus, from which mixed bacterial flora is most commonly isolated. Perforation of the abomasum or intestine is more likely to give diffuse fibrinous or fibrinohemorrhagic peritonitis, but occasionally will cause local chronic peritonitis and abscessation.

Extension of infection from the umbilicus of the neonate produces fibrinopurulent peritonitis, which is not localized, but is most severe along the ventral abdominal wall, or adjacent to associated liver abscesses, or along the urachus to the bladder. Fibrinous peritonitis may be an expression of *polyserositis* in neonatal calves with septicemic colibacillosis and neonatal streptococcal infection. Serofibrinous peritonitis, sometimes with very copious effusion (and with similar lesions on other serous membranes) is typical of sporadic bovine encephalomyelitis. Diffuse fibrinohemorrhagic peritonitis with prominent brick-red discoloration occurs in most cases of clostridial hemoglobinuria, and in some cases of blackleg and septicemic pasteurellosis; a more localized peritonitis of this type occurs in clostridial enteritis of calves caused by *C. perfringens* type B and type C and in braxy.

Tuberculosis causes white nodular granulomas up to several centimeters in diameter; actinobacillosis, although rather rare, produces the usual heavily scarified granulomas, especially about the peritoneum of the forestomachs.

Peritonitis in sheep and goats

Peritonitis of specific cause is uncommon in **sheep**, except for the very local reaction that accompanies penetration of the intestine by the larvae of *Oesophagostomum columbianum,* and with sporadic cases of ovine pseudotuberculosis wherein caseous lesions in internal organs rupture. The uterus is probably the most common site in adults from which infection spreads to the peritoneum, usually subsequent to postpartum septic metritis. The peritonitis is fibrinopurulent and bloody. Serofibrinous peritonitis is a potential feature of any disease caused by *Mycoplasma,* and outbreaks of peritonitis in lamb flocks are frequently ascribed to coliform infection.

Mycoplasma mycoides may cause acute fibrinous peritonitis in **goats**, although acute death from septicemia, or arthritis and mastitis are more common. Paratuberculosis (Johne's disease) frequently produces nodular granulomatous lymphangitis in the mesentery and sometimes caseous or mineralized lymphadenitis.

Peritonitis in swine

A few filmy strands of mucin with appearances of fibrin frequently overlie the intestine and the borders of the mesentery in many acute infectious diseases of swine, and in conditions that result in vascular damage, such as edema disease and vitamin E/selenium-responsive conditions; this does not qualify as peritonitis. Peritonitis is recognized as part of the pathological picture in several defined infectious syndromes in pigs, but changes in management, and emergence of porcine reproductive and respiratory disease and porcine postweaning multisystemic wasting syndrome as important entities have altered the patterns of expression of some infections.

Diffuse fibrinopurulent peritonitis is common in pigs (Fig. 1.214); the intestines may be so matted that they cannot be dissected. *Arcanobacterium pyogenes, Escherichia coli,* or a miscellany of organisms are frequently present in these, and in some the inflammatory process can be traced to castration wounds. In such cases, the peritonitis may be localized to the inguinal and pelvic regions; adhesions and death from intestinal obstruction may occur. Occasionally, *A. pyogenes* produces discrete encapsulated abscesses as profuse implants on both visceral and parietal peritoneum.

Serofibrinous peritonitis, with fibrinous arthritis and exudation on other serous surfaces, is indicative of Glasser's disease, caused by *Haemophilus parasuis. Mycoplasma hyorhinis* and possibly other mycoplasmas frequently complicate respiratory mycoplasmosis and produce serofibrinous peritonitis that becomes fibrous, with adhesions to a thickened serous membrane; this disease is to be distinguished from Glasser's disease, and from septicemias due to *Streptococcus suis* type 2. Small, firm, lemon-yellow nodules and flattened disks of inspissated fibrin are often found free in the peritoneal cavity in chronic *Mycoplasma* infections. In intestinal anthrax in swine, there is acute gelatinous hemorrhagic peritonitis typically localized to the mesentery between the intestine and the mesenteric node, the

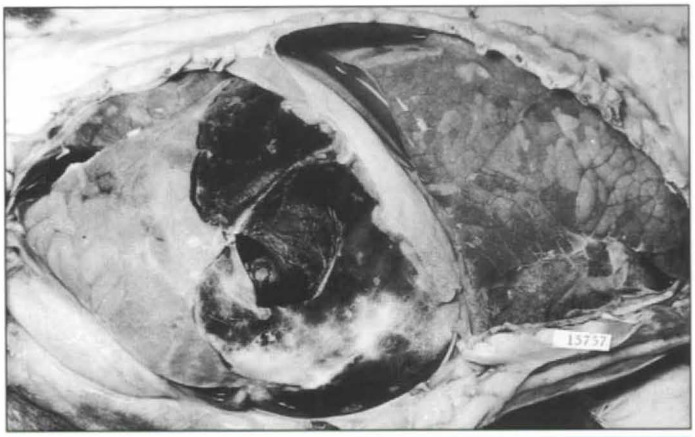

Figure 1.214 Fibrinous polyserositis in a pig with *Escherichia coli* septicemia.

distribution of the lesion being due to the lymphatic spread of the infection from the intestine. Tuberculous peritonitis in swine is localized and characterized by adhesions to the spleen. Rectal strictures in swine cause marked dilation of the colon and cecum. The serosa is frequently thickened, white, and covered with fibrin tags, similar to that of infectious serositis. Peritonitis is also common in pigs with gastric ulcers that perforate, but many pigs will die from catastrophic gastric hemorrhage prior to ulcers perforating the peritoneum.

Stephanurus dentatus larvae cause subserosal focal hepatitis and a mild reaction with edema in the perirenal fat and retroperitoneal tissue, and sometimes in the mesentery and local lymph nodes, as they move to the kidney.

Peritonitis in dogs

Fibrinohemorrhagic peritonitis, usually slight and easily overlooked, is common in infectious canine hepatitis and toxoplasmosis. The peritoneum, especially that covering the intestine, is gray and granular like ground glass and there are a few red strands of fibrin, most of them about the liver. There is edema of the intestinal subserosa and frequent petechiae or larger hemorrhages. In parvoviral infection and toxoplasmosis, similar lesions may be present on the serosa of affected segments of intestine.

Suppurative peritonitis is uncommon in dogs; it has been observed in puppies as an extension from umbilical and hepatic abscesses caused by streptococci. Septic peritonitis involving a variety of agents, often including *E. coli* and anaerobes, may follow surgical contamination of the abdomen; a penetrating wound or perforation of the gut; rupture of the urinary bladder; or rupture of pancreatic, hepatic, or prostatic abscesses. Putrid peritonitis occurs when the uterus ruptures, either as a result of pyometra or septic metritis with fetal putrefaction.

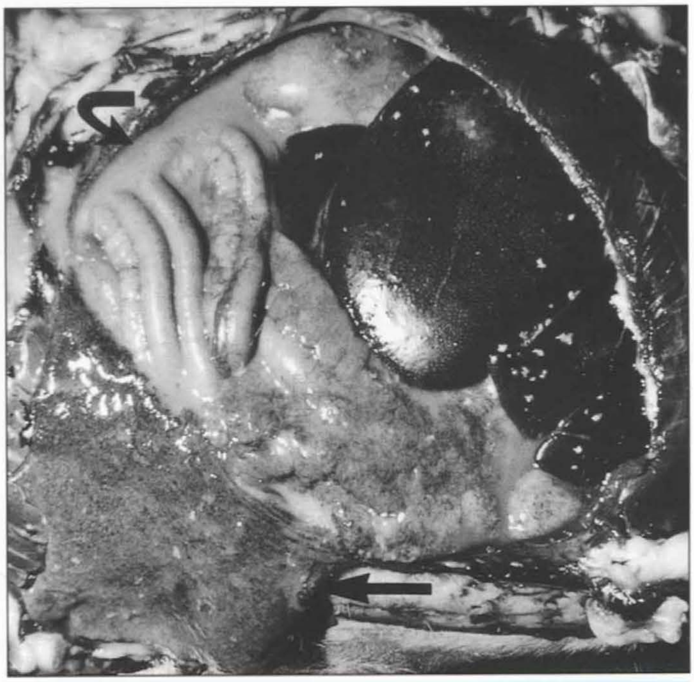

Figure 1.215 Nocardial peritonitis in a dog. The peritoneum of the reflected abdominal wall (arrow) and the omentum is granular due to adherent microcolonies of *Nocardia*. Note excess, cloudy peritoneal fluid (curved arrow).

A distinctive pyogranulomatous peritonitis occurs in dogs and cats. There is copious cellular exudate, red-brown and mushy (Fig. 1.215). The color is from blood derived from proliferation of thin-walled capillaries on serous surfaces (Fig. 1.216A), which are thickened, red, and edematous. Small yellow granules, free or attached to the peritoneum, should be seen (Fig. 1.216B). *Actinomyces* spp., most commonly *A. viscosus*, are mainly responsible for the gross lesions, often with small yellow sulfur granules free in the exudate, or in granulomas. The granulomas may be large and adherent, involving the omentum, mesenteries, and affected mesenteric lymph nodes (Fig. 1.217). *Nocardia asteroides* may be responsible for similar disease.

Chronic pyogranulomatous or granulomatous peritonitis occurs in the rare cases of eumycotic mycetoma and phycomycosis that involve the abdominal cavity. There is usually thickening and fibrosis of the serosa of affected segments of gut, with marked formation of adhesions, and the development of firm granulomatous masses on the gut wall and in the mesenteries and omentum. *Mycobacterium microti* (llama-type), the vole bacillus, is reported as a rare cause of severe diffuse granulomatous peritonitis.

Sclerosing encapsulating peritonitis, a characteristic pathologic syndrome, occurs rarely in the dog. A thick layer of progressively maturing granulation tissue lines the abdominal cavity, or parts of it, and covers or encapsulates the organs that are involved. The effect is to produce one or more thick-walled cystic spaces, enclosing some or most of the abdominal cavity and its organs. Within the space is a large volume of clear or serosanguineous fluid, with perhaps a few strands of more-or-less organized fibrin. The involved organs are often atrophic or misshapen due to the thick fibrous capsule on their surface.

Peritonitis in cats

Foul-smelling peritonitis occurs when the uterus ruptures due to pyometra or fetal putrefaction. Peritonitis also occurs from penetrating wounds or by extension from retroperitoneal tissues, and occasionally septic peritonitis is caused by anaerobes such as those associated with cat-bite abscesses. Actinomycotic peritonitis similar in appearance to the disease in dogs may complicate *Feline leukemia virus* infection in cats and the other myeloproliferative diseases.

Feline infectious peritonitis (FIP). The group 1 species in genus *Coronavirus*, family Coronaviridae, includes *Feline coronavirus* (FCoV), and its two biological types **Feline infectious peritonitis virus** (FIPV) and Feline enteric coronavirus (FECV), as well as *Transmissible gastroenteritis virus* of swine and *Canine coronavirus.* FCoVs can also be divided into types I and II based on cell culture cytopathic effect and other features; both FIPV and FECV strains are represented among FCoV types I and II. In domestic and wild felids, the various FCoV strains have a spectrum of virulence, from asymptomatic enteric infection and healthy lifelong carrier status, through symptomatic enteric infection (see the section on Enteric coronaviral infections), to virulent systemic infection, which is expressed as FIP. A small minority of cats resist infection, probably on a genetic basis.

FIPV appears to have evolved as a deletion mutation of FECV. Antibodies produced against FIPV cannot be distinguished readily from those stimulated by the other FCoVs. Genetic analysis of virus in catteries or closed colonies indicates that the viruses form a clade, but that individual cats may harbor a distinct quasispecies. In comparison to FECV, FIPV strains have less tropism for the gut. *FIPV replicates in macrophages*, which disseminate the virus to many parts of the body, and this is central to their virulence.

FCoVs are ubiquitous in cats, but the disease FIP is sporadic, and has a low prevalence. *Most cats do not develop disease when exposed to FIPV, and those cats that do develop the disease are usually under 2 years of age*. Resistance to FIPV infection is cell-mediated, and systemic clinical disease only occurs if the cell-mediated response is ineffective. The cytokine response appears to be important in the response to FPV infection; immunity against FIPV may be associated with low tumor

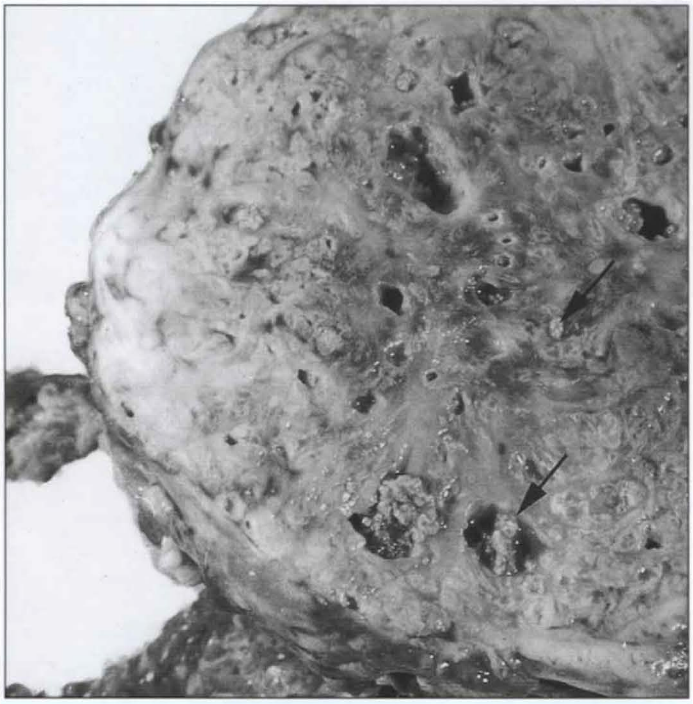

Figure 1.217 ***Actinomyces*** **peritonitis** in a dog. Granulomatous mass involving the mesentery and omentum; "sulfur granules" shell out of pyogranulomatous foci on the cut surface (arrows).

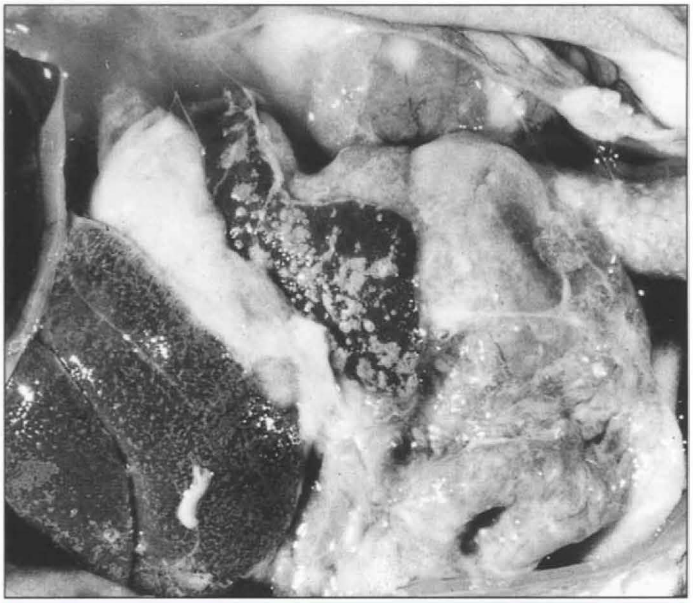

Figure 1.218 Feline infectious peritonitis. Exudative lesion with fibrin on mesentery and viscera, and granulomas in liver, spleen, kidney, and wall of large and small intestine.

necrosis factor-α/high interferon-γ mRNA responses, whereas high tumor necrosis factor-α/low interferon-γ mRNA responses favor disease. Cats that recover from FIP have humoral immune responses and immune complexes that are demonstrable in blood, but, although clearance of virus occurs, persistence may extend for several months with fecal shedding. Cats that do not clear FIPV develop either the dry or wet clinical forms of the disease depending on whether ineffective cell-mediated or humoral immunity dominates the clinical disease. Though often described as distinct entities, *the wet and dry forms of FIP are the extremes of a continuum of syndromes, with* ***vasculitis*** *and* ***pyogranulomatous inflammation*** *as the hallmarks.* Effusive disease is more common than the dry form.

Enteric infection may produce mild, subclinical blunting and fusion of villi. Incidence of the disease is not higher in cats infected with *Feline leukemia virus* or *Feline immunodeficiency virus*; however FCoV replicates 10–100-fold more in cats infected with FIV, thus enhancing the probability of spontaneous mutations.

Type III and type IV immune reactions occur in FIPV-infected cats with clinical disease. Arthus reactions occur in the walls of small venules and arterioles, especially in the serosal surfaces and parenchymatous organs, such as liver and kidney. *The cellular infiltrates around vessels are often characterized as pyogranulomatous, with mixed populations of neutrophils, macrophages, and lymphocytes.* Endothelial damage also results in disseminated intravascular coagulation in the terminal stages of the disease, with thrombocytopenia and increased circulating fibrin split products.

Cats with the effusive form of FIP may develop abdominal distension. Pleural effusion is present in ~25% of cases and may cause dyspnea. Cardiac tamponade due to pericardial effusion is rare. Ocular and central nervous signs are rare. The cats are hypergammaglobulinemic and may have leukocytosis and neutrophilia. Most go on to die; very few recover after passing through a phase of noneffusive disease.

Cats with noneffusive FIP have a chronic disease of insidious onset and frequently develop signs specific to organs severely affected by vascular lesions. These may include ocular disease; central nervous disorders such as ataxia, paraparesis, head tilt; specific nerve palsies, nystagmus, and behavioral changes; renal failure; and hepatic or pancreatic insufficiency. An uncommon intestinal manifestation may be seen as a protracted period of vomiting and diarrhea with a palpable mass usually at or about the ileocecocolic junction.

Peritonitis is present in most animals, although marked effusion is not found in those with the dry form. Up to 1 liter of abdominal exudate may be present in cats with effusive FIP. The fluid is usually viscous, clear, and pale to deep yellow, although it may be flocculent and contain strands of fibrin. The serosal surfaces may be covered with fibrin, giving them a granular appearance. Fibrin is frequently prominent over the visceral peritoneum (Fig. 1.218), and fragile adhesions may be present. There are white foci of necrosis or raised plaques or nodular cellular infiltrations on the serosa and extending into the organs or wall of the intestine. These vary in size from a few millimeters to a centimeter in diameter. The omentum may be contracted into a mass in the cranial abdomen, and adherent to itself and other abdominal surfaces. Mesenteries may be thickened and opaque.

The kidneys may be enlarged and nodular, with few or many, small to large, white, firm nodules protruding from the cortex (Fig. 1.219). Hepatitis and pancreatitis of variable degree may also be present, characterized by small, white foci of inflammation. The tunica vaginalis may be affected, resulting in periorchitis in intact males. Fibrin is usually less prominent in the thorax, but firm white foci may be present under the pleura, and the lungs may be dark and rubbery. Hydropericardium and epicarditis occur less frequently. Abdominal and thoracic lymph nodes may be enlarged and have a lobulated pattern on cut surface.

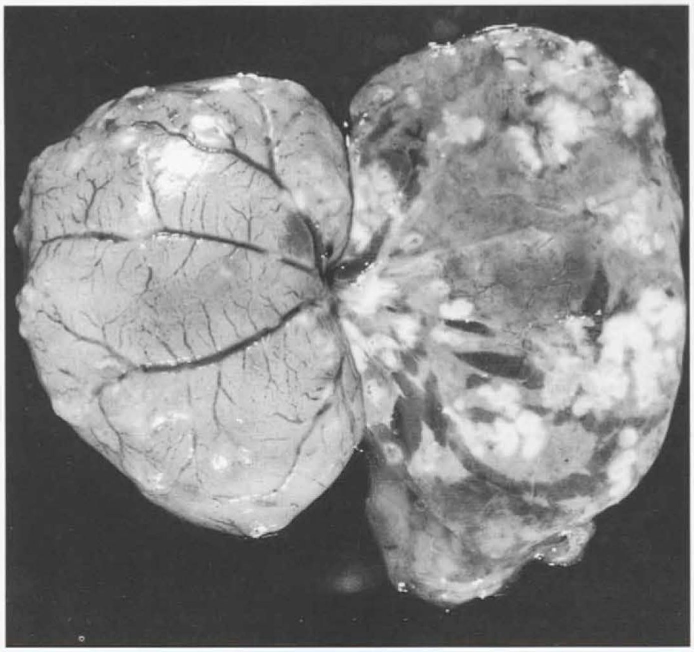

Figure 1.219 Feline infectious peritonitis. Focal pyogranulomatous lesions involving renal cortex and reflected capsule.

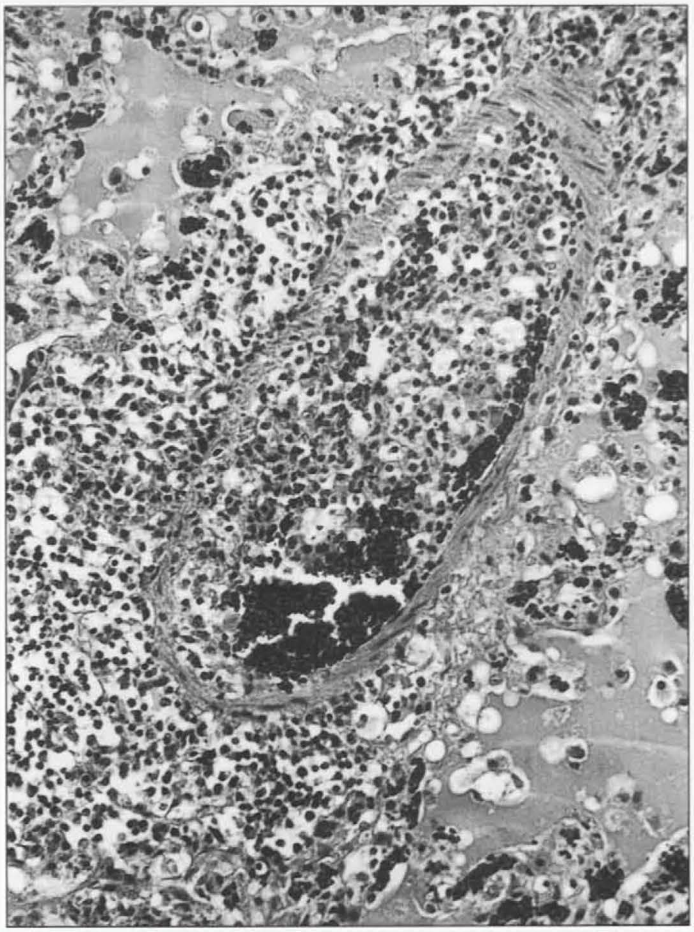

Figure 1.220 Feline infectious peritonitis. Vasculitis and perivasculitis in a lung with severe pulmonary edema.

In cats with noneffusive FIP, there may be inflammatory foci in the abdominal or thoracic organs as described above, or lesions may be restricted to the eyes and nervous system. Diffuse uveitis or chorioretinitis may progress to panophthalmitis; fibrin is often present in the anterior chamber. Lesions in the central nervous system can involve the leptomeninges, spinal cord, or brain, but usually are visible grossly only in the leptomeninges as thickening or white streaks. Occasionally, hydrocephalus or syringomyelia may result from ependymitis. The isolated intestinal lesion is marked thickening of the affected segment by nodular, firm, white tissue extending through the wall of the intestine with adhesion to enlarged lymph nodes.

The characteristic microscopic lesion is generalized vasculitis and perivasculitis, especially of venules (Fig. 1.220), with a focal mixed inflammatory reaction. This lesion occurs in the serous membranes, in the connective tissue of the parenchymatous organs, the eye, and the meninges. Neutrophils, lymphocytes, plasma cells, and macrophages accumulate in and around affected vessels. The endothelium swells, and medial necrosis may be evident, with narrowed vascular lumina; thrombosis may occur. The proportion of neutrophils in the reaction varies, and some lesions may be comprised mainly of a mixture of lymphoid and histiocytic cells. Fibroplasia is variable; occasionally, adventitial fibrosis occurs with little cellular infiltrate. The vascular lesion results in the serofibrinous and cellular exudate on the serosal surfaces, and the nodules visible on the surfaces and deeper in solid organs. The small random necrotic foci that are found in the parenchyma of the liver may be due in some cases to thrombophlebitis and infarction.

The microscopic changes on the omentum, mesentery, and serosal tissues vary in severity. Mild changes are proliferation of mesothelial cells, slight fibrin exudate with fibroblast proliferation, and scattered neutrophils and mononuclear cells. Severe changes result in a thick layer of fibrin adherent to the serosa, with necrosis and/or hypertrophy of mesothelium. Large numbers of neutrophils, mononuclear cells, and necrotic debris may be embedded in the fibrin. The vasculitis may extend from the serosa into the intestine, affecting the muscularis, myenteric ganglia, the submucosa, and the mucosa, which may be segmentally infarcted.

Lesions in various organs are caused by the vascular damage that occurs in the capsule and stromal connective tissue. They may be found throughout the body. Subcapsular infiltrates occur particularly in the liver, lung, and pancreas, and perivasculitis can develop deep in the parenchyma, especially in the kidney. In addition to focal lung lesions, there may be diffuse interstitial pneumonia, sometimes most severe close to the visceral pleura. Similarly, severe focal or generalized lymphoplasmacytic interstitial nephritis may develop. In the spleen and lymph nodes, there is histiocytosis, and either depletion or hyperplasia of lymphoid follicles. Lymphoid depletion may be a result of apoptosis of noninfected lymphocytes.

Cellular infiltrations in the spinal or cerebral meninges, the choroid plexuses, ependyma, and perivascular spaces tend to be more mononuclear and diffuse, with only occasional focal perivasculitis. Degenerative and necrotic lesions in the parenchyma of the central nervous system appear to be related to the vasculitis. The ependyma may be visibly roughened and develop reactive syncytia of lining cells. Ocular lesions are common, but usually subclinical (see Vol. 1, Eye and ear). *Effusive FIP must be differentiated from bacterial peritonitis in particular, but noneffusive forms may be similar to manifestations of lymphosarcoma, steatitis, mycotic infections, and toxoplasmosis.* With thorough necropsy, the constellation of lesions is usually sufficiently distinctive to allow a gross diagnosis with a high degree of accuracy. Testing by immunofluorescence or enzyme-linked immunosorbent assay may be useful in supporting a diagnosis of FIP, but *histopathology remains the only conclusive means of diagnosis of FIP.*

Parasitic diseases of the peritoneum

Most of the parasites found in the peritoneal cavity are there in the normal course of migrations to another site, or as an accident. Only a few larval and adult helminths use the abdominal cavity as their normal habitat.

Cysticerci (*Cysticercus tenuicollis* in ruminants; *C. pisiformis* in lagomorphs) may be found on the peritoneum during their normal development; they are nonpathogenic, and excite virtually no tissue response, beyond a thin, bland fibrous capsule. Rarely, cysticerci have been encountered in the abdomen of carnivores, which are abnormal hosts. Spargana, elongate larval forms of *Spirometra* spp., may encyst in a bland fibrous capsule in the peritoneal cavity of carnivores and swine. Tetrathyridia, the larvae of the tapeworm *Mesocestoides*, may proliferate extensively in the abdominal cavity of carnivores, where they cause a characteristic pyogranulomatous peritonitis, or "parasitic ascites."

Fasciola hepatica larvae can cause acute and chronic peritonitis in cattle and sheep; the inflammation involves the parietal peritoneum and sometimes the visceral peritoneum, especially that of liver, spleen, and omentum. The changes may consist of many tags of fibrin or more diffuse thickening, and the young flukes may be found in the inflammatory lesions both on and beneath the peritoneum.

Dioctophyma renale seems not as well adapted to canids as to mustelids. In dogs, worms may not complete their migration from the duodenum to the right kidney. As a result, they sometimes initiate chronic perihepatitis in which reactions to characteristic ova, if not the worm or its remnants, may be found.

Stephanurus dentatus, in the course of its migrations through the liver and peritoneal cavity to the kidneys in pigs, may cause local hemorrhage, peritonitis, and perihepatitis.

Strongylus edentatus and ***S. equinus*** pass through the liver, and the ligaments and lumen of the peritoneal cavity, in their migration. Fibrous tags on the liver, particularly the diaphragmatic aspect, are sequelae of *S. edentatus* migration. The larvae of both species may be found in the retroperitoneal tissues of the dorsal abdomen in horses, and in the mesenteries and omentum, where they sometimes incite eosinophilic granulomas.

Ascarids of all species may occasionally cause obstruction and rupture of the small intestine or bile duct, so that they may be found in the abdomen as a terminal event.

Some parasites use the peritoneal cavity as their final habitat. ***Setaria* spp.**, onchocercid filarioid nematodes, inhabit the peritoneal cavity of many domestic and wild ungulates such as horses, cattle, buffalo, camels, sheep, goats, swine, deer, and antelope. They are commonly found at autopsy in cattle and horses in endemic areas. Some species of *Setaria* have a cosmopolitan distribution and may be found in several species of wild and domestic ungulates (*S. equina* in equids; *S. labiatopapillosa* in cattle, buffalo, and perhaps deer and antelope), while others are restricted geographically (*S. digitata*, Asia; *S. marshalli*, Asia) perhaps by the distribution of intermediate hosts.

Adult *Setaria* do not usually cause significant peritoneal lesions in their normal host. There are rare reports of occlusion of the uterine tube by *S. labiatopapillosa* in cattle. As well, adult *S. labiatopapillosa* in the peritoneal cavity, or in the vaginal space around the testis, may incite granulomatous peritonitis or periorchitis if they die; remnants of the dead nematode may be detected in sections of the granulomatous reaction. Adult *S. digitata* may occasionally be found in abnormal locations, such as the heart, lungs, and mesenteric lymph nodes, where they incite eosinophilic granulomas. The larval form of *S. digitata* can produce mild adhesive peritonitis and granulomas in the retroperitoneum and bladder of cattle. The larvae of *S. equina, S. digitata*, and perhaps others that normally spend part of their time in the central nervous system, may occasionally penetrate the neural parenchyma and cause lesions. The sheathed microfilariae deposited by adult females in the peritoneal cavity are found in the blood. The intermediate host may be a mosquito, or for some *Setaria* spp., biting flies (*Haematobia* and *Stomoxys* spp). The microfilariae develop into infective larvae in 2–3 weeks. They are released from the feeding arthropod and enter the final host.

Setaria digitata is normally found as an adult in the peritoneal cavity of cattle and buffalo in Asia, but its larvae can cause *cerebrospinal nematodiasis* in aberrant hosts (see Vol. 1, Nervous system). *Setaria* species that may occur normally in cervids have been reported to cause central nervous system lesions in deer; however, *Elaphostrongylus* larvae produce similar signs and lesions, and differentiation may be difficult.

S. digitata larvae may invade the eye of horses, via the optic nerve, as do the microfilariae of *S. equina*. Here they may cause endophthalmitis.

Miscellaneous lesions of the peritoneum

Cysts of the peritoneum are rather common but insignificant. Those associated with genital adnexa are described with those systems. Cysticerci have been mentioned; *Echinococcus granulosus* may develop cysts on the peritoneum following the rupture of a mature hydatid into the abdomen. Small cysts, sometimes multiple, which are observed in the omentum, may be either inclusion cysts or sites of local lymphatic ectasia; they are inert.

The normal squamous mesothelial cells of the serosa may undergo **metaplasia** to a cuboidal or columnar type resembling epithelium. Such metaplasia is probably the mildest response of the peritoneum to irritation but may also be a response to estrogen. Inflammatory metaplasia leading to ossification may occur in peritoneal scars, especially in swine. It may also be found in the mesenteries and the dorsal retroperitoneum without obvious antecedent change, although ossification may occur following fat necrosis as well. Ossified areas are discoid, of variable size and shape, and are usually found in adipose tissue.

Neoplastic diseases of the peritoneum

Primary tumors of the peritoneum may arise from the serosa itself, from the subserous connective tissues, and from various differentiated tissues such as nerve sheaths. Tumors arising from the serosa are called **mesotheliomas**, sometimes termed "malignant." The qualification is without meaning, as virtually all can spread by implantation rather than metastasis, the latter being much less common.

Mesotheliomas are rare. They occur with greatest frequency in cattle and dogs but are occasionally reported in horses, cats, pigs, and other species. Interest in mesotheliomas has increased since the association between asbestos fiber and mesothelioma was discovered in humans. This association has not been confirmed in animals, though ferruginous bodies, suggestive of asbestos exposure, have been found in the lungs of some urban dogs with mesothelioma, and an association has been made between mesothelioma in dogs and exposure of owners to asbestos. *Many fiber types other than asbestos are capable of causing mesotheliomas and this ability seems to be related to fiber size and solubility*. In domestic animals, mesothelioma is notable because it occurs most frequently as a *congenital neoplasm* in fetal or young cattle (Fig. 1.221).

Mesotheliomas arise from the cells of the serous linings of pericardial, pleural, and peritoneal cavities, and they may involve all three locations simultaneously. They are typically pleural in pigs. They usually appear as *multiple firm, sessile, or pedunculated nodules*, from a few millimeters to 6–10 cm in diameter: *as villus projections*, on a thickened mesentery or serosal surface; or as *fibrous or sclerosing forms*, which are more plaque-like. The tumor is frequently associated with a milky or blood-tinged effusion, and in sclerosing tumors in which adhesions occasionally occur, the lesion might resemble chronic granulomatous peritonitis. Ascites is usually present as the result of blocked lymphatics.

Mesotheliomas of the pleura, pericardium, or peritoneum may assume a variety of histologic patterns. However, they usually appear *predominantly papillary*, and resemble adenocarcinoma, *or as spindle cells* resembling fibrosarcoma.

The most common tumor is a solid mass made up of single layers of dark, plump cuboidal, columnar or rounded, epithelioid cells with a distinct border and abundant pink cytoplasm, over proliferating fibrocellular stroma. Mitotic figures are typically not numerous. Some tumors have atypical cells with marked anisokaryosis and prominent nucleoli, or large multinucleate cells. The mesothelial cells form loops and festoons in a papillary pattern, or line cystic spaces and tubular structures. There may be a mucinous matrix in this acinar pattern. These mesotheliomas, which resemble adenocarcinoma, can mimic implantation of a true carcinoma so completely that adequate differentiation may rest on very careful examination for, and exclusion of, a primary focus of carcinoma. Especially challenging are those carcinomas that spread in subserosal lymphatics. Histochemistry and immunohistochemistry have not been successful in uniquely identifying malignant mesothelial cells in domestic animals.

Mesotheliomas that are predominantly fibrous may resemble fibrosarcomas. In the sclerosing forms, there may be a thick fibrous serosa with adhesions, and large anaplastic cuboidal cells may be found in clusters or lining cystic spaces within the fibrous tissue.

Lipomas are the most frequently encountered tumors of the peritoneal interstitium. These benign tumors are well known in horses, in which they usually originate in the mesenteries. They may reach enormous size, but their significance is that they tend to become pedunculated and may cause acute strangulation obstruction when the pedicle winds about a loop of intestine. In section, the core of some of these tumors is friable and necrotic, probably from ischemia; only the superficial centimeter or so remains viable, perhaps nourished by diffusion from the peritoneal environment (Fig. 1.222). In the dog, lipomas arise in the omentum, rather than the mesenteries, and settle on the abdominal floor. They may become very large, but tend not to be pedunculated. They do not, therefore, cause acute distress and, although they may appear malignant histologically, metastases are unusual. They too may develop a pseudocapsule and central area of necrosis.

Other tumors of the subserosal connective tissues, including myxomas, fibromas, and their malignant counterparts, are rare, although fibrosarcomas are observed in dogs, and an omental fibrosarcoma has been reported in a horse. Neurofibromatosis of cattle may involve the abdominal nerves and plexuses, and ganglioneuromas are also observed in this species. Extramedullary pheochromocytomas are observed in cattle and dogs, and nonchromaffin paragangliomas occur in dogs, the latter usually in association with similar tumors elsewhere.

Secondary tumors of the peritoneum are not common, but may occur in any abdominal neoplasia. These mainly arise by direct implantation, rather than by lymphogenous or hematogenous metastasis. Carcinomas are much more common than sarcomas.

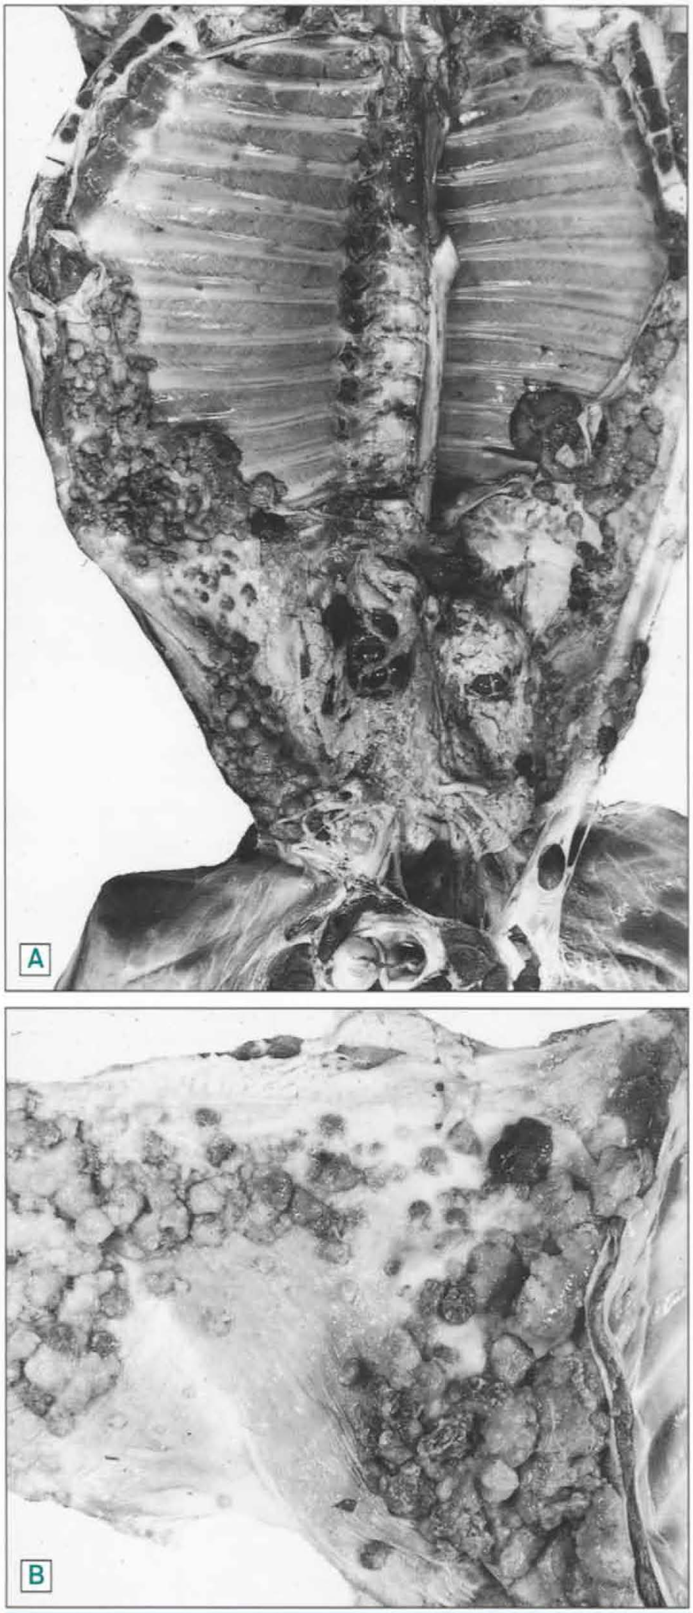

Figure 1.221 Congenital mesothelioma in a calf. **A.** Tumor nodules are confined to peritoneal cavity. **B.** Closer view of (**A**) showing nodules on peritoneal surface.

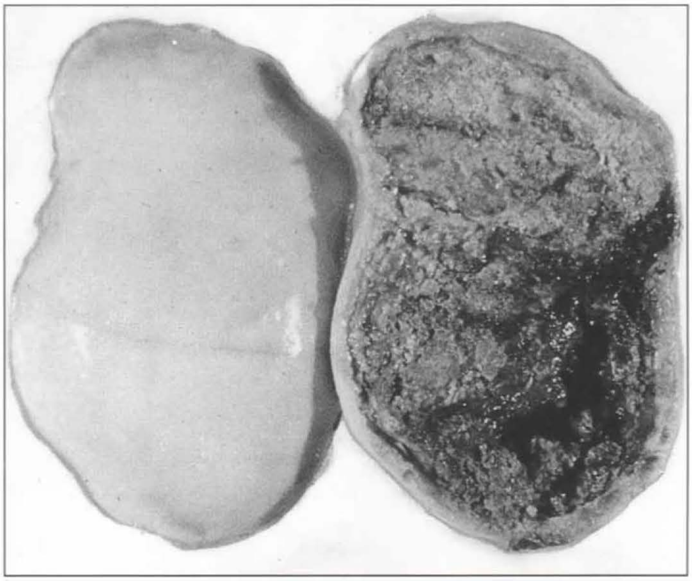

Figure 1.222 Pedunculated lipoma (transected) from the mesentery of a horse. Note necrotic core and thin capsule of viable tissue.

They may be very scirrhous and, when accompanied by ascites, may resemble chronic peritonitis; a relative or complete absence of adhesions is often a helpful distinguishing feature at necropsy. There are obviously many possibilities for the origin of secondary tumors; several common types are listed below.

Ovarian carcinomas are a cause of ascites, and may be difficult to differentiate from mesothelioma. Implants of ovarian carcinoma tend to be papillary. Bile duct carcinomas and pancreatic adenocarcinomas tend to be scirrhous, as do intestinal adenocarcinomas in cattle and sheep. Squamous cell carcinomas of the equine stomach form rather discrete implants that may resemble nodules of mesothelioma, or granulomas; they may be differentiated enough to be recognizably keratinized on gross inspection. Transitional cell tumors developing in cattle with enzootic hematuria implant locally on the pelvic surfaces; implants from rectal adenocarcinoma in dogs also tend to be confined to the pelvic peritoneum. Malignant melanomas of perineal origin in horses produce pigmented plaques on the peritoneum, or in the mesenteries, as may occasional metastatic melanomas in dogs. Pale raised plaques may arise on the peritoneum from implants of prostatic carcinoma in dogs.

Diseases of the retroperitoneum

Problems in the retroperitoneum may originate in the stroma of the space itself, from organs in this space, or may extend from adjacent organs.

Retroperitonitis may arise from sepsis involving the pelvic or abdominal urogenital tract, or the mesenteric root; from penetrating wounds; from rectal tears in horses; and from migrating grass awns or other foreign bodies. Frequently, it will evolve to form a fluctuant abscess or draining fistula in the flank, based on the anatomic path of least resistance for advancing phlegmon in the soft tissue of the region. The lesion is usually a poorly encapsulated sinus or abscess, with a wall of granulation tissue and containing liquid pus. It may extend to involve adjacent vertebrae in periostitis or osteomyelitis. A foreign body may be encountered on exploration, or the lesion may be traced back to a primary septic focus in the abdomen, perhaps a renal or perirenal abscess; an ovarian stump with a remnant of unresorbed suture; or an abscess or pyogranuloma in the root of the mesentery. Usually, a mixed flora will be isolated. If *Actinomyces* spp. are implicated, there may be granulomatous lesions with sulfur granules in the abdomen or flank.

Nonneoplastic retroperitoneal masses include hematomas, or accumulations of urine, following trauma to the caudal abdominal or pelvic area. Hemorrhage may dissect widely in this area, and the origin may be difficult to detect. Rupture of retroperitoneal hematomas may be fatal. Retroperitoneal hemorrhage in newborn calves is often an indication of fracture of the spinal column due to rotation during assisted calving. Sublumbar hemorrhage is frequent in male lambs castrated by traction of the testis. Renal and perirenal cysts, and pseudocysts or capsular cysts, may also be encountered, usually incidentally.

Neoplasms of the retroperitoneal space include lipomas, fibrosarcomas, lymphosarcomas, osteosarcomas, and nonchromaffin paragangliomas, as well as primary renal adenocarcinomas and adrenal tumors. Occasional highly malignant adenocarcinomas of obscure origin occur in the dorsal retroperitoneum of dogs.

Metastatic tumors to the region include those commonly involving the sublumbar lymph nodes, such as lymphosarcoma, and transitional cell, prostatic, colonic, perianal gland, and anal gland malignancies. Metastatic involvement of the sublumbar chain of lymph nodes frequently stimulates periosteal reaction on the ventral aspect of adjacent vertebral bodies. Occasionally, tumors metastatic to the region will lyse vertebral bodies or transverse processes, and they may occasionally invade the spinal canal. Lytic and osteophytic reactions must be distinguished from the effects of osteomyelitis.

GENERAL CONSIDERATIONS

The functional importance of the liver has long been recognized. Among ancient civilizations, the liver was regarded as both the seat of life and the mirror of heaven. Hepatoscopy, literally "looking in the liver" of sacrificial animals, was a widespread practice in ancient Babylonia and later in Rome. The detailed study of the liver for cosmological and divinatory purposes is perhaps best illustrated by the Etruscan liver of Piacenza, a bronze instructive model of a sheep's liver dating from the second century BC.

The liver plays a central role in processing dietary carbohydrates, lipids, amino acids, and vitamins; in the synthesis and turnover of most plasma proteins; and in the detoxification and biliary excretion of endogenous wastes and xenobiotic compounds. The liver also functions as an important organ of the innate immune system, integrated into the complex system of defense against foreign macromolecules. As such, hepatic disorders have far-reaching consequences, given the dependence of other organs on the metabolic function of the liver.

Structure and function

The number and shape of the liver lobes of the major domestic mammals vary among species. The typical shape enables the liver mass readily to enlarge or shrink as it adapts to functional demands. The **portal vein** supplies approximately 75% of total afferent blood flow, bringing venous blood from the forestomachs, glandular stomach, intestines, spleen, and pancreas. This portal flow is important for the rapid clearance of nutrients, xenobiotics, microorganisms, and potentially immunogenic materials that enter the circulation from the gastrointestinal tract. The liver is also supplied with oxygenated arterial blood via the **hepatic artery**, a branch of the celiac artery arising from the abdominal aorta. The hepatic artery contributes the remaining 25–30% of afferent blood flow, entering the liver at the hilus and branching in parallel with the portal veins. Most hepatic arterioles disperse into a peribiliary capillary plexus before entering the sinusoids, lowering pressure and preventing reversal of portal venous inflow. Portal and arterial blood eventually mix in the low-pressure hepatic sinusoids.

Hepatic sinusoids are cavernous microvessels lined by specialized endothelial cells, Kupffer cells, and pit cells that provide a suite of innate defenses and housekeeping functions. Hepatic sinusoids differ from vascular structures elsewhere in that they lack a typical basement membrane, and are supported by a specialized, discontinuous or loose extracellular matrix. Hepatic **sinusoidal endothelial cells** are fenestrated, and these 1000 Å diameter sieve-like pores control fluid, solute, and particulate interchange between blood and the perisinusoidal space, regulated by the action of the cellular cytoskeleton. Sinusoidal endothelial cells are actively pinocytotic and internalize and degrade various endogenous glycoproteins, glycosaminoglycans, and immune complexes. **Kupffer cells** are fixed macrophages attached to the inner sinusoidal wall in direct contact with blood moving at a relatively slow velocity. This arrangement facilitates phagocytic removal of particulates, especially bacteria that enter the portal blood via the lower alimentary tract. Kupffer cells also participate in the regulation of inflammatory and repair responses by secretion of various cytokines into the circulation and perisinusoidal space. **Pit cells** are large granular lymphocytes with natural killer activity that adhere to the sinusoidal endothelium where they are also well situated to participate in various innate immune defenses, for example targeting infected cells that enter the liver via the blood.

The sinusoids are separated from the adjacent hepatocellular plates by an extracellular space known as the **space of Disse** that contains **hepatic stellate cells** (also termed *lipocytes* or *Ito cells*), reticulin fibers, and nerves. The space of Disse is not readily visible by light microscopy unless there is fluid retention, such as can occur with impediment to venous outflow. While hepatic sinusoids in the normal liver lack a conventional basement membrane, the perisinusoidal space contains a low-density extracellular matrix consisting of collagen type IV, laminin, fibronectin, and minor amounts of collagen types I, III, V, and VI, nonfibrillar collagen XVIII, tenascin, and various proteoglycans. A conventional extracellular matrix composed of fibrillar collagen types I, III, V, and fibronectin is found in the external capsule (**Glisson's capsule**), septa, and around portal triads and central veins. "**Reticulin fibers**" refer to the components of the extracellular matrix that are stainable by silver impregnation techniques, consisting mainly of collagen type III with attached fibronectin and other glycoproteins. The fenestrated sinusoidal endothelium, coupled with the loose subendothelial matrix, allows for exchange of various macromolecules between hepatocytes and the sinusoidal blood. After hepatic injury, a denser, less permeable matrix resembling a true basement membrane may form and sinusoidal endothelial cells may lose their fenestrae (so-called "**capillarization" of sinusoids**), reducing uptake and secretion of plasma proteins and other metabolically important substances.

The **terminal hepatic venules** ("*central veins*") collect the outflow blood from the sinusoids. These venules converge into the larger **hepatic veins** that empty into the caudal vena cava. In most species, increased pressure in the vena cava during right-sided heart failure or hepatic vein thrombosis causes passive congestion and distension of the hepatic veins and sinusoids. However, the large and small hepatic veins in dogs and pigs have more prominent smooth-muscle valves that reduce the influence of central venous pressure on the sinusoids. Fluids from the perisinusoidal space drain into **lymphatics** in the extracellular connective tissue spaces of the liver capsule and the portal tracts. These flow out the portal hilus to the hepatic lymph nodes and eventually enter the thoracic duct. In some species such as the dog there are also lymphatics around the larger hepatic veins; these cross the diaphragm into the mediastinum.

The vasculature of the liver parenchyma defines its functional microanatomy, but *debate continues as to what best represents the hepatic structural–functional unit.* Mammalian hepatocytes are organized in plate-like monolayer arrays among the sinusoids. In section, these plates appear as "cords," but, in three dimensions, *plates, sinusoids, and tracts anastomose in a complex pattern.* Arrangements of hepatocytes are referred to as either **acini** or **lobules**.

- The **hepatic acinus** of Rappaport is a functional subunit divided into *zones* in relation to blood supply:
  - **zone 1** hepatocytes are closest to the oxygen- and nutrient-rich arterial and portal inflow.
  - **zone 3** (**periacinar**) hepatocytes are nearest the outflow (terminal hepatic venule).
  - **zone 2** is the transitional mid-zone.
- The **classical hepatic lobule** is a six-sided anatomic arrangement of hepatocytes centered on the terminal hepatic venule, also termed the "central vein" in this context. Peripherally, lobules are outlined by fibrovascular septa extending from the portal tracts. In the pig liver, septa form obvious lobular perimeters, but in most mammalian species the lobules are less pronounced because connective tissue is more restricted to portal tracts. The terms **periportal** and **centrilobular** are mainly used for pathological conditions that are centered on either the *portal tracts* or the *central veins* of the classical lobule.

The functional activity of hepatocytes is determined by their microenvironment, and virtually all liver functions have a zonal gradient. Zone 1 hepatocytes, exposed to the blood with the highest concentration of oxygen, insulin, glucagon, and amino acids, are the principal site of gluconeogenesis, protein synthesis, aerobic metabolism, urea cycle, lipid and cholesterol metabolism. In zone 3, glycolysis, lipogenesis, and the major biotransformation functions are more active, including the expression of most cytochromes P450, glucuronyl transferases, glutathione S-transferases and other biotransformation/detoxification enzymes. *Zone 3 hepatocytes are therefore more susceptible to hypoxic injury as well as injury by toxic substances that are metabolically activated by cytochromes P450.* By comparison, *hepatocytes in zone 1 are more susceptible to direct-acting toxicants*, such as ingested metal salts, due to their proximity to the vascular inflow. Under the influences of various inducers, the patterns of enzyme expression can extend beyond the resting limits. Zonal variation is not restricted to parenchymal cells, but is also apparent in the structure and function of sinusoidal endothelial cells, Kupffer cells, perisinusoidal stellate cells, and the composition of the matrix in the space of Disse.

The **portal tract**, or *portal triad*, is a well-defined structure *containing at least one small arterial branch, a portal vein branch, and a bile duct*, surrounded by connective tissue composed primarily of type I collagen. Due to the pattern of progressive branching of the portal tract system, individual tracts exhibit a range of sizes and shapes, from round to triangular or branching. In larger portal tracts, lymphatic channels and autonomic nerve fibers may be seen. The **bile duct** system is a branching outflow that ultimately enters the proximal duodenum. Most species, with the exception of the horse and rat, have a bile storage diverticulum (**gallbladder**). Cats occasionally have divided or bipartite gallbladders, and the bile duct joins the pancreatic duct before entry into the duodenum. Intrahepatic bile ducts range in size from the larger septal or trabecular ducts (internal diameter of more than 100 μm in humans) to the smaller interlobular ducts, and tend to be adjacent to a hepatic artery branch of approximately the same size. **Bile ductules** are smaller yet (lumen size of less than 20 μm) and are located at the periphery of portal tracts. Bile ducts are lined by cuboidal to low columnar **bile duct epithelial cells**, subtended by a periodic acid–Schiff (PAS)-positive basement membrane.

Cells of the liver

Hepatocytes (referred to as **parenchymal cells**) constitute about 70–80% of the liver mass. However, more than 50% of liver DNA is found in smaller **nonparenchymal cells** (bile duct epithelium, hepatic stellate cells, sinusoidal endothelium, Kupffer cells) and itinerant cells (such as leukocytes). The hepatocyte is a polygonal epithelial cell, arranged in single-cell-thick anastomosing plates, separated by hepatic sinusoids. Each hepatocyte is therefore exposed to sinusoidal blood on two sides. A discontinuous line of hepatocytes, termed the **limiting plate**, is found at the interface with the collagenous extracellular matrix of the portal tract. Normal hepatocytes have abundant eosinophilic cytoplasm and most have a single, round, centrally placed nucleus with finely dispersed chromatin and at least one nucleolus. Some binucleate hepatocytes are present normally in mammals and can become more numerous in response to various stimuli and injuries that induce or affect regeneration.

Hepatocytes are metabolically highly active cells, containing an array of organelles including smooth and rough endoplasmic reticulum, mitochondria, lysosomes, peroxisomes, Golgi complexes, and transport vesicles. A greater proportion of the genome is expressed in the normal liver than has been observed in any other tissue, an indication that brief surveys of liver functions are necessarily oversimplified. However, those constituents that are most abundant have most influence on the microscopic appearance of the liver. The normal hepatocyte contains abundant glycogen that can be demonstrated by PAS staining, as well as variable amounts of stored triglycerides and various proteins such as ferritin, an iron-binding protein. The cytoplasm of zone 3 hepatocytes may also contain uniform, golden-brown granules of **lipofuscin**. This so-called "wear-and-tear" pigment becomes more prominent with age, and progressively accumulates in midzonal and periportal hepatocytes. Hepatocytes have a cytoskeleton composed of microtubules, microfilaments, and intermediate filaments. Microtubules are found throughout the cytoplasm, and are involved in the movement of secreted proteins into the extracellular perisinusoidal space; accordingly, microtubule inhibitors such as colchicine and vinca alkaloids may reduce hepatic protein secretion. Microfilaments, composed of actin and myosin, are concentrated around the bile canaliculus, where they are involved in canalicular peristalsis and bile secretion; microfilament inhibitors result in cholestasis. Intermediate filaments (predominantly cytokeratins 8 and 18) form an irregular meshwork extending from the plasma membrane to the perinuclear zone, and are responsible for the spatial organization of the hepatocyte.

There are three morphologically and functionally distinct surfaces of the hepatocyte plasma membrane:

1. The **sinusoidal domain** has irregular microvilli that project into the space of Disse, increasing hepatocyte surface area and functioning in exchange of substances with the blood. Numerous membrane receptors for glycoproteins, asialoglycoproteins, peptides, hormones, growth factors, immunoglobulin A, and other endocytotic or signaling ligands are concentrated at the sinusoidal pole, on the surface or in trans-Golgi and endocytotic vesicles. In addition, transmembrane proteins involved in plasma exchange of small ionic substances with the sinusoidal plasma, and transmembrane proteins responsible for matrix recognition, are concentrated on the sinusoidal surface.
2. The **intercellular domain** is specialized for adhesion via junctional complexes, including desmosomes, tight junctions, and intermediate junctions, as well as for intercellular communication via gap junctions. Within the intercellular domain is the **bile canaliculus**, the beginning of the bile drainage system of the liver. *The canaliculus is an intercellular space between two adjacent hepatocytes, isolated by tight junctions.*
3. The **bile canalicular domain** contains various adenosine triphosphate-dependent carriers that export many products, including leukotrienes, bile salts, xenobiotics, and their metabolites into the bile.

The **canal of Hering** connects the bile canaliculus to the portal bile ductules. The epithelial cells in this transition zone between hepatocytes and bile ducts have considerable regenerative potential and can give rise to proliferating bile ductules seen in various forms of liver injury. This compartment is also believed to contain the greatest number of pluripotential stem cells that can differentiate into other liver cell lineages. Differentiated hepatocytes have a low rate of mitosis but most can replicate to maintain functional liver mass; however, with aging and in some disease conditions, the replicative potential of hepatocytes declines. During development and some chronic liver diseases, *undifferentiated ductal precursor cells known as* "**oval cells**" can emerge from the terminal bile duct or canals of Hering. Oval cells have been considered to be pluripotential **hepatic stem cells**, capable of generating new hepatocytes, although they are more likely to differentiate into bile duct epithelium. Bone marrow-derived pluripotential stem cells also appear to have the ability to differentiate into hepatocytes.

Although derived from common embryologic progenitor cells, **bile duct epithelial cells** differ from hepatocytes in both phenotype and function. They contain a strongly developed network of intermediate filaments, including cytokeratins 7 and 19. They also express marked heterogeneity along the anatomical course of the biliary system. Functionally, bile duct epithelial cells modify the composition of bile and secrete various substances into the bile. They express γ-glutamyltranspeptidase that removes glutamic acid from glutathione conjugates. Intrahepatic cholangiocytes express the sodium-dependent glucose transporter and aquaporins responsible for glucose and water uptake, as in the renal proximal tubule.

Kupffer cells *are specialized fixed-tissue macrophages located in sinusoidal lumens*, mainly at branch points. They are proficient phagocytes of apoptotic and necrotic cells, particulates, and microorganisms, and the liver is a major "filtering organ" for clearance of bacteria from the blood. There are species differences in the efficiency of this process, which is more effective in carnivores than in ruminants. Kupffer cells can kill bacteria, and can respond to various biologically active bacterial components, including lipopolysaccharides, lipoteichoic acids, and peptidoglycans. Activated Kupffer cells secrete tumor necrosis factor-α and other cytokines, and nitric oxide; these contribute to peripheral vasodilation and hypotension in systemic inflammatory response syndromes initiated by bacterial components. Other secreted cytokines such as interleukin-1 and -6 mediate the acute-phase response and some aspects of the immune and liver regenerative responses. These cytokine responses of Kupffer cells are also believed to be important in regulating the extent of adaptive immune response or tolerance to potentially antigenic macromolecules that can reach the liver through the portal blood.

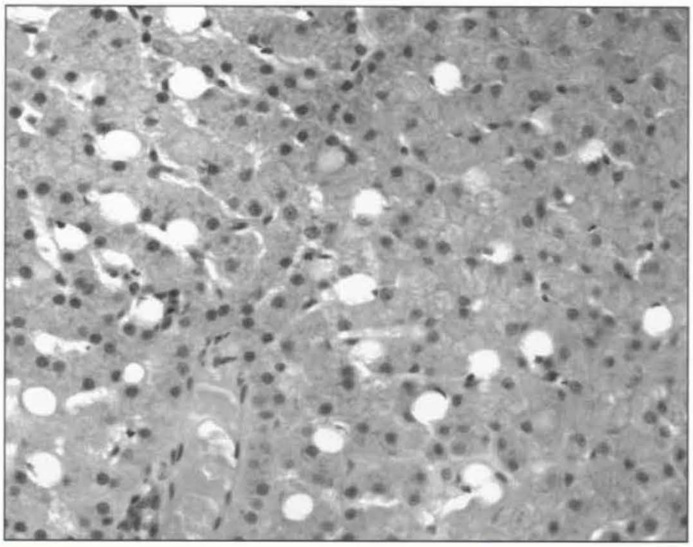

Figure 2.1 Perisinusoidal **hepatic stellate cells** (Ito cells) in a cat.

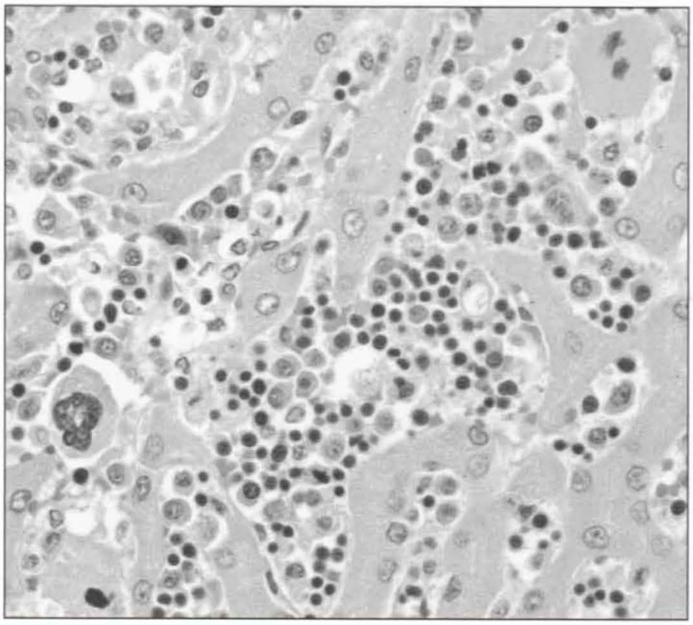

Figure 2.2 Hepatic **extramedullary hematopoiesis** in a dog.

Perisinusoidal **hepatic stellate cells** (also know as *lipocytes, Ito cells, or fat-storing cells*) envelop sinusoidal endothelial cells where they produce and maintain the extracellular matrix that supports the sinusoidal endothelium. They also store lipid droplets that are rich in **vitamin A**, and can become greatly distended with lipid in carnivores on some diets (Fig. 2.1). Stellate cells also function in the control of microvascular tone and regulate sinusoidal blood flow. Cytokines, such as transforming growth factor-β released in response to tissue injury, stimulate stellate cells to redifferentiate to myofibroblast-like cells that express desmin and smooth-muscle actin. Activated stellate cells increase the deposition of extracellular matrix, transforming sinusoidal endothelium to a less permeable capillary form and reducing transfer of macromolecules between the hepatocytes and the blood. In severe chronic injury leading to cirrhosis, the increased expression of contractile cytoskeleton within activated stellate cells can further restrict blood flow.

Hematopoiesis in fetal life of mammals occurs mainly in the perisinusoidal compartment of the liver sinusoids. Postnatally, hepatic hematopoiesis declines but can return as *extramedullary hematopoiesis* in conditions of increased demand (Fig. 2.2). The degree of hepatic extramedullary hematopoiesis in larger species can have diagnostic significance, but in rodents and other small animals, it can be an incidental observation.

DEVELOPMENTAL ANOMALIES

Congenital hepatic cysts

Congenital cysts of the liver occur in all species, and are of diverse origin. Their number, size, and degree of loculation are quite variable. Cyst walls are composed of connective tissue lined by flattened or cuboidal epithelium. The content is clear and serous.

Serous cysts are occasionally found attached to the capsule on the diaphragmatic surface in calves, lambs, and foals. These cysts are usually small and multiple, but some are isolated and very large (Fig. 2.3). Their origin is not known, but it is variously postulated that they are serosal inclusion cysts, part of congenital polycystic biliary anomalies, or of endodermal origin. They do not contain bile. The declining incidence of these anomalies with age suggests that a large proportion of them involute in the early postnatal period. *Serous cysts should be differentiated from acquired cysts, parasitic cysts, and biliary cystadenomas.*

Intrahepatic congenital cysts *are thought to derive from embryonic bile ducts*, which develop from bipotential liver progenitor cells in contact with the mesenchyme of the portal vein, forming the ductal plate. Failure of remodeling of the ductal plate into mature tubular ducts results in so-called *ductal plate malformations*. **Congenital fibrocystic diseases**, characterized by dilation of segments of intrahepatic bile ducts and variable degrees of fibrosis, likely represent ductal plate malformations at various levels of the biliary tree.

Congenital cystic lesions involving the hepatic biliary system and renal tubules have been reported in juvenile dogs, cats, pigs, goats, and Swiss Freiberger foals, and have been compared to congenital

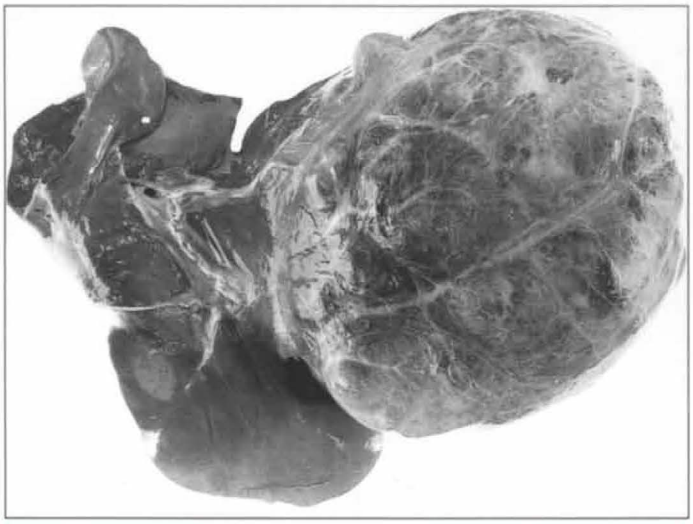

Figure 2.3 Hepatic **serous cyst** in a sheep.

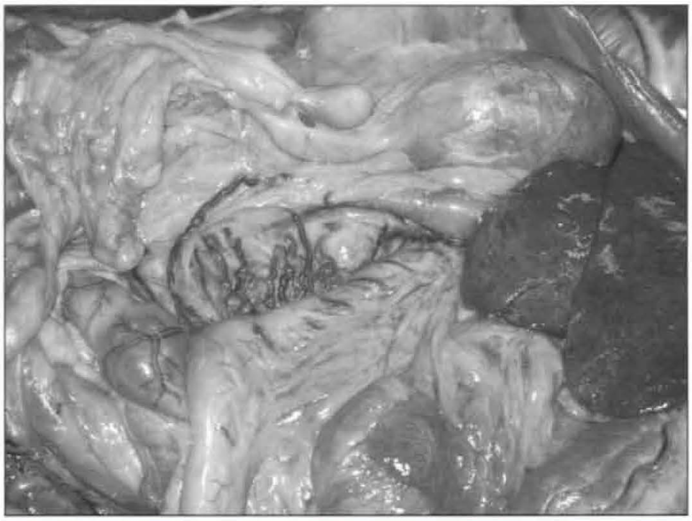

Figure 2.4 Multiple acquired **portosystemic vascular shunts** in a dog with chronic liver disease.

fibropolycystic disorders of humans. Affected livers may be enlarged enough to cause abdominal distension. The parenchyma is expanded by irregularly shaped, branching, cystic biliary structures, with cystic dilation of internal and external biliary tracts. Variable degrees of periportal fibrosis may be present. The common bile duct is patent, and may be dilated and tortuous. Polycystic renal anomalies may also be present, and cysts may also be found in pancreas or other organs. Animals may die from progressive renal insufficiency, and/or from hepatic dysfunction and portal hypertension associated with hepatic fibrosis. Hepatic fibrosis and cysts are present in a significant proportion of cats with *polycystic kidney disease*, inherited in Persian cats as an autosomal dominant trait, and similar to the adult form of polycystic kidney disease in humans. Polycystic kidney and liver disease reported in related West Highland White Terrier litters resembles the autosomal recessive polycystic kidney disease of children. An inherited basis for the disease has been proposed but not proven for dogs (Cairn and West Highland White Terriers) and Swiss Freiberger horses; however the exact mode of inheritance is unknown in the majority of cases in domestic animals. *Congenital hepatic fibrosis*, resembling a similarly named disease in humans related to autosomal recessive polycystic kidney disease, has been reported in a neonatal calf, accompanied by cyst formation in the kidney and lung. Macroscopic congenital dilation of the larger intra- and extrahepatic bile ducts and diffuse cystic kidney disease, resembling Caroli's disease in humans, has been reported in dogs.

Biliary atresia

Anomalies of the extrahepatic biliary system include *absence of the gallbladder*, and *absence or atresia of one or more ducts*. Biliary atresia has been reported in lambs, calves, foals, a cat, a dog, and a pig. In carnivores, bile duct atresia may lead not only to jaundice, but also to vitamin D-deficiency rickets, due to inability to absorb fat-soluble vitamins. Congenital atresia may be associated with defects in the developmental morphogenesis of bile ducts, or in utero vascular, inflammatory, or toxic insults to the biliary tree that culminate in the obliteration of the lumen. Most cases are sporadic, but an outbreak of idiopathic congenital atresia and dysplasia of the biliary tract has been reported in lambs and calves in Australia.

Congenital vascular anomalies

These include abnormal anastomotic connections between the hepatic artery and the portal vein, portosystemic shunts between the portal vein and other systemic veins, and primary hypoplasia of the portal vein. *Large extrahepatic* **congenital** *portosystemic shunts are readily distinguished from shunts that are* **acquired** *during portal hypertension; the latter are typically multiple, thin-walled, and tortuous collateral venous connections between the portal vein or its tributaries and caudal vena cava* (Fig. 2.4). While multiple acquired shunts do not develop in the presence of congenital portosystemic shunts, they can arise with other congenital abnormalities, such as arteriovenous fistulae or hypoplasia or dysplasia of portal veins, as a consequence of portal hypertension. Acquired shunts resulting from portal hypertension secondary to liver injury and repair are discussed in the section on Vascular factors in hepatic injury and circulatory disorders, below.

Congenital intrahepatic arteriovenous fistulae have been reported in dogs and cats. These are *arterioportal fistulae*, representing congenital communications between branches of the hepatic artery and the portal vein. Mixing of higher-pressure arterial blood with venous blood results in retrograde flow into the portal vein, arterialization of the portal circulation, and development of portal hypertension, with the opening of vestigial, low-resistance collateral extrahepatic portosystemic communications (acquired extrahepatic shunts). The fistulae may be macroscopic or microscopic, are typically multiple, and may involve one or more lobes of the liver. The hepatic parenchyma of affected lobes may be atrophied, with dilated, tortuous, pulsatile vessels visible on the capsular surface. Histopathological findings include hyperplasia and anastomoses of arterioles and venules (Fig. 2.5). Affected vessels have irregularly thickened walls with intimal hyperplasia consisting of smooth-muscle proliferation and deposition of elastin fibers, focal subintimal fibromuscular proliferation, and smooth-muscle hyperplasia of the tunica media. Degenerative changes characterized by deposition of mucinous

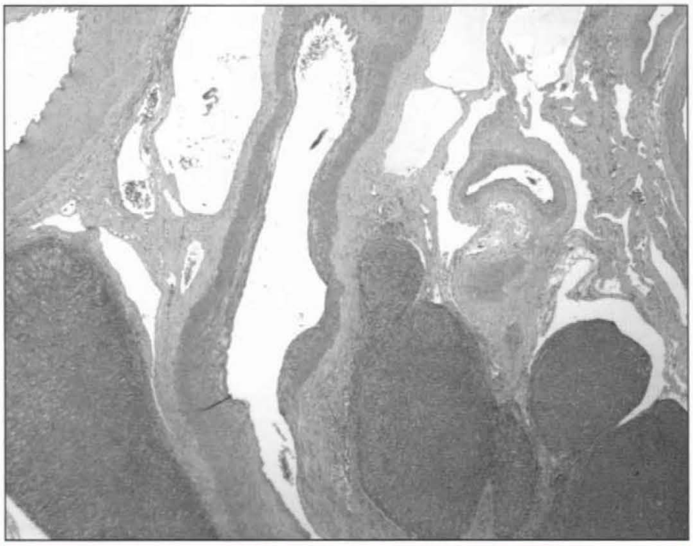

Figure 2.5 Congenital **intrahepatic arterioportal fistulae** with thick-walled anastomosing vessels and atrophy of adjacent parenchyma in a dog.

material and mineral in the intima and media of arterioles, as well as thrombosis and recanalization of portal veins, are also observed. Adjacent hepatic parenchyma may be atrophic, with periportal fibrosis, and bile duct hyperplasia, arteriolar proliferation, and relative collapse of portal vein branches within portal tracts. Arteriovenous fistulae may also be acquired, developing subsequent to abdominal trauma, rupture of hepatic artery aneurysms, and secondary to hepatic vein obstruction or cirrhosis with extreme portal hypertension.

Congenital portosystemic vascular anomalies *are typically single anomalous vessels that directly connect the portal venous system with the systemic venous circulation.* They occur in dogs and cats, and, rarely, in pigs, foals, and calves. These vascular anomalies may be either intrahepatic or extrahepatic in location. The most common **intrahepatic shunt**, located in the left hepatic division, is a *persistent patent fetal ductus venosus.* Central and right divisional intrahepatic shunts have also been described in dogs and cats. The major types of **extrahepatic shunts** include direct shunting from the portal vein or major tributary (typically left gastric or splenic veins, less commonly the gastroduodenal or mesenteric veins) to the caudal vena cava (*portocaval shunt*) or to the azygos vein (*portoazygos shunt*), or connection of the portal vein to the caudal vena cava which itself shunts to the azygos vein. Extrahepatic portosystemic shunts may have hypoplasia of the portal vein distal to the origin of the shunt. Large-breed dogs typically have large intrahepatic shunts, usually a patent ductus venosus, but sometimes other large intrahepatic communications. Small-breed dogs and cats usually have single large extrahepatic shunts between the portal vein and vena cava or azygos vein. An inherited basis is suspected for several breeds, including Irish Wolfhounds, Maltese, Yorkshire Terriers, and Australian cattle dogs.

Affected dogs are usually presented as adolescents with failure to thrive or with the neurobehavioral manifestations of hepatic encephalopathy (see section on Hepatic dysfunction, below). Often there is a clinical history of depression, convulsions, and other nervous signs that are exacerbated by a high-protein diet, and may be alleviated by dietary control. Because there is no cause of portal hypertension, these dogs do not usually develop ascites.

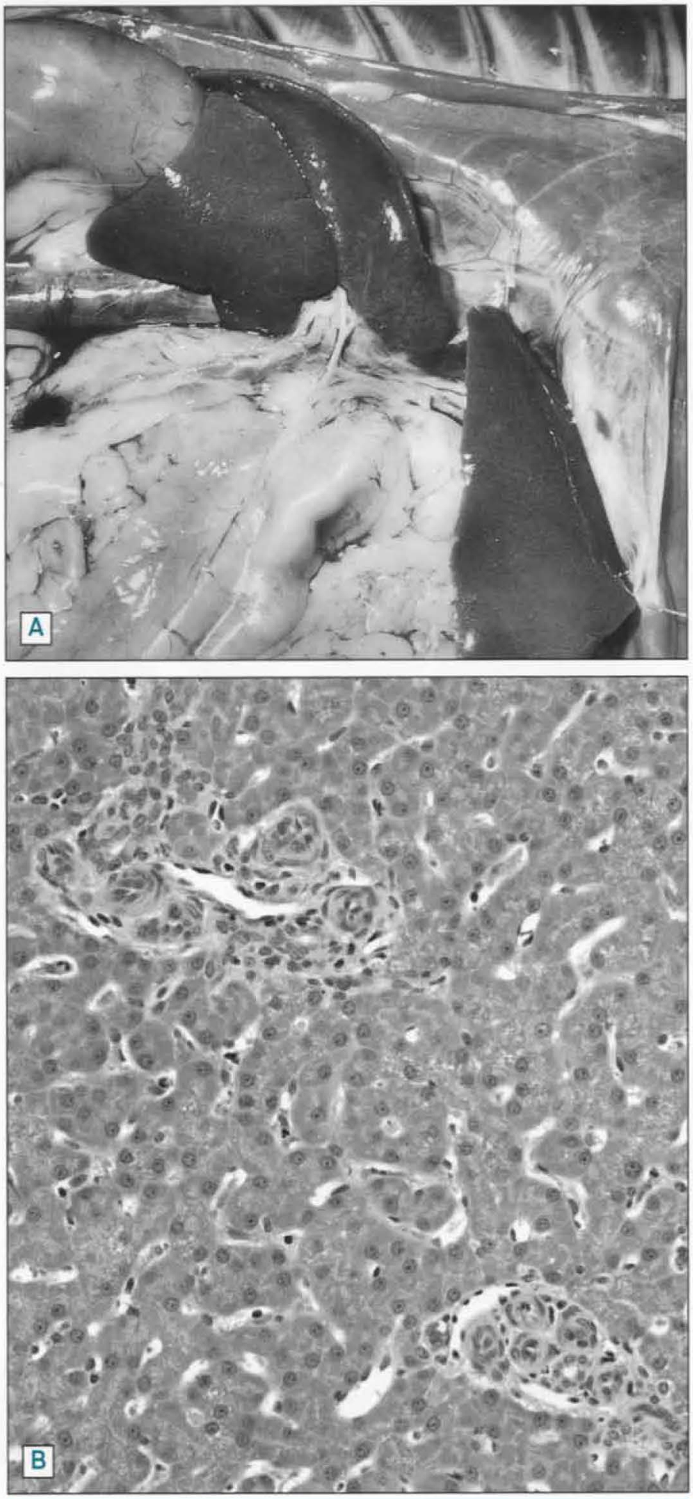

Figure 2.6 Congenital portocaval shunt. A. Small liver in a dog with persistent ductus venosus. **B.** Histology of the liver of a dog with an **extrahepatic congenital portocaval shunt**. Closely spaced portal triads contain multiple sections of hepatic arterioles, and lack discernable portal veins.

The liver that has been bypassed by a congenital shunt is hypoplastic (Fig. 2.6A), largely because of diversion of hepatotrophic factors, such as insulin, glucagons, and epidermal growth factor, that originate in the intestine and pancreas. These livers may be smooth-surfaced with normal color and texture. Histologically, hepatocytes and acini are small with close spacing of portal triads. Larger portal veins may appear collapsed and empty of circulating blood elements; portal veins in smaller triads may be small, collapsed, or indistinguishable. Hepatic arterioles are often more prominent, and may be multiple and tortuous (Fig. 2.6B), related to increased arterial perfusion. Numbers of juvenile-appearing vascular structures within triads may also appear increased. Dilated vascular structures devoid of blood, presumably small- and large-caliber lymphatics, are often prominent in the periphery of some portal triads. Dilated lymphatics may also be present in the connective tissue surrounding hepatic veins. Hepatic veins may have prominent smooth muscle. There may be increased deposition of fibrous connective tissue surrounding portal triads and hepatic veins. Multiple small lipogranulomatous foci with hemosiderin in Kupffer cells are typically present throughout the liver, especially in animals that have survived for some time.

Primary hypoplasia of the portal vein has been reported in dogs, affecting either the extrahepatic or intrahepatic portal vein, or both. Intrahepatic portal vein hypoplasia has been suggested to be the underlying lesion in conditions previously described as *hepatoportal fibrosis* and *idiopathic noncirrhotic portal hypertension* in some young dogs. *Primary portal vein hypoplasia is accompanied by portal hypertension and the development of multiple collateral portosystemic shunts.* Histologically, there is hypoplasia or absence of portal vein radicles, and secondary arteriolar proliferation. Moderate to marked portal fibrosis may also be present. These changes represent sequelae to underperfusion and thus can be indistinguishable from what occurs in conjunction with congenital portosystemic shunts.

A congenital **hepatoportal microvascular dysplasia** without accompanying macroscopic portosystemic shunts has been reported in a kindred of Cairn Terriers, and more recently in Yorkshire Terriers, Maltese, and other small and toy dog breeds. These dogs have elevated serum bile acids suggestive of a portosystemic vascular anomaly, but lack identifiable intrahepatic or extrahepatic shunting vessels. Histologically, cases resemble the changes reported with macroscopic portosystemic vascular anomalies, although the changes may be evident in only some of the liver lobes. Histologic abnormalities include small, poorly formed, or juvenile portal structures; increased numbers of arteriolar sections in portal triads; randomly distributed, small-caliber or juvenile-like vessels throughout the parenchyma; central venous mural hypertrophy with smooth-muscle proliferation, with or without fibrosis; dilation of pericentral vascular spaces, and endothelial cell hyperplasia in portal areas. Lipogranulomas containing hemosiderin are also typically present. In some Cairn Terriers, abnormal apposition of portal tracts with small hepatic venules has been observed, with no intervening hepatocellular parenchyma. These venules also exhibited irregular mural smooth-muscle thickening, and communicated with central veins. However, serial sections failed to reveal direct interconnections between hepatic venules and portal veins. *Unlike macroscopic portosystemic vascular shunts, portal hypertension may develop in severe cases of microvascular dysplasia, with secondary or acquired portosystemic shunting and ascites.* Microscopic capillary abnormalities at the level of the hepatic lobule, with intrahepatic sinusoidal or postsinusoidal shunting, have been postulated. More recently, this disorder has been viewed as part of the disease spectrum of portal vein hypoplasia.

Macroscopic and microscopic portosystemic vascular anomalies may potentially co-occur in dogs, as evidenced by a lack of resolution of histologic changes in additional liver biopsies subsequent to macroscopic shunt ligation. It has been suggested that some animals with portosystemic vascular anomalies have some degree of microvascular anatomic malformation, and it may be that these may represent varying expressions of a more general portal vascular malformation.

DISPLACEMENT, TORSION, AND RUPTURE

The position of the liver should be observed as soon as the abdomen is opened at necropsy. *Most* **displacements** *are caudal, so that the margins of the liver extend behind the costal arch.* Caudal displacements are the result of hepatic enlargement, or caudal displacement of the diaphragm secondary to pleural effusion or other space-occupying lesion in the thorax. Congenital or acquired displacements associated with ventral and diaphragmatic hernias are common. Usually only one lobe goes into the thorax with other viscera; lobar blood supply may not be compromised, but the affected lobe is usually severely congested and may rupture, or, given time, become indurated.

Liver lobe torsion has been reported in swine, dogs, a cat, and a horse. The left lateral lobe appears to be predisposed, due to its mobility, large size, and relative separation from other lobes. *The resultant infarction can cause death due to shock or hemorrhage.* The lobe may contain clostridial spores that are likely to germinate in the necrotic tissue, which will undergo putrefaction and be dry and crepitant compared to the other lobes.

Rupture *of the liver occurs commonly as the result of trauma, because the organ is fragile relative to its mass.* It is quite common for fatal liver rupture to be produced by the sudden accelerations and pressures of vehicle collisions, without much evidence of trauma to other parts of the body. Large tears may be obvious in the liver capsule and hepatic parenchyma after trauma. However, in some cases, anastomosing linear patterns of fine shallow capsular fissures, concealed in part by clotted blood, can be found. Moderate blood loss from capsular ruptures is followed by rapid coagulation, then fibrinolysis of most of the free clot. The liquid blood is then rapidly returned to the circulation by transdiaphragmatic lymphatic absorption, and, a day or so after the trauma, all that is seen is a delicate tracery of capsular tears that have been sealed by residual thrombus, with a little associated pale necrotic parenchyma. Liver rupture is often clinically occult, since quite large ruptures may not disturb liver function unless severe enough to cause rapid exsanguination, or unless the biliary tract is involved. Rupture of major bile ducts leads to yellow-stained *bile peritonitis*, which may remain sterile and become chronic, or may be fatal, particularly if infected by enterohepatic circulation of bacteria such as clostridia.

The liver is more likely to rupture after trauma in young animals. Fatal ruptures occur in foals during parturition, sometimes concurrently with costal fractures, and in the smaller species subject to energetic emergency resuscitation. Diffuse hepatic conditions with enlarged friable parenchyma (e.g., acute hepatitis, amyloidosis, severe congestion, severe lipidosis, and infiltrating neoplasms) are more likely to rupture, sometimes spontaneously, and the clinical consequences relate to the extent of hemorrhage. Parasites that penetrate the capsule cause numerous small ruptures but seldom lead to significant hemorrhage.

HEPATOCELLULAR ADAPTATIONS AND INTRACELLULAR ACCUMULATION

The liver must be highly adaptable to balance function with changing demand. Increases in the size of hepatocytes (*hypertrophy*) and their numbers (*hyperplasia*) collectively bring a larger population of hepatocytes into service. Such adaptations in hepatic mass and function result from alterations in the expression of many genes. These responses are more evident in smaller species, notably in laboratory rodents that have a very pronounced liver growth response after exposure to various xenobiotics. The liver can also adapt to reduced demand by a combination of *cellular atrophy* and *apoptosis*. Removal of surplus hepatocytes involves local phagocytosis of membrane blebs and apoptotic fragments, with degradation in phagolysosomes of neighboring hepatocytes and Kupffer cells. Hepatocytes can be lost by apoptosis in substantial numbers with minimal elevation in serum enzymes such as alanine aminotransferase.

Hepatocellular atrophy

Hepatic mass readily adapts to metabolic demands, and *the liver can undergo marked atrophy due to catabolism during illness and/or starvation without much evidence of impaired hepatic function.* During prolonged starvation, some hepatocytes are removed by apoptosis without replacement, but most of the atrophy is explained by loss of cytoplasmic mass. Atrophic livers, as seen, for example, in old grazing herbivores with poor teeth, are dark and small, and the capsule may appear too large for the organ, showing fine wrinkles on handling. These livers may even appear to be firmer than normal due to condensation of normal stroma. Histologically, portal triads and hepatic venules are closer together, and lobules contain increased numbers of smaller hepatocytes with scanty cytoplasm (Fig. 2.7).

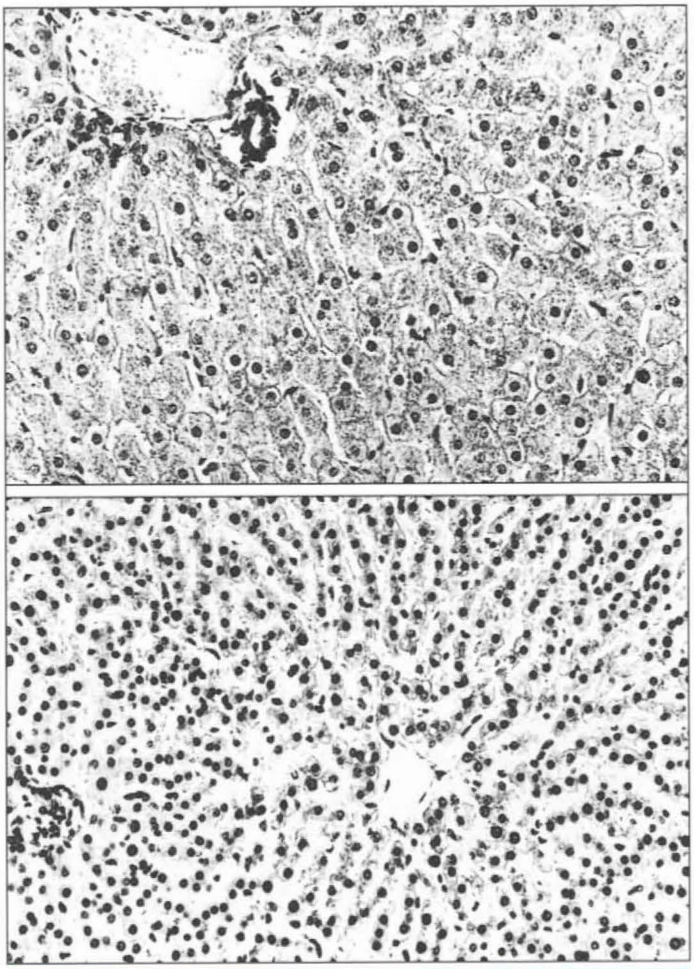

Figure 2.7 Normal (top) and **atrophic liver** (bottom) from a starved sheep, at same magnification.

Hepatic atrophy can also result from impaired replication of hepatocytes. Most adult hepatocytes are replicatively competent, although mitotic figures are infrequent because healthy hepatocytes have a relatively long lifespan of several months. Trophic factors supplied via the portal circulation regulate replication and mass of the liver. Atrophy of part of the liver may be a response to pressure or to impairment of blood or bile flow. The histologic features of this atrophy are similar to those of starvation atrophy. However, the functional consequences of focal hepatic atrophy are minor because the remaining liver can adapt by *compensatory hypertrophy*, a process that involves replication and enlargement of hepatocytes. Local pressure atrophy occurs adjacent to space-occupying lesions in the liver or as a result of chronic pressures from neighboring organs, such as distended rumen in the ox. *Right hepatic lobe atrophy*, reported in horses, has been suggested to result from long-term compression from abnormal distension of the right dorsal colon and base of the cecum. Chronic diffuse diseases of the biliary tract, such as sporidesmin poisoning and fascioliasis, are likely to cause atrophy of the left lobe in ruminants, probably as a result of the greater difficulty in maintaining adequate biliary drainage from this lobe, whose bile ducts are longer than those of the right in these species. The atrophy of biliary obstruction is complicated by some degree of superimposed inflammation and fibrosis.

Hepatocellular mass can be rapidly lost by autophagocytosis and apoptosis (see section on Patterns of cell death in the liver, below). **Autophagocytosis** is the aggregation of cytoplasmic organelles that are subsequently transferred to autolysosomes, whereas **apoptosis** results in fragmentation and phagocytosis by neighboring cells. Autolysosomes lack fragments of DNA seen in lysosomes that contain nuclear portions of apoptotic cells; however, many apoptotic bodies composed of cytoplasm alone are indistinguishable. In hepatocytes, large, histologically obvious inclusions associated with atrophy have been referred to as *cytosegresomes, Councilman bodies, or acidophilic bodies*. These are spherical, refractile, eosinophilic structures seen in liver cells that have been sublethally injured by various insults, including hypoxia, intoxications, malnutrition, nutrient deficiencies, and some viral infections. Note that hepatocytes during autolysis can imbibe plasma that forms similar round but less eosinophilic, non-membrane-bound cytoplasmic inclusions. The long-term sequel to increased cell turnover in this manner is atrophy accompanied by *hepatocellular residual bodies* containing oxidized lipid debris known as *lipofuscin*. Residual bodies are slowly lost by degradation or by extrusion (exocytosis) into the canaliculi or the extracellular space, where they are taken up by Kupffer cells, and accumulate in hemosiderin- and lipid-enriched tertiary lysosomes. The amounts of residual debris in hepatocytes and hemosiderin in Kupffer cells are indicators of cumulative cell turnover due to aging, liver injury, or both.

Hepatocellular hypertrophy

As the liver adapts to increased functional demand, it enlarges, partly by hypertrophy of individual hepatocytes, and partly by their replication. These complex responses are still poorly understood, although many trophic factors that act on hepatocyte surface and nuclear receptors are involved. *Exposure to various xenobiotics can induce the expression of many genes, resulting in increased volume of hepatocyte cytoplasm*, especially components of the smooth endoplasmic reticulum (SER). Agents that elicit this response act via nuclear receptors such as the arylhydrocarbon-activated receptor, the constitutive androstane receptor, or the pregnane X receptor. Phenobarbital, for example, is a potent inducer of the various enzyme systems of the SER, including several cytochromes P450. The amount of induced synthesis of SER is greatest in periacinar hepatocytes, where it is observed as loose aggregates of pale eosinophilic material, often intermixed with glycogen, that may distend the cell or displace the nucleus and other organelles to the periphery (Fig. 2.8). The response can be seen within a few days after exposure to various drugs and other xenobiotic compounds. Accordingly, the liver becomes grossly enlarged and darker brown. This induction is reversible, and after discontinuation of exposure to the inducing agent, the additional SER is removed by autophagocytosis and many hepatocytes undergo apoptosis. While these changes are considered physiological adaptations, there are potential adverse sequelae; accordingly, this response has considerable toxicological significance, and will be dealt with further in the section on Toxic hepatic disease (see below).

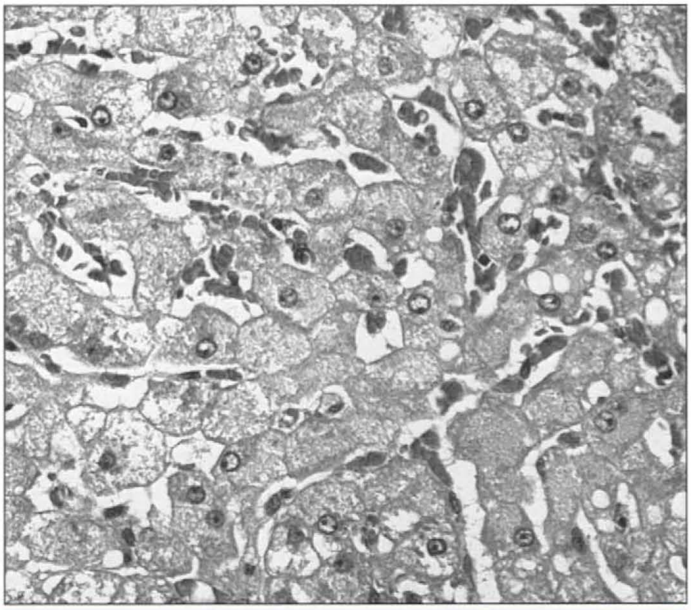

Figure 2.8 Smooth endoplasmic reticulum induction secondary to chronic phenobarbital administration in a dog.

Polyploidy and multinucleation

Most mature mammalian hepatocytes are tetraploid or octaploid, whereas many immature and replicating hepatocytes are diploid. The relative proportion of these varies among species, with a shift towards increasing polyploidy with increasing age. Polyploidy is more common in rodents and is believed to result from asynchrony of cell division in which binucleated diploid cells undergo a second round of DNA replication, giving rise to two tetraploid daughter cells. Impaired replication can also increase numbers of polyploid cells. The term **megalocytosis** was first used in the description of the changes of liver cell cytoplasm and nucleus that occur in pyrrolizidine alkaloid poisoning (Fig. 2.9). This form of megalocytosis has some specific features and is described in the section on Chronic hepatotoxicity, below. Impaired regeneration, atrophy and >4N polyploidy can also

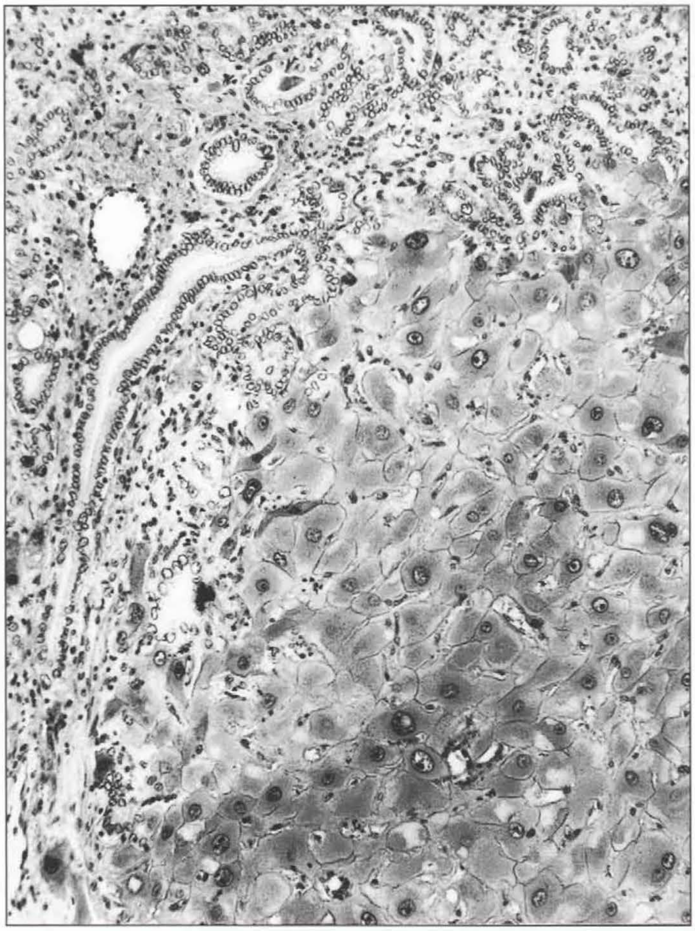

Figure 2.9 Megalocytosis and bile duct proliferation in *Crotalaria* poisoning in a horse.

be produced by other DNA-damaging agents such as aflatoxins. A feature of these patterns of atrophy with polyploidy is the persistence of larger replicatively impaired polyploid hepatocytes amid regenerating smaller diploid hepatocytes, hepatocellular nodules, and hyperplastic bile ductules.

Most hepatocytes are mononuclear but a variable proportion are binucleated, especially in young or regenerating livers of small animals. Multinucleation of nonneoplastic hepatocytes is a rare phenomenon in domestic mammals, and its diagnostic or pathogenetic significance is usually unclear. Multinucleation can result from incomplete cell division or cell fusion, but this distinction is difficult to determine. Hepatocytes can fuse during severe steatosis, but the degree of multinucleation in fatty livers is hard to discern because the plasma membrane perimeters of fatty hepatocytes are ill defined. Syncytial multinucleation of hepatocytes has been observed in various degenerative and regenerative conditions. In protoporphyria of Limousin cattle, small clusters of hepatocytes contain 4–10 or more closely packed nuclei but it is not clear whether this represents fusion or multiple nuclear divisions. Syncytial hepatocytes are a characteristic of postinfantile giant cell hepatitis of children, and similar hepatocyte multinucleation can be observed in association with some forms of hepatitis in cats, foals, and piglets. Multinucleated hepatocytes have been described in young cats with neoplasms (thymic lymphomas), and in cats with experimental dioxin poisoning.

Intranuclear inclusions

In addition to the various nuclear inclusions associated with some viral infections, *three types of inclusions may be found in hepatocyte nuclei*:

1. Spherical, apparently hollow globules within the body of the nucleus are *membrane-bound entrapped nuclear membrane invaginations* that ultrastructurally contain cytoplasmic components such as glycogen and mitochondria. These inclusions are infrequent in otherwise normal livers but are more often seen in chronically injured livers, especially in chronic pyrrolizidine alkaloid poisoning, in which polyploid nuclei are more likely to indent and invaginate.
2. Eosinophilic block-like intranuclear inclusions with a regular crystal lattice ("*brick inclusions*") are common in hepatocytes and renal proximal tubular epithelium. They are more numerous in old animals, particularly dogs. Their composition and pathogenesis are still unknown, but they evidently have little effect on the health of the cells in which they occur, even when they are large enough to distort the nucleus. They do not contain heavy metals and can be distinguished from the acid-fast, noncrystalline intranuclear inclusions observed in renal epithelial cells and occasionally in hepatocytes in lead poisoning.
3. *Lead inclusions* consist of a lead–protein complex and have a characteristic furry electron-dense ultrastructure.

Pigmentation

Congenital melanosis occurs in calves and occasionally in lambs and swine. The melanin deposits may be numerous, and vary in size from flecks to irregular, blue-black areas 2 cm or more in diameter. The melanin is confined to the capsule and the stroma. These deposits are sharply defined in young animals, but become more diffuse and fade with age.

A condition known as **acquired melanosis** is the massive accumulation of black pigment (not melanin) in hepatocytes and Kupffer cells of mature sheep and, less frequently, cattle after prolonged grazing on extensive unimproved pastures in inland eastern Australia, the Falkland Islands, and Scandinavia. The condition in Norway has also been described as *hepatic lipofuscinosis*. The color of the affected livers ranges from a dull gray to uniform black, and there is usually a prominent acinar pattern. In severe cases, there is also pigmentation of the hepatic lymph nodes, lungs, and renal cortex. Histologically, the pigment is present as granules in lysosomes in periportal and midzonal hepatocytes and macrophages of the liver (Fig. 2.10), the proximal tubular epithelium of the kidneys, and in alveolar and interstitial macrophages in the lung. There is no evidence of liver dysfunction, even in the blackest livers. The source of this pigment is not known, but the epidemiologic features of its occurrence indicate that it is derived from a component of the diet that is sequestered within lysosomes.

Lipofuscin *is the term given to small, golden, granular cytoplasmic deposits derived from the lipid component of membranous organelles*, more obvious in cells near the periphery of the acinus. Lipofuscin accumulates in hepatocellular lysosomes and indicates senility, atrophy, or increased turnover of membrane lipids. The pigment is particularly common in the liver of old cats. **Ceroid** is a yellow pigment similar to lipofuscin and is associated with *peroxidation of fat deposits*.

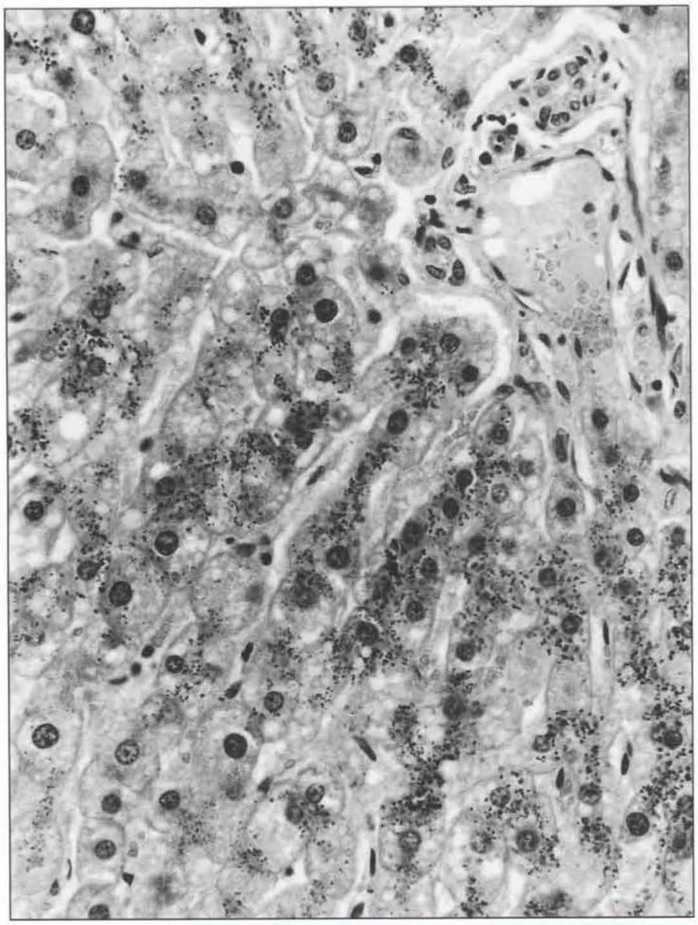

Figure 2.10 Lysosomal pigment in periportal hepatocytes in acquired melanosis in a sheep.

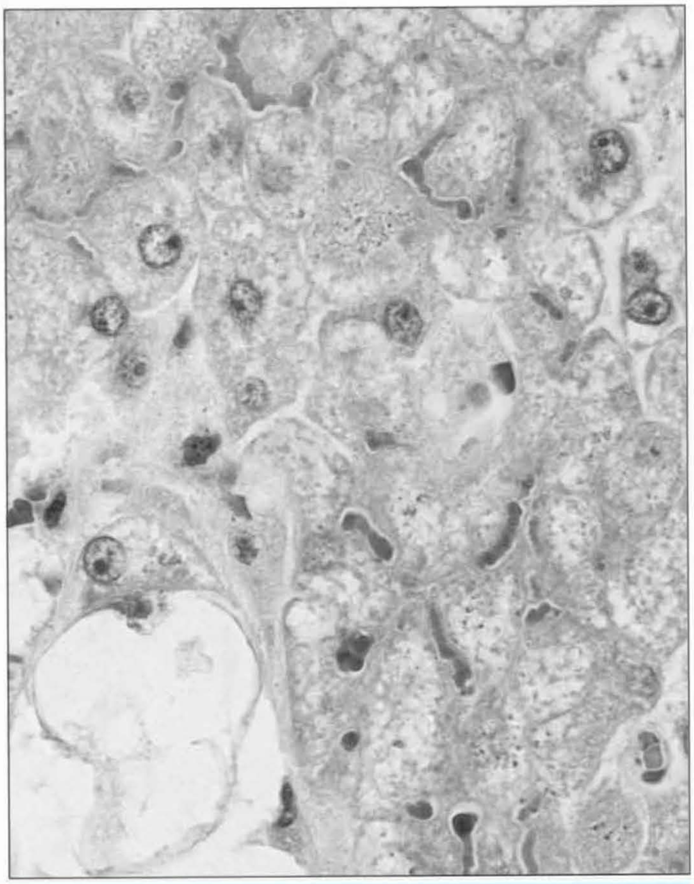

Figure 2.11 Bile plugs distending bile canaliculi (with concurrent hepatocyte hydropic degeneration secondary to corticosteroid therapy) in immune hemolytic anemia in a dog.

Black pigment also accumulates in hepatocellular lysosomes of mutant Corriedale sheep with hyperbilirubinemia. These sheep have a condition resembling the human Dubin–Johnson syndrome, in which there is mutation in the canalicular multispecific organic anion transporter. This suggests that retention of the pigment might be a sequel to a hepatic excretory defect.

In **congenital erythrocytic protoporphyria** (ferrochelatase deficiency) of Limousin and Blonde d'Aquitaine cattle, a dark golden-brown lipofuscin-like lysosomal material is present in portal areas, in Kupffer cells, sinusoidal endothelial cells, and heavily concentrated in the cytoplasm of hepatocytes.

Hemosiderin deposits are seldom sufficient to give gross discoloration, but if so, the color is dark brown. The pigment is detected microscopically as yellow or brown crystals chiefly in the Kupffer cells, although small amounts may be found in hepatic cells. The ferric iron component of this pigment can be demonstrated by *staining with Prussian blue*, otherwise it can easily be confused with lipofuscin. Diffuse hemosiderosis occurs quite commonly in all species, and its presence is usually *suggestive of excess hemolytic activity* relative to the rate of reutilization of iron. Thus it is seen in hemolytic anemias, anemia of copper deficiency, in cachexia, and after blood transfusions. It may be seen in the periacinar zones in severe chronic passive congestion of the liver. Localized hemosiderosis occurs in areas of hemorrhage. *Most hemosiderin deposits are punctate Prussian blue staining aggregates in Kupffer cells* but can also be seen as finer particles in hepatocytes. Hemosiderin is normally present in the liver in the early neonatal period, when fetal hemoglobin is being replaced by mature hemoglobin.

Hemosiderin should be distinguished from **hematin**, which is produced by the action of formic acid on hemoglobin following a prolonged postmortem interval, and is usually regarded as a *histological artifact*. Hematin is also an iron-containing pigment, but the iron is in the reduced ferrous state and does not stain with ferricyanide. It takes the form of crystalline brown deposits that are birefringent under polarized light, mainly within hemoglobin-rich areas such as blood vessels. Hematin is darker than hemosiderin and occurs in irregular clumps, often extracellularly. Hematin may, however, be found in Kupffer cells and macrophages in small amounts.

Bile pigmentation may impart an olive-green color to the liver in diffuse or segmental obstructive biliary disease or intrahepatic cholestasis. Histologically, conjugated bile pigments may distend bile canaliculi, visible microscopically as green-yellow stellate lakes between the hepatocytes (Fig. 2.11). In this case, the identity of the pigment is obvious, but when it is present in granular form in hepatocyte or Kupffer cell cytoplasm, it may easily be confused with hemosiderin and hematin. Death of individual hepatocytes releases the canalicular plugs into the space of Disse and the sinusoids.

Hemochromatosis is common in humans and some birds but rare in domestic mammals. A form resembling heritable hemochromatosis has been reported in Salers cattle. Affected animals have a

30–100-fold increase in liver iron content, with hepatomegaly, hemosiderin accumulation in hepatocytes, and periportal bridging fibrosis with nodular regeneration. Hemosiderin also accumulates in Kupffer cells, lymph nodes, pancreas, spleen, and other organs.

Hemochromatosis resembling the secondary form of the disease in humans has been observed in sheep and cattle exposed to *high levels of iron in pasture and water.* The liver is enlarged and brown with diffuse fine nodularity, and the hepatic and adjacent lymph nodes are also darkened. Large amounts of iron are present in the hepatic parenchyma, the biliary epithelium, and the cortex of lymph nodes, and lesser amounts are present in the broad fibrous septa. The iron is stored predominantly in lysosomes. Brown discoloration of bone marrow resembles the osseous pigmentation of porphyria. The pathogenesis of nutritional siderosis is unknown. Hemochromatosis has also been described in horses, with animals displaying signs of liver failure and neurologic impairment. The microscopic lesions in the livers of these animals are similar to those for other species.

Brown crystalline deposits of **2,8-dihydroxyadenine** have been described in hepatocytes and in other tissues in slaughtered cattle with no evidence of other disease. These accumulations are strongly birefringent under polarized light, and are seen in the cytoplasm of hepatocytes and macrophages of hepatic lymph nodes and as extracellular deposits in portal stroma and renal tubular lumens. Grossly, the portal stroma stood out as a green network, and affected lymph nodes were enlarged and the medullary sinusoids were distended with green pasty material. The crystals were identified as 2,8-dihydroxyadenine by a panel of crystallographic methods and mass spectrometry, and it was suggested that a deficiency of adenine phosphoribosyltransferase might be responsible; however, this has not yet been confirmed.

Pigments of parasitic origin are particularly associated with flukes. Heavy deposits of *black iron–porphyrin compound* are formed around the cysts and migratory pathways of *Fascioloides magna.* Lesser amounts of similar pigment are deposited about bile ducts infested by *Fasciola hepatica* (see section on Helminthic infections, below). The presence of this pigment in the hilar nodes should suggest otherwise inapparent infestations by flukes. In schistosomiasis, the liver may be gray owing to the accumulation of black pigment in Kupffer cells.

Vacuolation

The term "**vacuolar hepatopathy**" *has been used to denote multifocal or diffuse zonal hepatocellular cytoplasmic vacuolation* before a more specific term can be applied, for example, before contents of vacuoles are identified. Specific forms of hepatocyte vacuolar change include hydropic swelling, glycogenosis, and lipidosis or steatosis. **Hydropic degeneration** is an early cytoplasmic ballooning seen after various toxic and metabolic insults, hypoxia, and cholestasis. Water and sodium ion influx expands membranous compartments of mitochondria, lysosomes, and endoplasmic reticulum. The term **feathery degeneration** is applied to the type of hydropic change that occurs in hepatocytes in which there has been prolonged cholestasis. The cells are swollen and vacuolated and crisscrossed by a fine protoplasmic network that is brown with bile pigments.

Hepatic glycogenosis or **glucocorticoid hepatopathy**, often referred to as **steroid-induced hepatopathy**, is probably the most severe example of hepatocellular vacuolar change in dogs. *It involves glycogen accumulation induced by hyperadrenocorticism, due to either functional adrenocortical or pituitary tumors, or to treatment with glucocorticoids* (Fig. 2.12). The liver is enlarged and pale tan. Hepatocytes are swollen, and the cytoplasm appears as a fine, feathery reticulum that encloses multiple spaces with poorly demarcated edges. Vacuolar change may range from mild to severe, with swelling of hepatocytes from 2 to 10 times normal size, and displacement of the nucleus and organelles to the cellular periphery. Early changes are midzonal in distribution, but the zonal distribution may be very variable and may become diffuse in long-standing cases or with higher doses. Single-cell drop-out, multifocal small aggregates of neutrophils, and scattered small foci of necrosis are also commonly observed, but few hepatocytes are lost in this manner. The ill-defined vacuolar boundaries in steroid hepatopathy are readily distinguishable from spherical lipid vacuoles in hepatic steatosis. *The pathogenesis of this condition is uncertain*, since glycogen storage alone does not fully explain the influx of fluid, and possible perturbations in hepatocellular ion channels or aquaporins have not been assessed. The amount of glycogen remaining in affected cells is widely variable, a function of the original glycogen concentration, recent catabolism, and postmortem dissolution. Glycogen content can best be demonstrated after rapid fixation in alcohol, followed by staining with periodic acid–Schiff, and can be confirmed as glycogen by its sensitivity to digestion with diastase. Livers affected by glucocorticoid hepatopathy maintain normal hepatocyte functions, but the condition can be confirmed by the induction and *serum increase of glucocorticoid-inducible alkaline phosphatase* with minor or negligible increases in alanine aminotransferase.

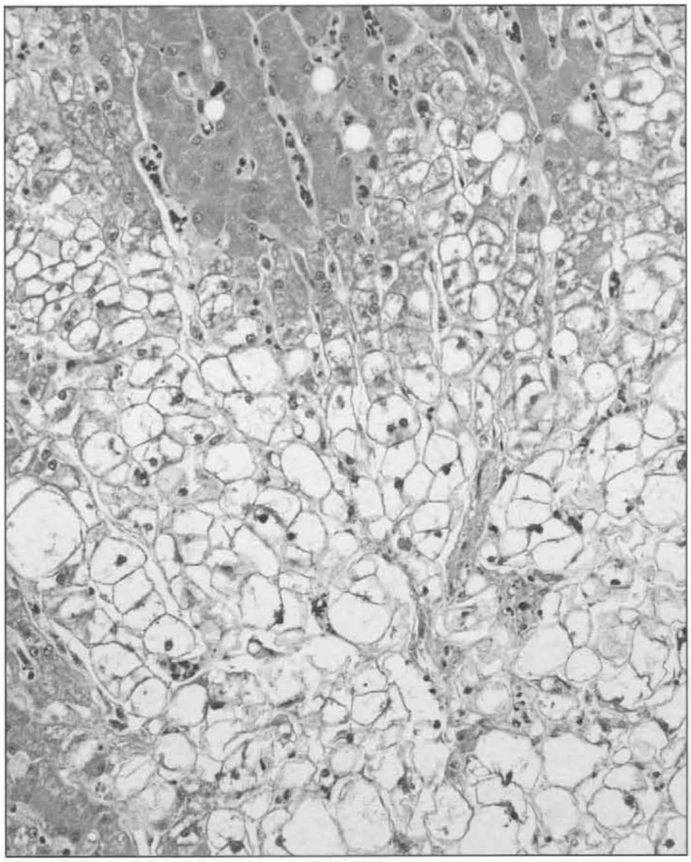

Figure 2.12 Severe **hydropic degeneration** associated with glucocorticoid administration in a dog.

Loss-of-function mutations in hepatic and renal glucose-6-phosphatase resulting in increased hepatic glycogen storage have been reported in littermate Maltese puppies. These dogs have severely debilitating problems in maintaining their blood glucose because dephosphorylation of glucose-6-phosphate is a key step in both glycogenolysis and gluconeogenesis. The condition is typified by severe hepatocellular glycogenosis resembling glucose-6-phosphatase deficiency in humans (von Gierke's disease or **glycogen storage disease type Ia**). Livers are markedly enlarged, pale, and have diffuse vacuolation of hepatocytes with large amounts of glycogen and small amounts of lipid. Renal tubular epithelium is also vacuolated. **Type II** and **type III glycogenosis** have also been reported in dogs, the latter with hepatic glycogen storage.

Characteristic hepatocellular vacuolation is also described in dogs with nodular livers presented clinically with superficial necrolytic dermatitis collectively known as *hepatocutaneous syndrome* (see below).

Hepatic lipidosis

Hepatic lipidosis *is the term most often used to describe fatty livers of animals*, whereas in humans, the term *steatosis* is more commonly used. Both refer to the *visible accumulation of triglycerides (triacylglycerols) as round globules in the cytoplasm of hepatocytes.* The threshold for application of these terms is vague because triglyceride storage and transport are normal hepatic functions, but they are appropriate when the amounts are greater than would normally be seen. Hepatic lipidosis can be physiological or pathological. Increased mobilization of triglycerides during *late pregnancy or heavy lactation in ruminants* is associated with hepatic lipidosis. The lipid represents increased transit of triglycerides in an otherwise healthy liver, so there is little diagnostic significance in mild degrees of hepatic lipidosis in lactating cows. In some of these animals, severe energy deficiency can also lead to clinical ketosis with metabolic acidosis. In addition, severe lipidosis occurs in high-producing diary cows fed diets where either the mix of available fatty acids is incorrect or lipids are oxidized and rancid.

Hepatic lipidosis is common in injured hepatocytes because the normal high throughput of fatty acids and triglycerides can be readily impeded at various points in the complex pathway of hepatic lipid metabolism and secretion of very-low-density lipoproteins (VLDL). Hepatocytes obtain some fatty acids from albumin and other carrier proteins in the portal blood, but most is hydrolyzed by sinusoidal endothelial hepatic lipase from triglyceride in chylomicrons or VLDL in plasma. Very-long-chain fatty acids are initially oxidized by acyl-coenzyme A oxidase in peroxisomes to shorter acyl-coenzyme As that can be transported via a carnitine-dependent process into mitochondria for further oxidation. While some fatty acid is utilized for energy in hepatic mitochondria, most from dietary or adipose sources is converted to triglycerides that are further processed into lipoproteins in the hepatocyte endoplastic reticulum and actively secreted into the plasma as VLDL. Endothelial lipoprotein lipase in muscle and adipose tissue hydrolyzes triglycerides in the VLDL, and the fatty acids released are utilized locally by beta-oxidation in mitochondria of muscle or re-esterified into triglyceride in adipocytes. The depleted VLDL, referred to as low-density lipoproteins, are returned by receptor-mediated endocytosis into hepatocytes where their constituents are catabolized and recycled.

The synthesis and export of VLDL in hepatocytes are energy- and resource-dependent, so any disturbance of the supply of apoproteins, phospholipids, cholesterol, or adenosine triphosphate, or physical disruption of the organelles involved in synthesis, assembly, and secretion has the potential to inhibit lipoprotein synthesis or secretion. Incoming fatty acids can continue, allowing triglyceride globules to accumulate in the hepatocyte cytoplasm. In some species, damage to peroxisomes reduces the initial peroxisomal oxidation step for catabolism of long-chain fatty acids and also upregulates various genes regulated by peroxisome-proliferator activated receptor-α. Lipoproteins in the endoplasmic reticulum, Golgi, and membrane-bound secretory vesicles can also accumulate if there is selective damage to the distal secretory apparatus. Damage by various toxic and hypoxic insults will not lead to triglyceride accumulation in hepatocytes if supplies of mobile triglycerides from adipose tissue or the diet are low.

The microscopic appearance of triglyceride globules in hepatocytes ranges from small discrete microvesicles to large coalescing macrovesicles (Fig. 2.13). Small droplets of fat, usually in a periportal and juxtasinusoidal position, can normally be found in the liver. The amount of triglyceride present in the earlier stages of degeneration while globules are small is usually much more than can be appreciated microscopically. Increased mobilization and acute injury tend to produce microvesicular lipidosis in which numerous small and discrete micellar lipid globules are distributed around the central nucleus. VLDL within secretory vesicles and endoplasmic reticulum can be retained but cannot coalesce. This pattern can also occur in some toxic hepatopathies. Acute lipidosis with predominantly microvesicular accumulation tends to result in a modestly enlarged pale liver without much change in texture.

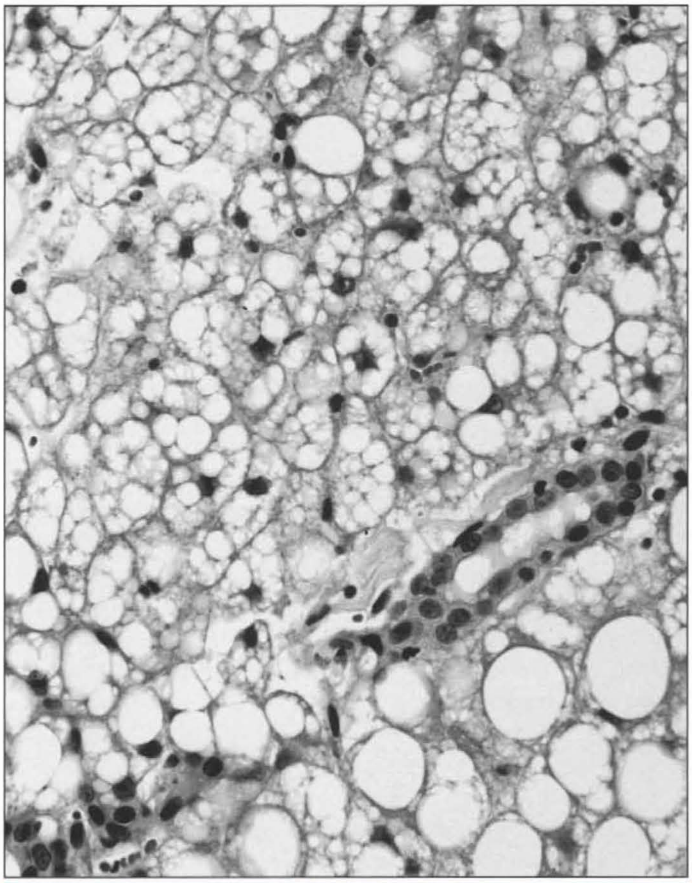

Figure 2.13 Microvesicular and macrovesicular **hepatic lipidosis** in a cat.

In some more protracted toxic injuries, lipid globules tend to coalesce into large central macrovesicles that displace the nucleus. The pathogenesis of the larger globules is not well understood, but it involves some alteration of the globule–cytoplasm interface that normally prevents coalescence of the small micellar globules. These fatty livers tend to be more yellow, enlarged, and the texture is more friable. Each hepatocyte usually contains one large globule (macrovesicle) that alters the contour of the cell and displaces the nucleus. The sinusoids are compressed and appear underperfused, and the tissue at low magnification resembles adipose tissue. In severe degeneration, the liver is moderately or greatly enlarged, with a uniform light yellow color. The edges are rounded, and the surface is smooth. The cut surface has a diffuse greasy appearance, or a red and yellow lobular pattern if there is also hepatic congestion or zonal necrosis (Fig. 2.14). *In severe diffuse hepatic lipidosis, the parenchyma is less dense and portions will float in water or fixative.*

Assessment of the functional significance of lipidosis depends on the differentiation of physiological lipidosis due to increased mobilization by otherwise normal hepatocytes from pathological changes that represent some degenerative change in hepatocytes. However, *fat accumulation is a sensitive response to hepatocellular injury and can occur in the absence of other obvious alterations in hepatic structure or function.* The triglyceride globules themselves are not harmful to hepatocytes, so the amount of fat present is more an indicator of the duration of insult and triglyceride supply than of the severity of hepatic injury. Lipidosis is usually reversible, although a liver that has been fatty for some time is more likely to have concurrent damage, including fibrosis, pigment accumulation, and nodular hyperplasia, mostly attributable to ongoing peroxidative damage, cell turnover, and activation of stellate cells. Fatty livers are more vulnerable to a wide range of toxic and nutritional insults, so other necrogenic insults and responses can be concurrent. Increased levels of fatty acids in the liver increase the oxidative stress and contribute to membrane lipid peroxidation, reduced hepatocyte lifespan, and some local repair responses. Some chronic changes commonly seen in the *livers of old dogs* can be associated with fatty liver; these include lipogranulomas, fatty cysts, ceroid accumulation, and, rarely, mineralizing focal fibrous reactions to accumulations of cholesterol.

When lipid accumulates in large amounts, there is a tendency for *groups of the fat-laden cells to rupture or fuse and eventually form a multinucleate rim about a foamy mass of lipid.* This epithelial structure is known as a **fatty cyst**, as is the next stage, which occurs when released lipid is picked up by macrophages that form foamy aggregations in sinusoids, in the stroma of portal triads, and in hepatic venules (Fig. 2.15). Subsequent peroxidation of the less saturated fatty acids and covalent modification and polymerization of oxidized lipids form a complex of lysosomal residues known collectively as **ceroid**. This material is only slightly soluble in lipid solvents and is periodic acid–Schiff-positive, variably acid-fast, and autofluorescent. In histologic sections, ceroid pigment appears as colorless or yellow

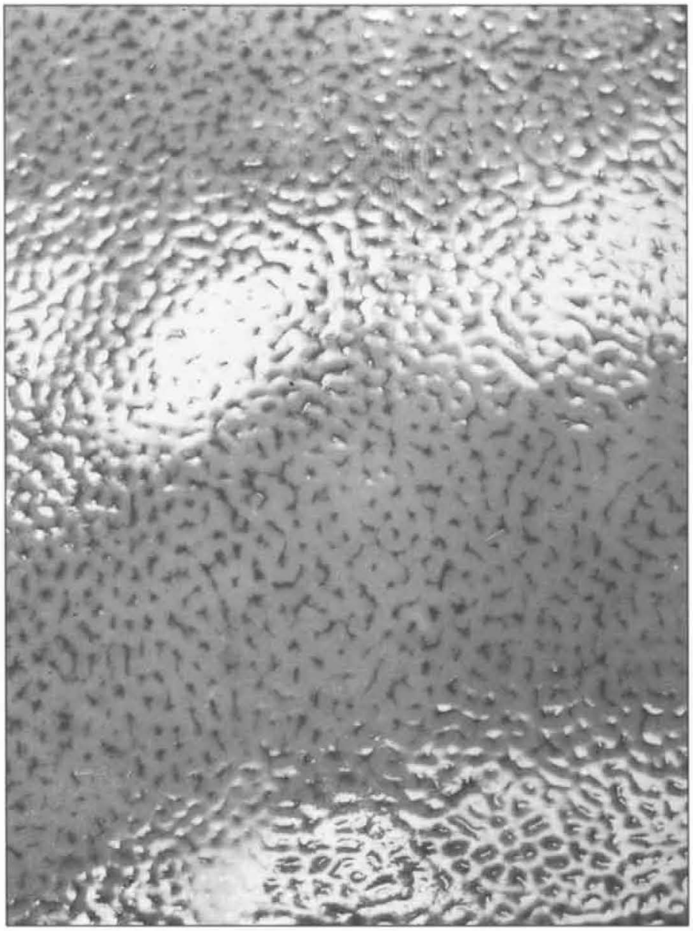

Figure 2.14 Severe fatty liver with periacinar necrosis resulting from acute anemia in a fat goat.

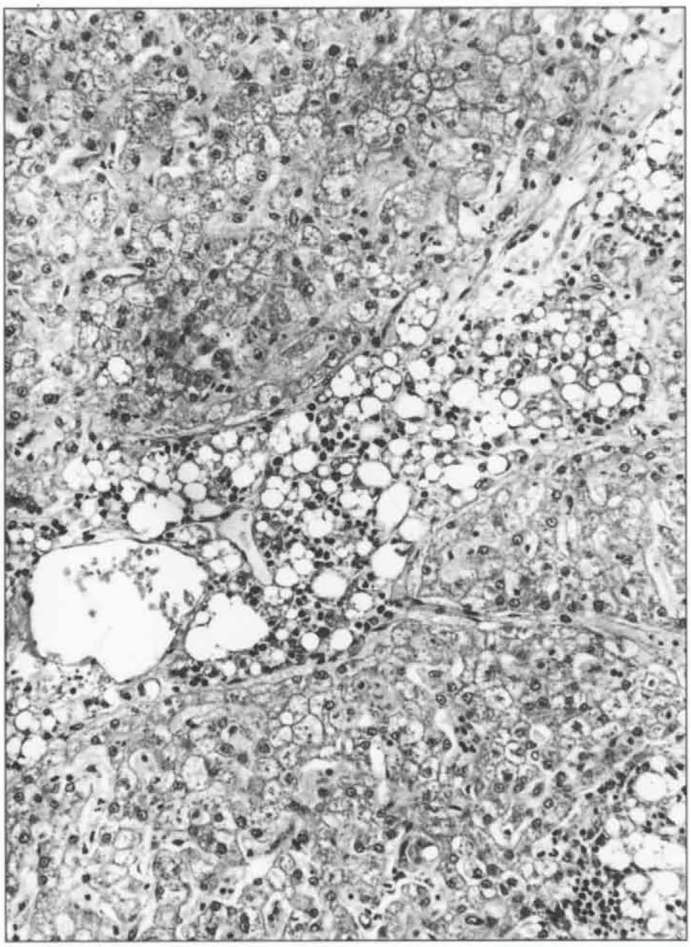

Figure 2.15 Accumulations of lipid-filled macrophages, some of which are coalescing into **"fatty cysts"** in hepatic stroma in a dog.

irregular fragments associated with the lipid globules in macrophages and, to a lesser extent, hepatocytes and portal lymph nodes that become slightly enlarged, yellow-green, and rather oily on section. If the hepatocellular lipidosis subsequently resolves, the fatty cysts with ceroid residue remain. These may be larger than, but otherwise not readily distinguished from, the more common hepatic **lipogranulomas**. These are discrete perisinusoidal clusters of macrophages and stellate cells, containing cytoplasmic lipid vacuoles, lipofuscin, and hemosiderin, that accumulate and congregate with age and hepatocellular turnover.

Occasionally in the liver of old dogs there can be found sharply defined, fibrous, stony, hard masses, usually close to the surface, sometimes as much as 3–4 cm in diameter. These masses are usually sufficiently mineralized to show up distinctly on clinical radiographs. The mineral appears to be deposited on a matrix of degenerate collagen, laid down about perivascular foci of foamy macrophages and accumulations of cholesterol. The fibrous tissue may be laid down in response to the continued presence of fat, ceroid, or cholesterol, but no reason is apparent for the strictly localized distribution of the reaction. There are no recognizable hepatocytes in these lesions.

Physiologic fatty liver *occurs in late pregnancy and heavy lactation, particularly in ruminants.* Obvious lipidosis is also seen in neonates, especially in those species whose milk is relatively rich in fat. These livers are fatty enough to be pale to the naked eye. The high rate of mobilization of triglycerides is mainly responsible for fatty liver in lactating ruminants. However, the condition is a concern because mobilization also increases when the dietary energy intake is insufficient relative to the production demands that are greatest in early lactation of high-producing cows. Insufficient dietary intake by an animal with adequate fat reserves depletes hepatocellular glycogen and initiates a heavy demand for triglycerides from adipose tissue. The liver depends primarily on fatty acid oxidation for its own considerable energy needs. It must also synthesize a large amount of protein and phospholipids for lipoprotein export to other tissues, and this can be rate-limiting, resulting in accumulation of triglyceride in the cytoplasm. In starvation, the reduced availability of protein and lipotrope cofactors such as choline can exacerbate the bottleneck. The liver is the main supplier of glucose for the brain and milk saccharides, and it adapts by converting fatty acid metabolites to glucose (gluconeogenesis) and ketones.

Acute **ketosis** of lactating dairy cows with intake insufficiency or secondary to abomasal displacement is usually associated with fatty liver with a predominantly diffuse microvesicular pattern. *Cows are more tolerant of ketosis associated with lactation than are pregnant ewes that can die from starvation-induced* **pregnancy toxemia** *and ketoacidosis.* In cows, hepatic lipidosis is predominantly periacinar, whereas it is most severe in the periportal zone in pregnancy toxemia of sheep. The hepatic changes reflect increased mobilization of triglycerides from adipose tissue rather than hepatic disease per se. In cows and ewes with increased mobilization of triglycerides, there may be indistinct foci of white discoloration of abdominal fat that tend to be obscured when adipose tissue solidifies postmortem.

Fatty liver of **diabetes** *occurs when insulin is deficient or inactive due to lack of functioning receptors.* Reduced insulin-dependent glucose uptake by cells leads to accelerated lipolysis from adipose tissue in much the same way as when energy intake is limiting. The liver is thus presented with a large load of fatty acids, and the rate by which this moves through the liver can be impeded in various ways. Insulin deficiency alone will produce fatty liver. Some cases in carnivores are also complicated by concurrent exocrine pancreatic insufficiency, so protein malabsorption can be a contributing influence on diabetic hepatic lipidosis. The periacinar hepatocytes usually show the greatest degree of lipidosis, but in advanced long-standing diabetes, the change is often diffuse and marked.

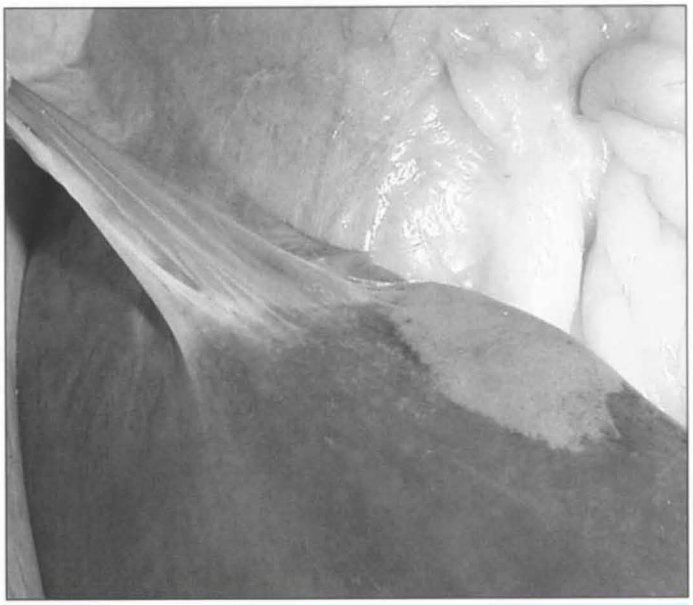

Figure 2.16 Subcapsular focal fatty change (**"tension lipidosis"**) associated with capsular ligamentous attachment in an ox. (Courtesy of AP Loretti.)

Lipoprotein synthesis and transport are dependent on oxidative metabolism, so **hypoxia** of hepatocytes leads to triglyceride accumulation. The two most common causes of hepatocellular hypoxia are *anemia* and reduced sinusoidal perfusion in *passive venous congestion.* In these situations, hepatic lipidosis is most severe in the periacinar zone provided that the adipose and dietary supply of triglyceride is sufficient. Hepatic lipidosis can be grossly visible as a yellow zonal pattern in chronic passive congestion of the bovine liver, but is less obvious in carnivores with passive hepatic congestion.

Local hypoxia is probably the basis for another example of fatty liver. Small, sharply demarcated patches of intense fatty infiltration are often seen in bovine livers at or adjacent to sites of capsular fibrous adhesions – so-called "**tension lipidosis**" (Fig. 2.16). These patches are neither swollen nor shrunken, usually extend less than 1 cm into the parenchyma, and are of the same consistency as normal liver. The acinar structure of these lesions is undisturbed, but the hepatocytes therein show pronounced lipidosis, presumably related to interference with local perfusion caused by tensions transmitted to the parenchyma by the adhesion.

Fatty liver due to **intoxication** is common. There are several stages of the cycle of hepatic lipid metabolism that can be affected selectively by various toxins to produce fatty liver. For example, it is possible experimentally to cause triglyceride accumulation by interfering with mitochondrial fatty acid oxidation with sublethal doses of cyanide, or by inhibiting apolipoprotein synthesis by administration of orotic acid. Most toxins that cause fatty liver in naturally occurring situations, however, also produce a greater or lesser degree of hepatocellular necrosis. Fatty liver occurring as a manifestation of toxic hepatic disease will be further discussed in the section on

Toxic hepatic disease, below, but the generalization may be made here that most important veterinary hepatic intoxications cause widespread membrane damage and/or disturbance of protein synthesis. These cause lipid accumulation in the hepatocyte by interfering with lipoprotein synthesis and export, as well as with fatty acid oxidation. *Lipidosis requires time and a negative energy balance to develop, so it is more likely to occur in toxicoses with a longer clinical course.* However, if adipose reserves are depleted, there is less lipid available to accumulate in the liver.

While fatty liver in domestic animals is more frequently associated with generalized interferences with energy metabolism, there are some specific **nutritional deficiencies** that will produce fatty liver. These have usually been defined under experimental conditions. *Choline deficiency*, in conjunction with deficiency of other lipotropic factors such as *L-methionine* and *vitamin* B_{12}, rapidly produces fatty liver, largely as a result of reduced synthesis of phosphatidylcholine, a component of secreted lipoproteins. Fatty liver in experimental choline deficiency involves lipid peroxidation and increased hepatocellular turnover, leading to cirrhosis and neoplasia. It is unlikely that primary choline deficiency occurs in domestic animals, but other lipotrope deficiencies have been reported.

Ovine white-liver disease, first described in lambs in New Zealand and now known to occur in southern Australia, the UK, and continental Europe, and in goats, is a syndrome of ill-thrift, anorexia, mild normocytic normochromic anemia, occasionally with photosensitization and icterus. The condition is associated with low liver cobalt levels and low plasma concentrations of vitamin B_{12}, and the disease has been shown to be *cobalt- and vitamin* B_{12}*-responsive.* Lambs up to 1 year of age are more commonly affected than ewes, and pastures are likely to be adequate at the times of peak incidence in late spring and early summer.

In the early stages, the liver changes consist of vacuolar accumulation of triglyceride in hepatocytes, usually most severe in the periacinar zones. In addition, ceroid pigment is present in all cases, early in hepatocytes and later also in sinusoidal cells and macrophages. The fatty change may be very severe in the early stage, the liver being grossly swollen. A moderate degree of bile ductular proliferation is also a consistent feature (Fig. 2.17), and the epithelium of the smaller ductules in the triads is dysplastic. Spongy degeneration of cerebral white matter, typical of the hyperammonemia of hepatic failure, is present in some cases.

Experimental feeding of a diet low in cobalt to sheep resulted in reduced growth rate, anorexia, lacrimation, alopecia, and emaciation, and marked reduction in plasma and liver vitamin B_{12} concentrations. At necropsy, livers were pale, swollen, and fatty, with severe fatty degeneration characterized by accumulation of lipid droplets and lipofuscin in hepatocytes, dissociation and hepatocyte necrosis evident on histology, characteristic of spontaneous cases of ovine white-liver disease. The disease can be produced in cobalt-deficient sheep fed diets high in propionate precursors, which may help explain the explosive nature of outbreaks on lush pasture.

Hepatic lesions similar to lipotrope-deficient forms of experimental nutritional cirrhosis have been reported in sheep, goats, cattle, deer, and pronghorn antelope from Texas, New Mexico, and northeastern Mexico. *Hard yellow-liver disease, or* **hepatic fatty cirrhosis**, *is a progressive, chronic disease characterized by weight loss and hepatic encephalopathy.* The disease typically appears in years following above-average winter rains, followed by drought conditions in the summer months. Grossly visible liver lesions in sheep begin in the subcapsular hepatic parenchyma along the porta hepatis as pale yellow, firm areas, spreading peripherally to involve approximately 80% of the liver in the final stages of the disease. Microscopic changes include accumulation of fine cytoplasmic lipid droplets in periacinar hepatocytes, later involving the entire lobule, with rupture and formation of fatty cysts. Periacinar fibrosis accompanies the ruptured fatty cysts, progressing to widespread bridging periacinar fibrosis, with islands of regenerating hepatocytes. Kupffer cells and macrophages in regional lymph nodes, spleen, and lung contain abundant ceroid. The etiology of this condition is unknown, although unidentified hepatotoxins, possibly altering lipoprotein synthesis and secretion, combined with nutritional stress, have been postulated.

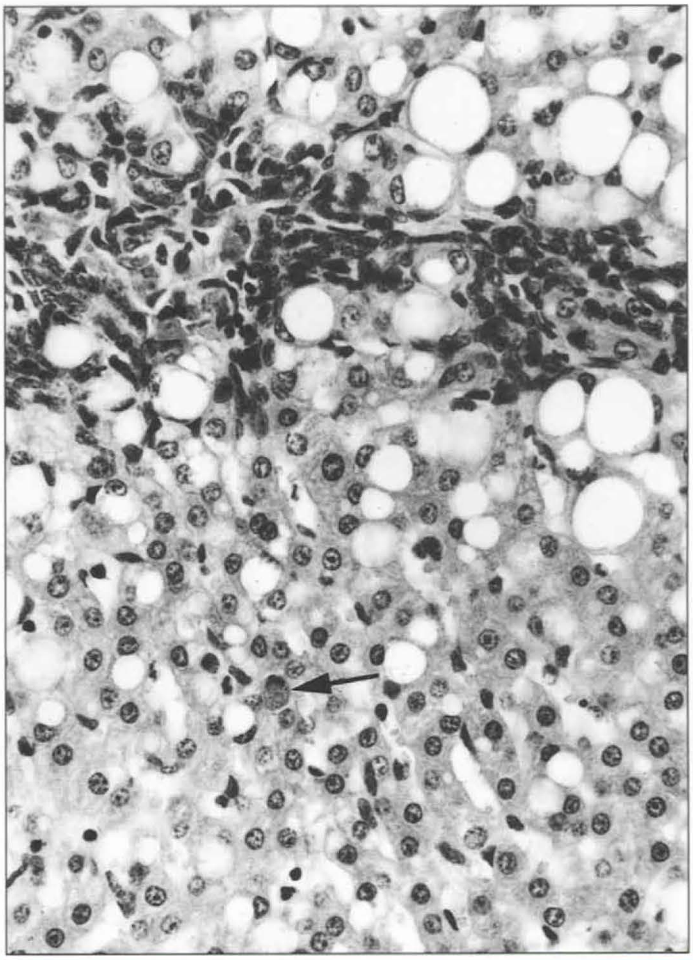

Figure 2.17 Fatty change and cholangiolar proliferation in **ovine white liver disease**. Note ceroid in sinusoidal macrophage (arrow). (Courtesy of S.McOrist.)

Equine hyperlipemia *is almost exclusively a disease of ponies*, and among these the Shetland breed predominates. The disease has also been reported in American miniature horses and donkeys. The disease is usually fatal after about a week. Pregnant or lactating mares are most likely to develop the disease, particularly if they are excessively fat and have recently suffered reduced feed intake due to onset of parturition, conditions such as laminitis or parasitism, or other causes of stress. The clinical course is marked by somnolence, complete anorexia, and colic, progressing to mania in some cases, although most simply become progressively more depressed. Some ponies develop ventral subcutaneous edema and most develop moderate diarrhea. All show marked increase in plasma triglyceride concentration, predominantly VLDL, but all other lipid fractions are elevated, and the lipemia is sufficient to impart a striking milkiness to the serum and blood. Metabolic acidosis is a consistent feature in animals that die.

The liver at necropsy is severely fatty and may have ruptured; the lipidosis also extends to heart and skeletal muscle, kidney, and adrenal cortex. *The hepatic lipidosis is remarkable only by its severity*; there may be some focal hepatocellular necrosis, and there is consistent prolongation of bromosulfophthalein retention times and elevation of serum alkaline phosphatase levels. Evidence of disseminated intravascular coagulation is seen as serosal hemorrhages and microscopic thrombi in various organs, and even gross infarction of myocardium and kidney. *Small lipid emboli* may be detected in frozen sections of lung, myocardium, and brain in these animals; their relationship to the microthrombosis is uncertain.

The pathogenesis of this disease is obscure. Since the excess lipid in liver and blood is in the form of triglyceride, the implication is that the liver is capable of esterifying fatty acid mobilized from depot fat. The triglyceride thus formed is presumably then exported to the plasma as VLDL until the plasma transport mechanisms are saturated, at which stage lipids begin to accumulate in the hepatocytes. Another possibility is that there is an inability on the part of all tissues other than the liver to utilize fatty acids from VLDL at the normal rate, while triglyceride synthesis from fatty acids continues in the liver.

It has been proposed that an underlying cause of pony hyperlipemia is a *comparative resistance to insulin* in susceptible animals, and that this is compounded in stressful episodes by *increased levels of circulating cortisol.* Various steroid hormones, including glucocorticoids, have been shown to interfere with insulin action, and hyperlipemic ponies often have elevated plasma insulin levels, which suggests reduced function of insulin receptors. However, plasma ketones are much less consistently elevated; this suggests that there is not much evidence of the increased ketogenesis that one might expect in insulin resistance.

Hepatic lipidosis is common in companion animals. Dogs eating diets deficient in vitamin E may develop severe hepatic lipidosis, but there are many circumstances in companion animals where the exact cause for individual cases of lipidosis cannot be determined.

The syndrome of **feline hepatic lipidosis** *most commonly occurs in obese, nutritionally stressed female cats, presented with vomiting, anorexia, weakness and weight loss, jaundice, and hepatomegaly* (Fig. 2.18). Neurobehavioral signs indicative of hepatic encephalopathy, other than drooling and depression, are rarely reported. Affected cats generally have hyperbilirubinemia, and a significant increase in serum alkaline phosphatase activity, in the face of normal or modest increases in γ-glutamyltranspeptidase activity. Untreated, the mortality rate is high. The liver has diffuse, macrovesicular or microvesicular lipidosis, by definition affecting greater than 50% of hepatocytes. Focal or zonal lipid accumulation in less than 50% of the parenchyma is considered more likely to be physiologic, or associated with other systemic abnormalities, rather than idiopathic feline hepatic lipidosis. Bile pigment accumulates in canaliculi or Kupffer cells and can be confused with lipofuscin and ceroid.

The pathogenesis of hepatocellular triglyceride accumulation in this disease is obscure, and likely multifactorial, involving increased mobilization and uptake of nonesterified fatty acids by the liver, alterations in formation and release of VLDL, and impaired oxidation of fatty acids within hepatocytes. Ultrastructural studies have demonstrated decreased numbers and abnormal morphology of hepatic peroxisomes as well as mitochondria, both of which are important in the oxidization of fatty acids, but whether these changes are significant or simply adaptive responses is unknown. Starvation may reduce the availability of proteins, choline, and other precursors necessary for lipoprotein synthesis.

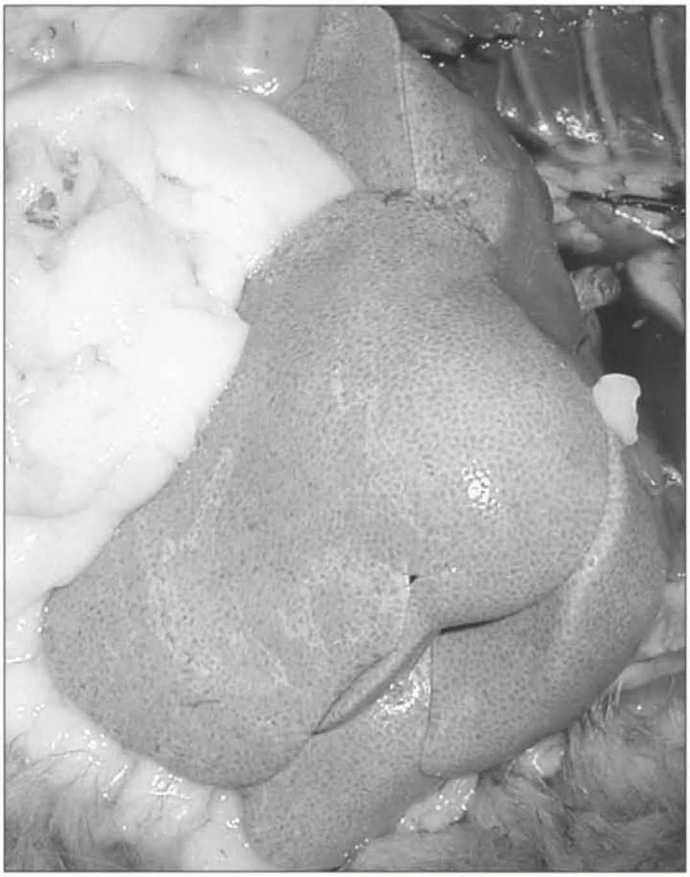

Figure 2.18 Hepatomegaly due to **hepatic lipidosis** in a cat. (Courtesy of AP Loretti.)

Severe hepatic lipidosis can also develop in cats *concurrent with or secondary to other major medical problems* such as diabetes mellitus, which alter metabolism of fat. Acute pancreatitis appears to be an important predisposing disease to secondary hepatic lipidosis in cats – an association with clinical significance as it has a poorer prognosis than uncomplicated idiopathic hepatic lipidosis. Secondary hepatic lipidosis has also been reported with concurrent inflammatory liver disease such as cholangiohepatitis, renal disease, small intestinal disease, neoplasia, and hyperthyroidism.

Familial hyperlipoproteinemia has been described in cats, associated with *congenital lipoprotein lipase deficiency.* The condition is characterized by lipid and ceroid accumulation in liver, spleen, lymph nodes, kidney and adrenal glands, multifocal xanthomas, and focal arterial degenerative changes. An autosomal recessive mode of inheritance is suspected. **Idiopathic hyperlipoproteinemia** has also been reported in Miniature Schnauzer dogs, although the metabolic defect has not been identified. Affected dogs have fasting lipemia,

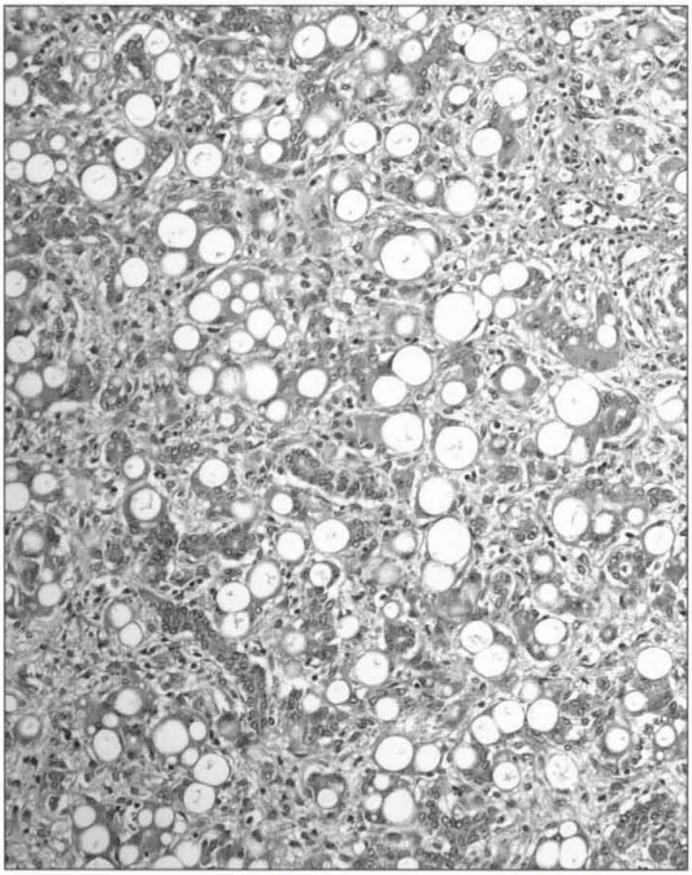

Figure 2.19 Hepatic lipidosis, portal fibrosis, and bile duct hyperplasia due to **hepatic lipodystrophy** in a Galloway calf. (Courtesy of MJ Hazlett.)

hyperchylomicronemia, and elevated plasma VLDL. Affected animals may develop severe vacuolar hepatopathy associated with both glycogen and triglyceride accumulation, with eventual stromal collapse and regenerative nodule formation.

An incompletely characterized condition known as **hepatic lipodystrophy** has been recognized in pedigree Galloway calves since 1965. Calves initially appear normal but develop lethargy, tremors, and opisthotonos, and die by 5 months of age. On postmortem examination, affected calves have an enlarged, pale, mottled liver. Histologically, there is marked hepatic lipidosis with portal fibrosis and bile duct hyperplasia (Fig. 2.19). Vacuolar changes in the white matter of the brain are consistent with hepatic encephalopathy. A metabolic defect has been proposed.

Lysosomal storage diseases

In common with other tissues in animals with heritable deficiency of specific lysosomal enzymes, liver cells may accumulate substrates normally catabolized by the missing enzyme. These lysosomal stores can be less obvious in the liver than in other tissues such as the central nervous system, and although they are unlikely to affect hepatic function, they can sometimes be recognized in liver biopsies. However, *hydropic and fatty changes in hepatocytes can obscure or lead to misidentification of lysosomal storage vacuoles.* Kupffer cells and bile duct epithelium may be more severely affected than hepatocytes, which have additional catabolic and excretory pathways, including the ability for lysosomal exocytosis into the bile canaliculi. In animals with ceroid lipofuscinosis, lysosomal storage is minimal in hepatocytes compared to that in the brain. Examples of storage disorders associated with hepatomegaly and abnormal hepatic or Kupffer cell lysosomal inclusions include *GM_1 gangliosidosis* (beta-1-galactosidase deficiency) in cats, *mucopolysaccharidosis type I* (alpha-L-iduronidase deficiency) in dogs (Fig. 2.20), and *α-mannosidosis* in cats. These and others are discussed in more detail in Vol. 1, Nervous system.

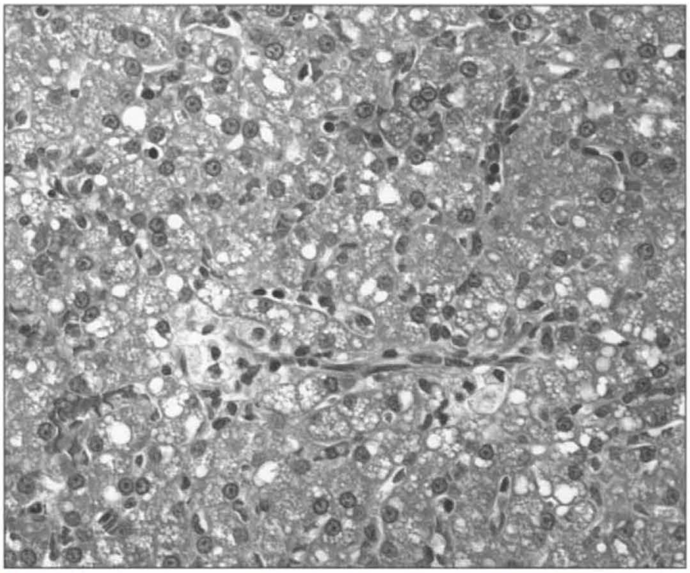

Figure 2.20 Vacuolated hepatocytes and Kupffer cells due to lysosomal accumulation of glycosaminoglycans in **mucopolysaccharidosis type I** (alpha-L-iduronidase deficiency) in a dog.

Toxic inhibition of lysosomal hydrolases can cause acquired lysosomal storage disease. For example, *swainsonine* in various plants inhibits α-mannosidase. Some *amphophilic drugs* can partition into the lysosome and inhibit normal catabolism of membrane phospholipids. This can appear as a systemic phospholipidosis in which Kupffer cells and hepatocytes can be affected. While this is a well-recognized side-effect of some drugs in experimental exposures, it is unlikely to occur with regular therapeutic regimens.

Amyloidosis

In most species, *hepatic amyloidosis is usually part of generalized amyloidosis.* **Systemic amyloidosis** of domestic animals is typically associated with overproduction of amyloid A (AA), an amino-terminal fragment of serum amyloid A, a highly inducible acute-phase protein in most species. In humans, AA amyloidosis occurs either as a familial trait (familial Mediterranean fever), or secondary to a sustained acute-phase reaction in chronic inflammatory or neoplastic diseases. Amyloid infiltration of the liver occurs sporadically in cattle, horses, dogs, and cats as a secondary response to chronic disease or tissue-destructive process. In horses, hepatic amyloidosis occurs chiefly as a result of chronic inflammation and has been well recognized in horses used for the production of hyperimmune serum. Horses may develop icterus and other signs of hepatic failure, but cattle die first of the primary disease or from uremia resulting from concurrent renal amyloidosis. Dogs and cats typically develop signs of renal dysfunction, although cats may be presented with spontaneous hepatic rupture. **Familial AA amyloidosis** is recognized in Chinese Shar-Pei dogs. The condition resembles familial Mediterranean fever in humans, and is characterized by febrile episodes, swollen hock syndrome, and the development of renal and sometimes hepatic amyloidosis. Familial AA amyloidosis is also recognized in Abyssinian cats, and suspected in Siamese and Oriental cats.

Affected livers in horses are pale, enlarged with rounded edges, friable, and prone to fracture (Fig. 2.21); in cattle, affected livers may be firm. Amyloid is deposited first in the parenchyma about the portal tracts and appears gray and waxy. Amyloid is deposited in the perisinusoidal space between the sinusoidal lining and hepatocytes (Fig. 2.22) and is sometimes found in the walls of the afferent vessels. The surrounded hepatocellular cords atrophy. On hematoxylin and eosin staining, amyloid appears as *homogeneous eosinophilic amorphous extracellular material*. Staining with Congo red results in apple-green birefringence when viewed with polarized light. Thioflavine T stain produces yellow-green fluorescent staining of amyloid viewed under ultraviolet light. Affected livers are predisposed to rupture and bleed.

PATTERNS OF CELL DEATH IN THE LIVER

All cells in the liver can die after lethal injury, but most studies of cell death in vitro and in experimental and spontaneous liver disease deal with hepatocellular death. Typical **necrosis** and **apoptosis** of hepatocytes (as described below) can be differentiated by morphologic and other features in routine sections of a diseased liver. **Necrosis** *is generally regarded as a somewhat passive but more severe injury to cell membrane integrity or other vital functions*, leading to enzyme leakage, inflammation, and tissue repair. By comparison, **apoptosis** *is a form of programmed cell death* that permits removal of cell debris without such leakage or inflammation. However, it is becoming evident that there is *considerable overlap between the two main forms of cell death*, and some patterns of cell death, including "**single-cell necrosis**" cannot be neatly assigned to either. There is increasing evidence of nonapoptotic patterns of programmed cell death, for example during epithelial exfoliation and in death of large nonreplicating cells, e.g., neurons, that involve some of the effectors and events responsible for apoptosis, but the affected cells do not fragment into smaller apoptotic bodies that can be efficiently cleared by phagocytosis.

Types of cell death

In routine diagnostic settings, the terms necrosis, apoptosis, and single-cell necrosis can be based on descriptive criteria recognized in routine hematoxylin and eosin-stained sections of liver (Fig. 2.23). There have been attempts to refine the terminology and criteria for cell death in the liver, but this is still hindered by our lack of understanding of different cell death pathways and responses of hepatocytes in various diseases. Some recommend the use of the term necrosis for all death responses in hepatocytes, with further qualification by descriptors such as apoptotic, oncotic (cell swelling), and single-cell necrosis. This approach can be useful in experimental studies in which the appropriate cytologic cell death markers can be applied to justify the descriptor.

One might expect that the different types of cell death might be informative in relation to causes and pathogenesis. However, *many insults can initiate either necrosis or apoptosis of hepatocytes*; these include hypoxia, reactive oxygen metabolites, hepatotoxic chemicals, viral infections, bacterial toxins, and inflammation. Some of the molecular events are common to both. Mitochondrial damage and several other activation responses are common to apoptosis and necrosis, and programmed cell death responses can be activated before they are overwhelmed by more intense injury responsible for necrosis. Susceptibility therefore depends on many factors, including the level and duration of insults, replication status, and integrity of the various homeostatic and cytoprotective functions. For a detailed review of these complex death pathways as they apply to the liver, readers are referred to the bibliography.

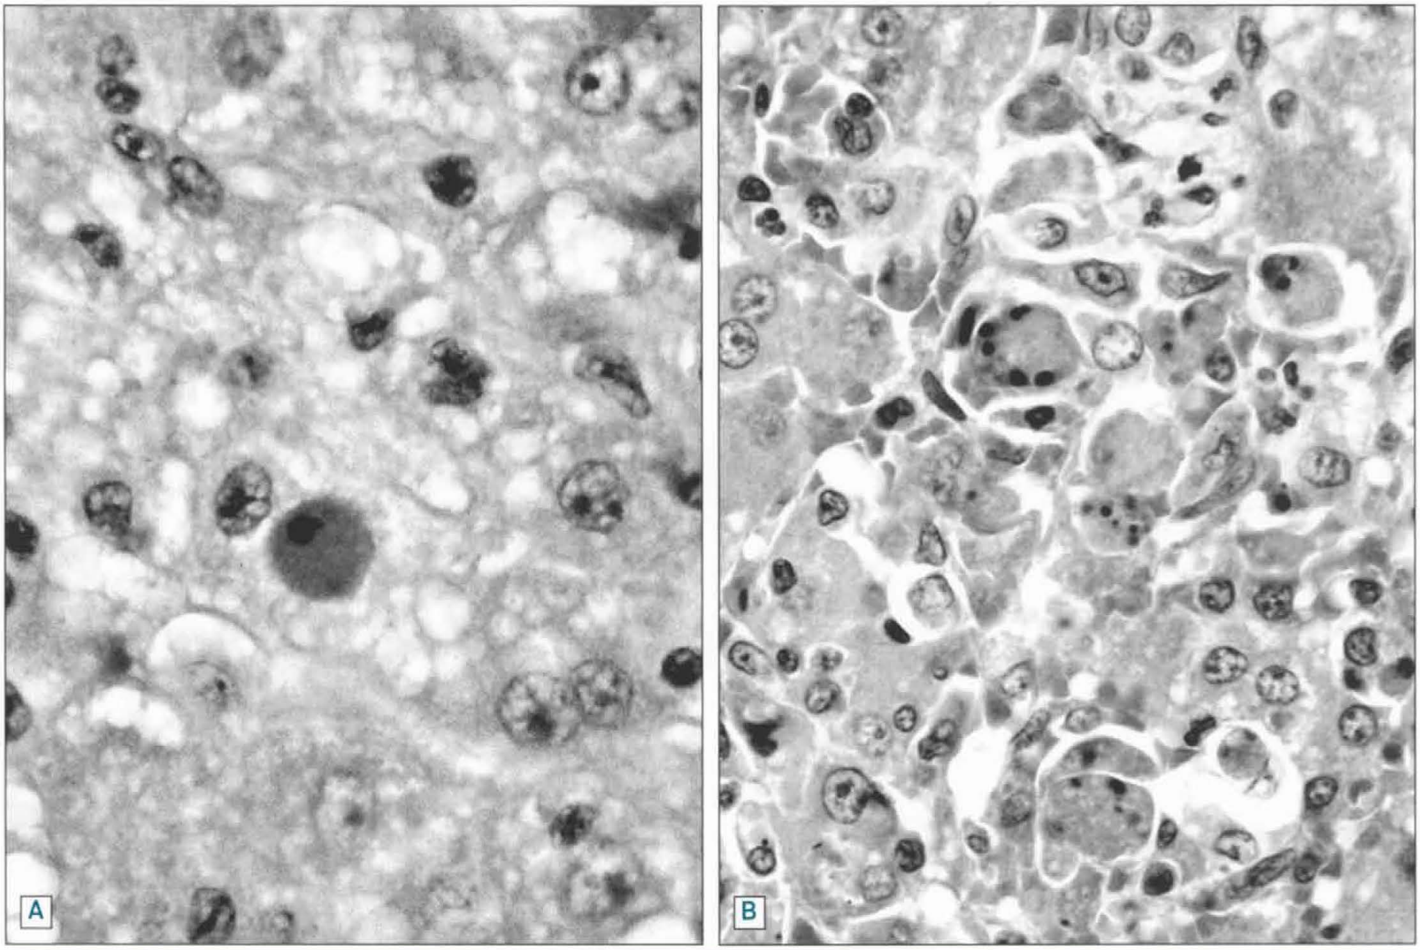

Figure 2.23 **A. Apoptotic hepatocellular fragment** engulfed by an adjacent hepatocyte, without a cellular inflammatory reaction. **B.** Multiple hepatocytes undergoing **"single-cell necrosis"** in association with an inflammatory response. The dead cells exhibiting karyorrhexis are intact and extracellular.

Apoptosis

Hepatocytes can undergo typical **apoptosis** (Fig. 2.23A), *with nuclear and cell fragmentation into smaller apoptotic bodies bound by intact plasma membrane that are rapidly phagocytosed and degraded by neighboring hepatocytes or Kupffer cells.* The rapid disappearance of these fragments means that very few in a section can indicate a rapid rate of hepatocellular death and turnover. Rapid phagocytic removal of apoptotic hepatocyte fragments typically minimizes secondary inflammation, although in some instances the capacity to remove dead cells may be exceeded. Apoptotic fragmentation occurs most obviously in lethally injured replicating cells, elicited by insults that damage DNA and activate cell cycle checkpoints. However, most adult hepatocytes are not replicating and remain in the G_0 phase of the cell cycle, so apoptosis is more likely to be observed in livers that are immature, regenerating, or hyperplastic. Apoptosis can also be observed during acute atrophy and during hepatic involution after adaptive hypertrophy.

Apoptosis can be initiated by extrinsic or intrinsic events. *Extrinsic mechanisms* can be activated via cell surface death receptors by cytokines such as the fas ligand and tumor necrosis factor-α. *Intrinsic mechanisms* involve either DNA damage with activation of p53 and p21, or mitochondrial injury with release of proapoptotic factors. Activators of the latter pathway include oxidative stress, redox changes, covalent binding, and lipid peroxidation, all of which are also necrogens for the liver. These increase mitochondrial membrane permeability, either through direct membrane damage, or more commonly by opening of regulated transmembrane pores formed by *bax* and other members of the *bcl-2* family. Cytochrome C and other intermembrane mitochondrial factors form an apoptosomal complex that activates the distal caspase pathways that execute many of the cell fragmentation events.

Both extrinsic and intrinsic pathways lead in turn to disruption of the cytoskeleton and nucleus primarily through the activation and direct action of caspases 3, 6, and 7. *An important feature of apoptosis is the requirement for adenosine triphosphate (ATP) to initiate the execution phase.* If the degree of mitochondrial damage is sufficient to exhaust ATP stores, membrane ion homeostasis deteriorates and leads to a mechanism of cell death more consistent with necrosis. For example, while mild to moderate oxidative stress may initiate intrinsic pathways of apoptotic cell death, processes leading to marked oxidative stress typically cause cell death by necrosis due not only to the severity of mitochondrial damage, but also to direct inhibition of the proapoptotic caspase cascade.

Injury to the endoplasmic reticulum (ER) leads to "*ER stress*" that can also activate the distal caspase pathway by a separate mechanism. Hepatocytes are also susceptible to an intrinsic mechanism of apoptosis that is active after removal of hepatotrophic influences, including those that function via cell adhesion or via the constitutive androstane receptor, and other nuclear receptors.

Phagocytosis of apoptotic fragments follows flipping of phosphatidylserine from the inner leaflet of the plasma membrane to the outer leaf, where it can then be recognized by the phosphatidylserine scavenger receptor. Various assays can be used to detect portions of these pathways in hepatocytes; caspase-cleaved cytokeratin 18 can be recognized by antibodies to an internal domain, while chromatin fragmented by a calcium-activated endonuclease generates double-strand breaks that can be tagged by the TUNEL technique. However, there are still few diagnostic situations in which these indicators have been shown to be useful. Increased numbers of apoptotic hepatocytes can be more readily assessed with a suitable cytological marker. *In routine sections, a previous increase in apoptosis can be suggested by increased amounts of lysosomal debris and pigment in Kupffer cells, but this is not specific for apoptosis.*

Necrosis

Necrosis *is morphologically recognizable by initial cell swelling and subsequent loss of plasma membrane integrity, leading to cell lysis. Release of cellular contents typically elicits a secondary inflammatory response and provides the serum enzymes that are useful clinically to detect liver necrosis.* However, these sequelae can also occur after hepatocyte apoptosis, either because the capacity for phagocytic removal of dead cells is exceeded, or because the insult worsens such that necrosis may supervene.

Necrosis is often a consequence of profound loss of mitochondrial function involving the opening of the membrane permeability transition pore, a megachannel composed of inner- and outer-membrane proteins. This results in mitochondrial depolarization and ATP depletion. Much of the ATP in hepatocytes is used for membrane homeostasis of Na^+, K^+, and Ca^{2+} ions. ATP depletion or physical damage to membranes of the cell surface, mitochondria, and ER leads to loss of ion homeostasis, altered cellular volume regulation, and increased intracellular calcium ion concentrations. Activation of calcium-dependent endonucleases, proteases (e.g., calpains), and phospholipases is responsible for the terminal events in necrosis. Some authors prefer the term "*oncosis*" to emphasize the cell swelling response in necrosis to contrast with cell shrinkage in apoptosis.

The term **coagulative necrosis** *may be applied to groups or zones of intact but dead hepatocytes that have shrunken slightly, stain intensely with eosin, and may have visible but distorted nuclei* (Fig. 2.24). These cells may also be dehydrated but, unlike apoptosis, the removal of water is not an active process and the affected cells do not undergo spontaneous fragmentation. It seems that coagulative necrosis, which is often seen in acute hepatotoxicity, is the *result of sudden and catastrophic denaturation of cytosolic protein*, which imparts a rather dense, rigid texture to the dead cells, somewhat preserving their shape. *The term* **lytic necrosis** *has been used for areas of necrosis in which the hepatocytes are disintegrating, usually in the presence of infiltrating phagocytes, especially neutrophils* (Fig. 2.25). This is consistent with the later stages of postnecrotic inflammation that follow necrosis rather than apoptosis.

Single-cell necrosis

Hepatocytes sometimes die in a spotty or random manner in a form of cell death referred to as "**single-cell necrosis**" (Fig. 2.23B). The Councilman body in viral hepatitis is a classical example in this process. Hepatocytes remain intact but shrink into a single rounded detached cell that is more slowly removed by macrophages, preceded by a few neutrophils. Single-cell necrosis has some features of apoptosis, but the pattern of nuclear and cytoplasmic degeneration and the inflammatory consequences are more consistent with those that follow necrosis. Intact hepatocytes are too large to be phagocytosed so they are more likely to leak cytoplasmic enzymes and elicit an inflammatory response. Single-cell necrosis of hepatocytes often occurs in livers in which more typical apoptotic fragments are also present,

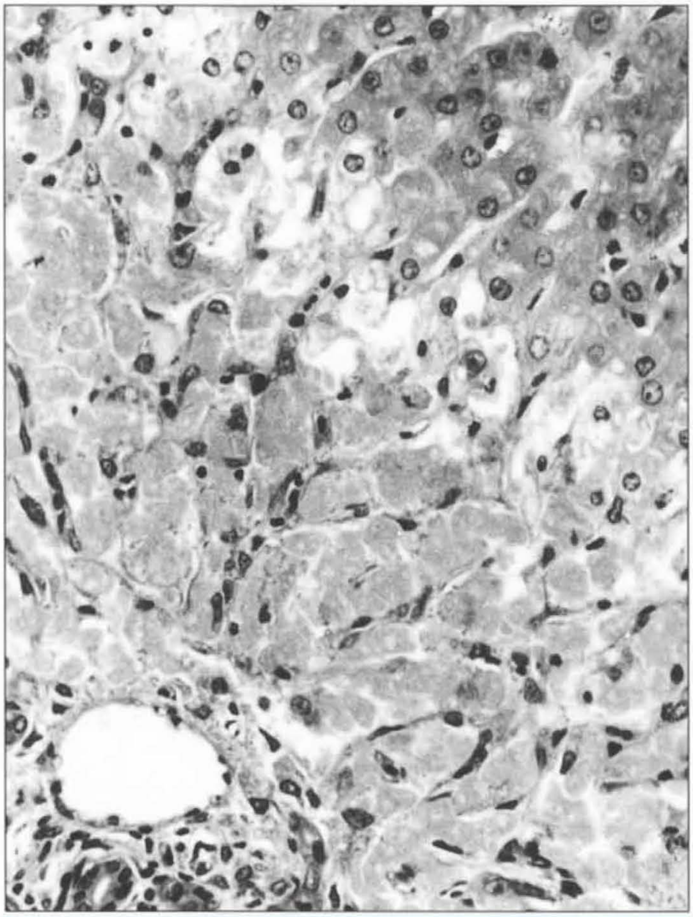

Figure 2.24 Coagulative necrosis of periportal hepatocytes due to ngaione poisoning in a sheep. (Courtesy of AA Seawright.)

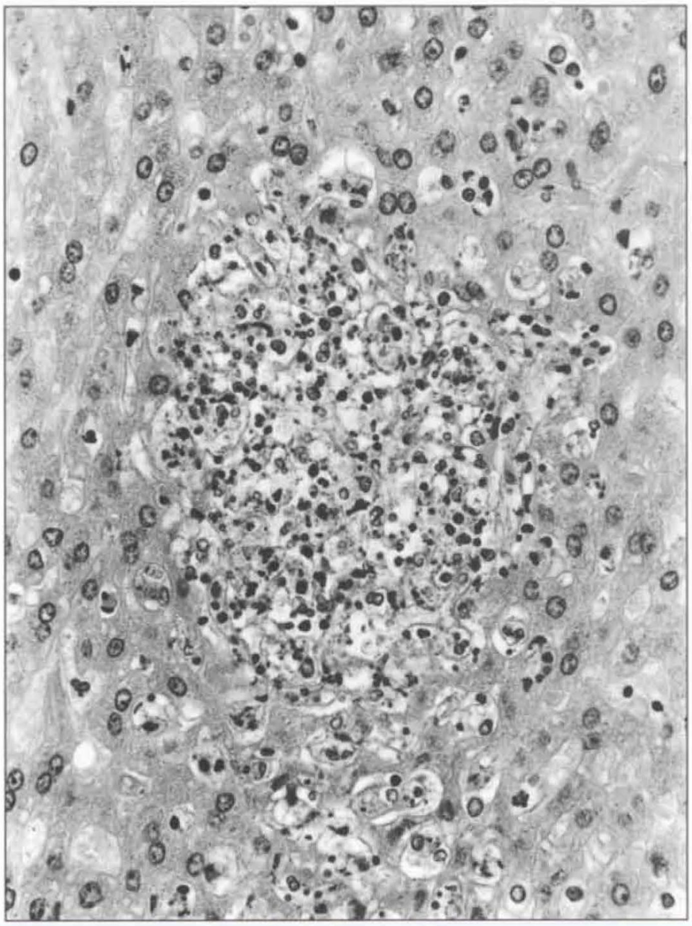

Figure 2.25 Focal inflammation and **lytic necrosis** in salmonellosis.

but in some conditions, individual necrotic cells are observed with the expected neutrophil and phagocyte response, indistinguishable from those in focal or zonal necrosis. It remains to be seen if non-apoptotic programmed cell death is responsible for some forms of single-cell necrosis.

Loss of cell anchorage can activate a form of programmed cell death related to apoptosis that is referred to as **anoikis**. Detached cells can die intact, as in exfoliation, or undergo typical fragmentation into apoptotic bodies. Hepatocyte survival in vitro depends on their integrins that adhere to the extracellular matrix, but it is still unknown how loss of these contributes to cell death of hepatocytes in the intact liver.

Tissue patterns of cell death

Focal necrosis

Focal necrosis is very common in necropsy material. The lesions are microscopic or barely visible to the naked eye and are usually numerous. Their designation as focal depends on their size and on a random distribution relative to the acini. There may be a tendency for focal necrosis to occur nearer to the axial portal vessels than to the periphery of the circulatory fields, and to be concentrated in some acinar agglomerates rather than others.

Focal necrosis occurs in many infections, parasitic migrations, and instances of biliary obstruction, and in these the designation **focal hepatitis** will often be more appropriate, since most are attended by some degree of focal inflammation. The infectious causes may be viral, such as *Equid herpesvirus 1* in the fetus (Fig. 2.26), or bacterial. Many septicemic bacterial infections consistently produce focal hepatic lesions; examples are salmonellosis, tularemia, pseudotuberculosis, listeriosis in the fetus and newborn, and *Mannheimia haemolytica* septicemia in lambs. The focal necrosis may be the outcome of a Kupffer cell reaction, as in salmonellosis, or of bacterial embolism. The cause can usually be determined by histologic examination.

In cattle, focal necrosis in few or many visible foci is common at necropsy and is common enough to be important at slaughter; it is responsible for the descriptive appellation "*sawdust liver.*" The pathogenesis is not known and probably varies, but it may be caused by organisms from the gut that reach the liver in the portal blood. *The lesion is not specific and consists of focal parenchymal necrosis with disruption of reticulin fibers and infiltration of neutrophils and lymphocytes* (Fig. 2.27); frank suppuration does not occur. This lesion is said to be more frequent in livers from feedlot-fattened cattle.

Focal necrosis in biliary obstruction follows rupture of distended canaliculi or smaller cholangioles, with the formation of small bile lakes. The yellow pigment is readily visible microscopically and provokes small granulomas with giant cells.

Focal necrosis is of very little functional significance for the liver, even when numerous. They heal with some scarring, but this too probably disappears in time. They are of diagnostic importance in some diseases

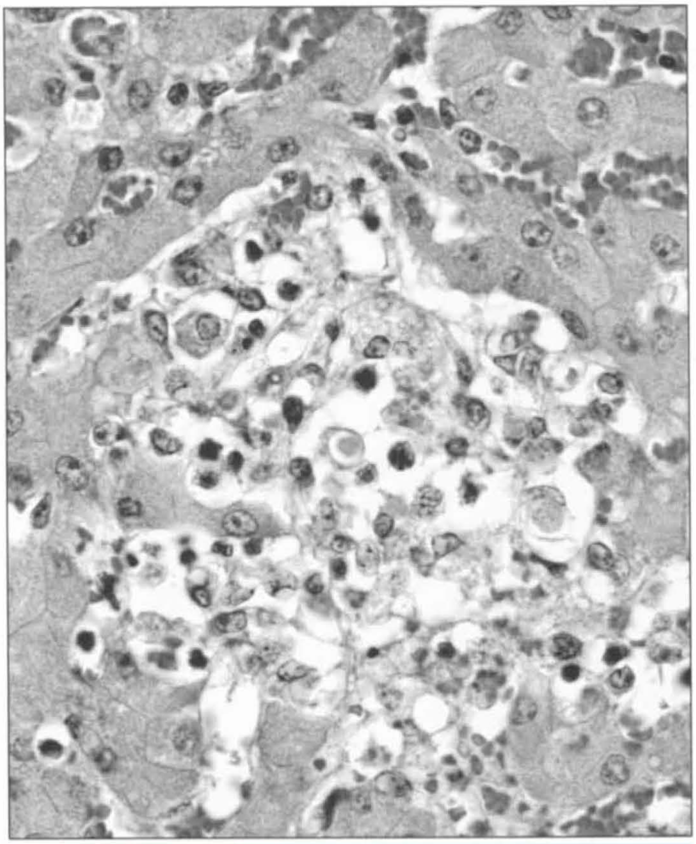

Figure 2.26 Focal necrosis due to *Equid herpesvirus 1* in a foal.

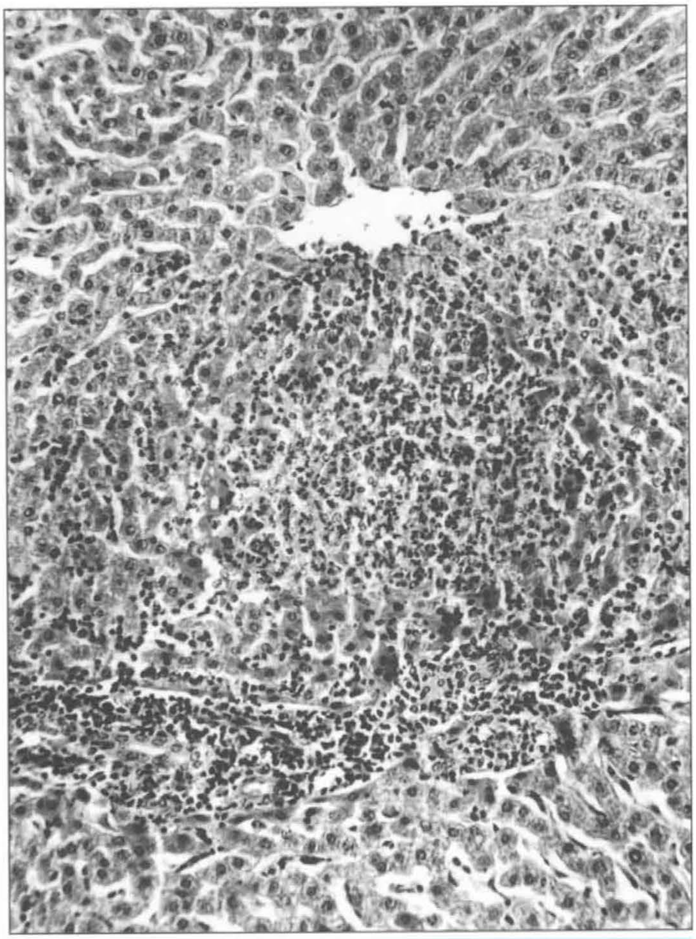

Figure 2.27 Focal hepatitis – the so-called **"sawdust liver"** of cattle.

such as salmonellosis, and as indicators of possible bacteremia for meat inspectors.

Zonal necrosis

While various terms are used, the simplest way to visualize and designate zonal patterns of necrosis is by the numerical zonation of the liver, as proposed by Rappaport. This can become awkward when necrosis extends from hepatocytes into the adjacent portal or central vascular tracts. In these circumstances, the terms *periportal or periacinar descriptors* might be more useful.

Zone 3 necrosis (periacinar necrosis) *is the most common form of zonal necrosis in domestic animals.* The hepatocytes in the periacinar zone are particularly vulnerable to necrosis, in part because they are farthest from incoming arterial and portal venous blood bearing oxygen and essential nutrients. They also contain the greatest concentration of cytochromes P450 that activate various exogenous compounds into reactive metabolites capable of injuring or killing hepatocytes (see section on Toxic hepatic disease, below).

Severe viral infections, such as *Canine adenovirus 1* and *Rift Valley fever virus*, can produce periacinar necrosis, and the reasons for the increased susceptibility of the hepatocytes of this zone in these diseases are not established. Plausible explanations include zonal expression of entry receptors used by viruses to infect hepatocytes, or ischemia-related hepatocellular swelling and sinusoidal damage that reduce effective perfusion of the periacinar hepatocytes.

Periacinar degeneration and necrosis are seen commonly in animals that have died rather slowly. It is assumed that, in the agonal period, the hepatocytes in this zone are disproportionately affected by tissue hypoxia as a result of the failing circulation. This necrosis is more extensive if the animal is anemic. Periacinar necrosis is also seen in passive venous congestion of the liver.

In the liver with periacinar necrosis, there is usually a prominent zonal pattern, which takes the form of a fine, regular, pallid network of surviving, often fatty hepatocytes in the periportal zone, which stands up above the red, collapsed areas adjacent to the hepatic venules (Fig. 2.28). The zonal necrotic insult frequently affects the sinusoidal endothelium, allowing erythrocytes to enter the perisinusoidal space and contribute to the redness of the necrotic zones. Necrotic cells that are removed can be replaced by stagnant blood, at least in the acute phase. However, this red-on-yellow zonal pattern is difficult to interpret grossly because hepatic lipidosis may also have a zonal distribution without having significant necrosis.

Periacinar coagulative necrosis gave rise to the time-honored designation "**centrilobular necrosis**" based on the classical hepatic lobule. However, vascular influences on the susceptibility to necrosis mean that segments of the lobule can be differentially affected. Frequently, the areas of necrosis are joined to one another, thus cutting the conventional lobules into segments, and at the same time outlining the periphery of the circulatory fields of the hepatic acini (Fig. 2.29). Some of these areas of necrosis extend up to larger portal triads, because the periphery of some acini may lie against the larger portal tracts. Often, the hepatocytes between the necrotic

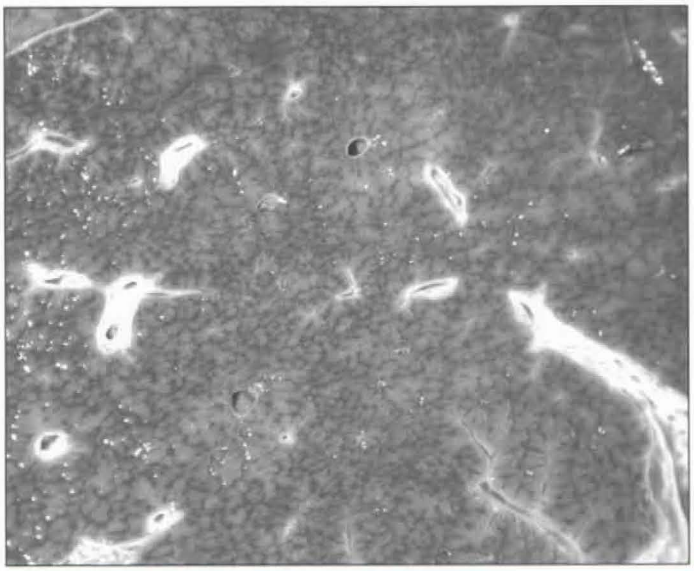

Figure 2.28 Chronic passive congestion (**"nutmeg liver"**) in an ox.

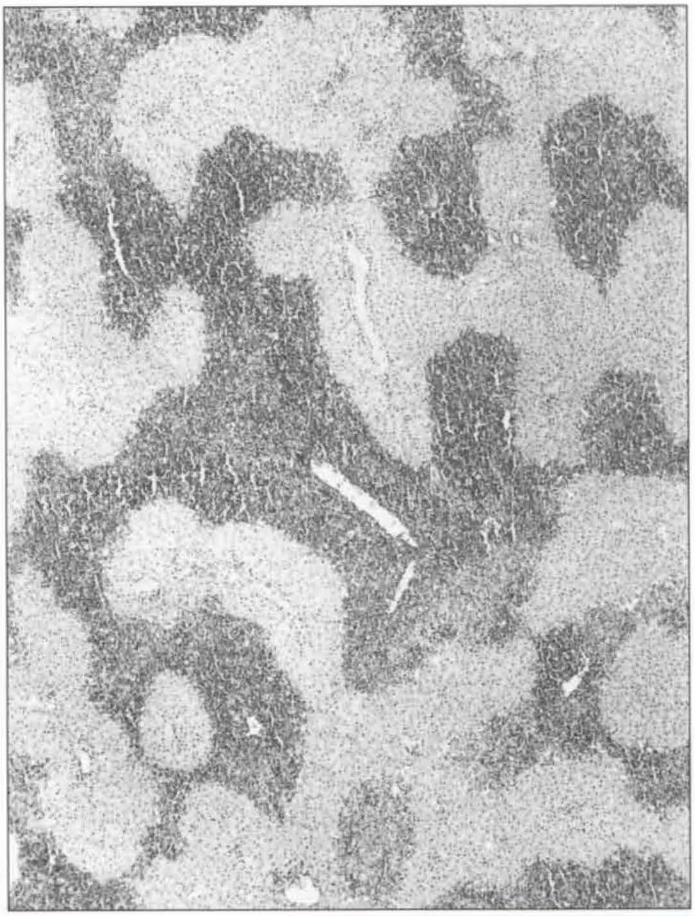

Figure 2.29 Acini outlined by **periacinar hemorrhagic necrosis** due to *Cestrum* poisoning in a sheep.

and more normal zones show hydropic degeneration or fatty change (Fig. 2.30). However, not all acini in a classical lobule may be equally affected, so the terms zone 3 or periacinar necrosis are preferable.

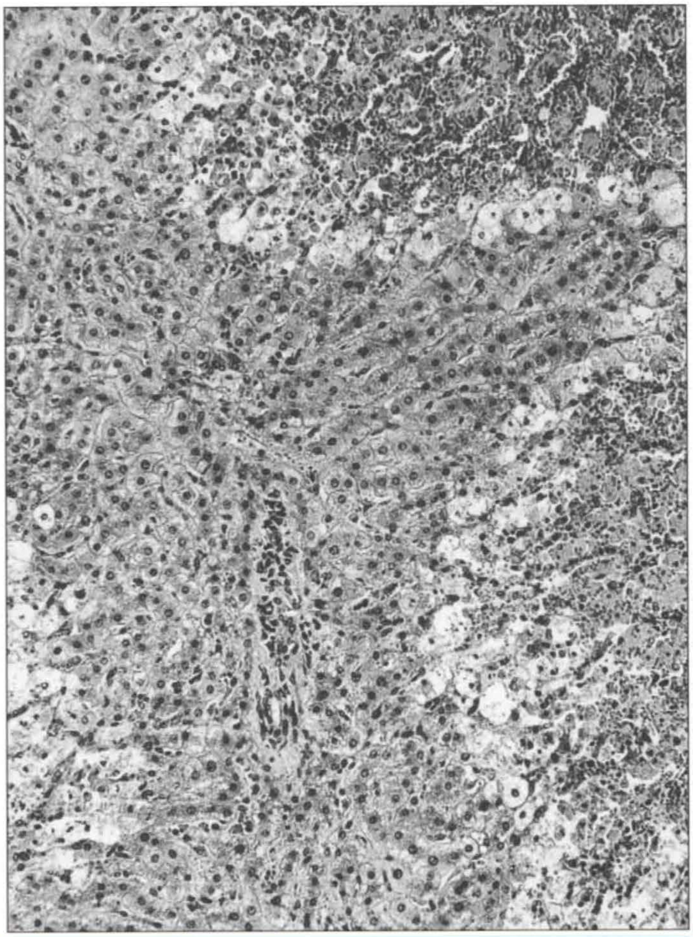

Figure 2.30 Acute **periacinar necrosis** in *Cestrum parqui* poisoning in an ox. Necrotic zone is bordered by hydropic hepatocytes.

If the insult is of short duration, quite extensive periacinar necrosis may be followed by phagocytic infiltration and hepatocellular proliferation and complete restoration of normal structure and function within a few days. Severe periacinar necrosis may be followed shortly by proliferation of cholangiolar and bile duct epithelia that also respond to the regenerative stimulus. With restitution of the normal complement of hepatocytes, the proliferative response in the biliary tract subsides unless the original insult is continuous or repeated.

Some intoxications can produce selective **zone 2 (midzonal) necrosis**, affecting only a narrow, sharply defined band of hepatocytes (Fig. 2.31). It may be more diffuse within the acinus, so that periportal or periacinar degeneration may be superimposed on the more severe midzonal lesion.

Zone 1 (periportal) necrosis (see Fig. 2.24) *is also an uncommon lesion*, perhaps more often seen than midzonal necrosis, and can be caused by direct-acting hepatotoxins. It is usual to find in the same liver areas that show one or more of the patterns of zonal necrosis.

The various forms of zonal necrosis cannot reliably be distinguished from one another grossly, but one may expect to see in periportal necrosis a reversal of the pattern seen in periacinar necrosis; that is, in periportal necrosis the surviving hepatocytes about the hepatic venules may appear as pale, raised islands within a regular network of red, collapsed periportal tissue. Careful scrutiny may reveal the smallest hepatic venules at the center of the pale islands.

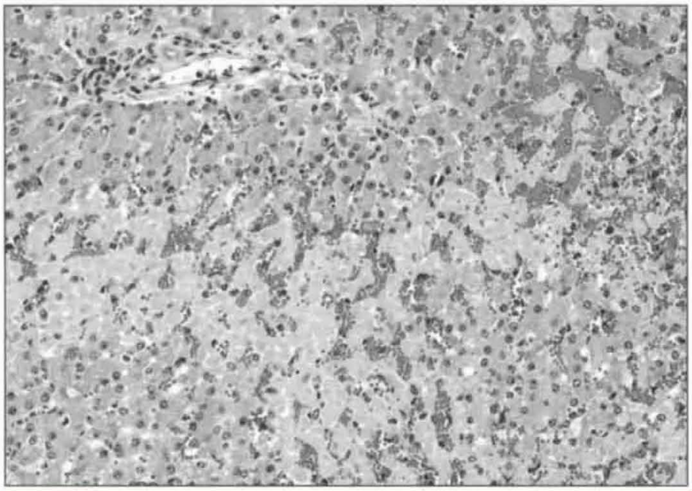

Figure 2.31 Acute **midzonal necrosis** in a foal.

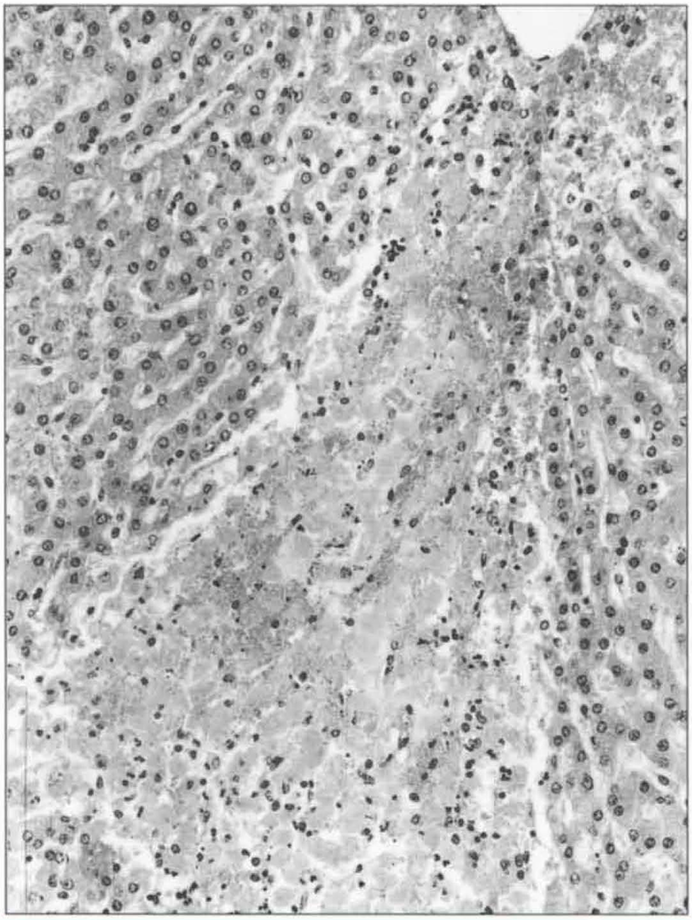

Figure 2.32 **Paracentral necrosis** in ngaione poisoning in a sheep.

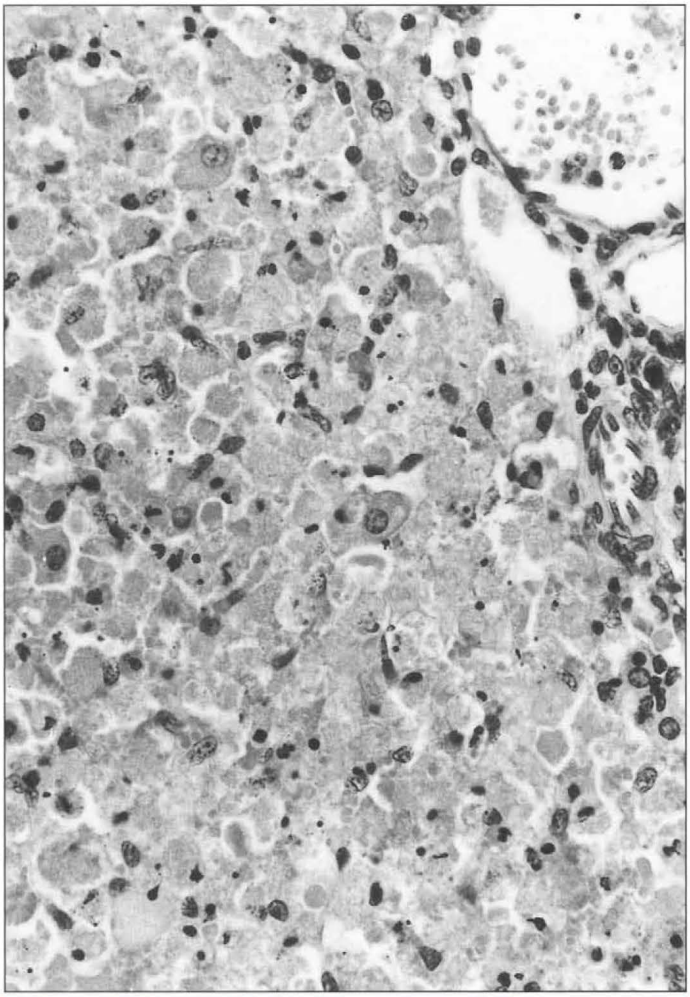

Figure 2.33 **Massive necrosis** with destruction of the periportal limiting plate due to algal poisoning in a sheep. (Courtesy of ARB Jackson.)

Paracentral necrosis, *a form of coagulative necrosis, occurs when an isolated complete hepatic acinus dies and is viewed in transverse section.* It is possibly an *ischemic lesion* or *infarct* produced by an occlusion of a terminal portal venule, such as may occur in disseminated intravascular coagulation. Its appearance in certain of the acute hepatotoxicities (Fig. 2.32) probably represents the death of a single complete acinus as a result of local vascular insufficiency, although, theoretically, high local microsomal enzyme activity or local deficiency of hepatocellular protective factors may play a part. Occlusion and rupture of a bile ductule or cholangiole are other potential causes of paracentral necrosis.

Massive necrosis

Massive necrosis refers to necrosis of entire hepatic acini, not necessarily necrosis of the liver as a whole. By accepted definition, *every cell in the affected acinus is dead, including the hepatocytes of the limiting plate* (Fig. 2.33). Without surviving parenchyma to support regeneration, affected acini collapse, so that portal areas and hepatic venules are approximated and the intervening stroma is condensed. Such a liver must regenerate from surviving hepatocytes in other, less severely affected lobules. The distribution of massive hepatic necrosis often relates to the distribution of larger vessels. Collapse, condensation, and subsequent scarring are characteristic, the end result being known as **postnecrotic scarring**. The liver is typically not uniformly involved. Large areas of parenchyma remain intact and these enlarge amid scarring areas during compensatory regeneration.

A liver that is the seat of massive necrosis may be of normal size or smaller. Fine red threads of fibrin may be present on the surface, especially in the grooves between the lobes. There is a surface mosaic appearance of red, gray, or yellow areas intermingled with areas of dark red. The gray or yellow areas of parenchyma, representing surviving tissue, form irregular, coalescing patches that may be less than 1.0 cm in diameter. *The intermingled red areas represent areas of necrosis, hemorrhage, and collapse, and these are depressed a few millimeters below the surface.* In the healing stage, the depressed areas of hemorrhage and necrosis are condensed, shrunken, and scarified so that the surface of the liver is traversed by fine or heavy scars that separate large nodules of regenerative hyperplasia. Further acute episodes may be superimposed so that the presented lesion may be a mixture of acute massive necrosis and postnecrotic scarring.

Hepatosis dietetica *of swine is an increasingly uncommon syndrome of massive hepatic necrosis in association with its immediate or late effects, namely "yellow-fat disease," degeneration of skeletal and cardiac muscle, serous effusions, ulceration of the squamous mucosa of the stomach, and fibrinoid necrosis of arterioles.* These lesions may occur alone or in any combination, although all seldom occur in one animal. They are known to be of nutritional origin, and the fact that the various lesions can occur separately indicates the complexity of the pathogenesis. Experimental observations have revealed the *need for concurrent deficiencies of sulfur-containing amino acids, tocopherols, and trace amounts of selenium if hepatic necrosis is to develop.* Selenium protects efficiently against the hepatic necrosis and massive effusions, and tocopherols are probably protective against other lesions that occur as part of the syndrome. The pathogenesis is incompletely understood, but is in part related to the generation of free radicals, exacerbated by deficiency of free radical scavengers such as vitamin E, and selenium, protective against reactive oxygen radicals through its role in glutathione peroxidase and some other selenoproteins. Hepatosis dietetica occurs in rapidly growing pigs fed diets largely of grain and containing protein supplements lacking in either quality or quantity. There is some evidence that in pigs that are nutritionally predisposed, a cold, damp environment or some other stress may precipitate the disease. Death usually occurs without signs of illness or after a short period of dullness. Melena, dyspnea, weakness, and trembling may be observed in some cases. Jaundice is indicative of a relapsing course.

Affected pigs are usually in good condition. The carcass may be anemic if ulceration of the gastric mucosa has occurred, and, in these cases, free and digested blood may be found in the stomach and intestine. Jaundice is not common, but *yellow staining of adipose tissues (yellow-fat disease)* is. In relapsing cases, hemorrhagic diathesis may occur, manifested mainly by hemorrhage into and about joints. Protein-rich fluid collects in the serous cavities in small volume. Fine strands of fibrin are present in the peritoneal cavity.

Pulmonary edema accompanies myocardial lesions that consist of intramural and subendocardial hemorrhages with focal areas of hyaline degeneration. The changes in the liver dominate the autopsy findings. The massive hepatic necrosis is of the typical appearance described earlier (Fig. 2.34), and in a number of cases, both acute and chronic lesions are found. The sites of severest injury are the dorsal parts on the diaphragmatic surface. The right lobe may escape and later undergo marked hypertrophy. The gallbladder is often edematous.

The histologic changes that occur in this syndrome are described elsewhere with the particular organs involved. Additionally, fibrinoid degeneration of small arteries occurs in some cases. The arterial degeneration may occur in any organ or in most organs but is relatively common in only the small vessels of the mesentery, gut, and heart (see mulberry heart disease, in Vol. 3, Cardiovascular system).

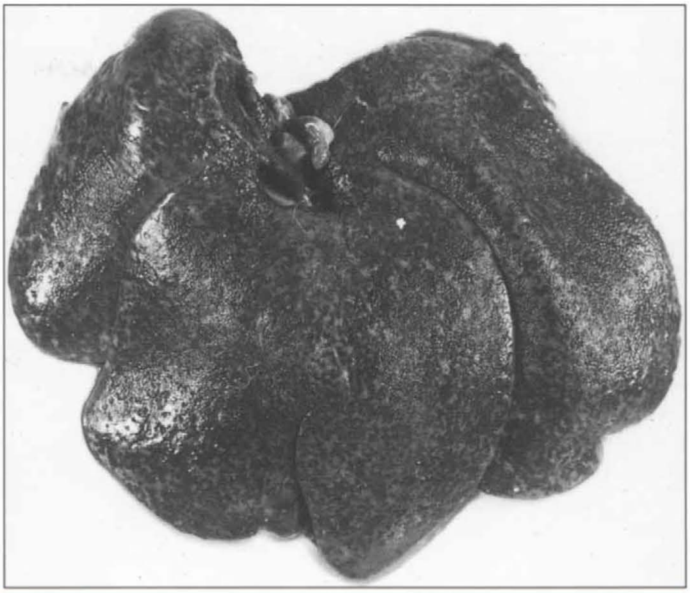

Figure 2.34 Massive necrosis with early postnecrotic collapse in **hepatosis dietetica** in a pig.

Piecemeal necrosis

Models of *immune-mediated hepatocyte necrosis* have emerged from studies of human viral hepatitis and some forms of drug-induced chronic hepatitis. *This pattern of necrosis amid sites of more active inflammation is sometimes referred to as piecemeal necrosis.* The mechanisms may involve either direct damage to hepatocytes by the uptake of antigen–antibody complexes, or cooperation between macrophages and T lymphocytes. These may cause cell-mediated destruction of hepatocytes that have taken up these complexes or, perhaps, native antigen or virus. Whatever the agency, the mode of cell removal in this sort of injury often takes the form of *single-cell necrosis or apoptosis*, which may be directly triggered by immunologically competent cells. This type of liver injury, in which *inflammation characteristically disrupts the limiting plate,* giving an irregular appearance to the periportal zone, is discussed further in the section on Chronic hepatitis, below.

Necrosis of sinusoidal lining cells

When hepatocytes are being destroyed by the elaboration of toxic molecules within their cytoplasm, it is to be expected that the *sinusoidal lining cells may also suffer should the products of these biotransformations spill into the space of Disse.* Erythrocytes increase in the perisinusoidal space and, when endothelial damage is severe, the regions of necrosis are hemorrhagic. Necrosis of sinusoidal endothelial cells is seen very early in the course of hepatotoxicities, such as acute acetaminophen and ngaione poisoning. Microcystin-LR is a highly toxic cyclic heptapeptide produced by *Microcystis aeruginosa*, an aquatic cyanobacterium (blue-green alga). This toxin is selectively injurious to hepatic sinusoidal endothelial cells by inhibiting protein phosphatases. When the cytoskeleton becomes hyperphosphorylated, endothelial cells undergo apoptosis, leading to hemorrhagic necrosis. *Sinusoidal phagocytes are sometimes vulnerable to necrosis* by virtue of their role in clearing the portal blood of particulate or colloidal material; should these particles be toxic or infectious, Kupffer cell necrosis may occur alone, but more usually there is damage to surrounding hepatocytes as well.

Necrosis of bile duct epithelium

It is unusual for the bile duct epithelium to be singled out by specific necrogenic insults, but this is seen in intoxication by *sporidesmin* (see section on Toxic hepatic disease, below). Usually there is accompanying portal inflammation. Some experimental toxicants such as α-naphthylisothiocyanate are necrogenic to bile duct epithelia and elicit a local inflammatory cholangitis. Idiosyncratic drug-induced cholestasis can lead to acute cholangiolar injury as well as chronic cholestasis with damage and loss of bile ducts (*vanishing bile duct syndrome*).

RESPONSES OF THE LIVER TO INJURY

Hepatocellular replication

Hepatocytes replicate normally during embryogenesis, growth, and maintenance replacement. However, in various disease conditions, notably during adaptive hypertrophy or loss of functioning liver mass, replication or "regeneration" of hepatocytes and nonparenchymal cells increases. The liver can grow or shrink to meet metabolic demands after injury or in response to situations of excess functional mass, such as after lactation or weight loss. The remarkable ability of the liver to regenerate was recognized in ancient Greek mythology. The Titan Prometheus offended Zeus by giving mankind the gift of fire, and for punishment was chained to a rock on Mount Caucasus, where, every evening, an eagle devoured his liver. Overnight, his liver grew back, perpetuating his torture until his rescue by Heracles.

Hepatic mass is tightly regulated by control of mitosis and apoptosis, and similar mechanisms appear to control hepatic growth across species, although time courses may differ. *As much as 70% of the normal liver can be removed surgically without clinical insufficiency, and in the course of a few weeks it is back to normal size, although not its original shape.* Such regrowth of the liver is commonly termed "*regeneration;*" however, *new lobules and lobes cannot regenerate*; rather, *there is diffuse replication of surviving hepatocytes on the existing stromal matrix.* In situations in which replication cannot quickly satisfy the regenerative stimulus, nodular regeneration can arise from areas or cells that are more responsive.

Mature hepatocytes are usually in the postmitotic or G_0 resting stage of the cell cycle, but, under the influences of growth factors such as hepatocyte growth factor and interleukin-6, they can enter the cell cycle and replicate. The proportion that can do this varies with species and age, but in young animals in which most hepatocytes can replicate, only one or two rounds of replication are required to restore hepatic mass. Thus, increased numbers of mitotic hepatocytes are most numerous in the first few days after loss of liver mass. Enlargement of hepatic mass can also occur in part by increased production of cytoplasmic components or by the inhibition of apoptosis, in effect an extension of hepatocyte lifespan.

The initiation, progression, and cessation of this growth response are regulated on many levels, with built-in redundancy of signaling. Experimental studies in normal rodent liver have shown that, while hepatocytes in their normal state turn over very slowly, they retain replicative capacity that declines with age. Replication can be elicited by the action of various growth factors on hepatocytes that have been primed to respond. Priming can involve proteolysis of the extracellular matrix of the liver, and activation of Kupffer cells by tumor necrosis factor-α. These secrete interleukin-6, that renders hepatocytes competent to respond to other growth factors, particularly hepatocyte growth factor, transforming growth factor-α, and epidermal growth factor, facilitated by the co-mitogens insulin and epinephrine. Hepatocyte growth factor is produced by stellate cells and binds to the extracellular matrix, from which it is released during proteolysis. Cessation of liver growth when mass is restored is regulated by multiple pathways that are less well understood. Increased expression and responsiveness to growth inhibitors such as transforming growth factor-β and activin A induce extracellular matrix and suppress hepatocyte replication; these are downregulated during liver regeneration and increase as replication subsides.

Other cells in the hepatic lineage can respond to a protracted stimulus to regenerate by proliferating and differentiating into hepatocytes. These include **ductal precursor cells**, a bipolar (common ductal-hepatocyte) determined stem cell, represented in the adult liver by small "**oval cells**" in the terminal bile ductules (canals of Hering), and a putative multipotent **periductular liver progenitor cell** derived from circulating bone marrow stem cells.

These concepts of regeneration do not apply neatly to regeneration in livers with various age- or disease-related conditions. *Affected areas of liver require a supply of arterial and portal blood and free drainage of bile*, and these can be less than ideal. Also, some insults impair replicative competence of hepatocytes and nonparenchymal cells and this impedes and distorts regeneration. After massive necrosis or partial hepatectomy, surviving cells everywhere in the liver could contribute to the replacement of liver mass. After focal necrosis, proliferation is more restricted to adjacent differentiated cells. Accelerated single-cell necrosis, such as occurs in chronic copper poisoning in sheep, is compensated by replication of hepatocytes of seemingly random distribution. In the common periacinar necrosis, surviving hepatocytes, especially those in the periportal zone, can, after a delay of 24 hours or so, rapidly replace the lost cells. In periportal and midzonal necrosis, regeneration is provided by surviving cells in other zones.

Regeneration in livers during sustained or repetitive hepatocellular injury by toxic and idiopathic insults is often nodular rather than diffuse. Under these conditions, the liver tends to become smaller, atrophic, and the nodularity may be impressed on the liver by constricting bands of fibrous tissue. The toxins most active in this regard are not lytic liver necrogens but rather DNA-damaging toxicants such as pyrrolizidine alkaloids, phomopsin, aflatoxin, and various carcinogens with alkylating properties. All of these impair hepatocellular replication, and over time and the loss of hepatocytes through attrition or necrosis, *nodules emerge and enlarge as clones of hepatocytes with induced resistance to toxic injury.* The size of the nodules is a reflection of their opportunity to contribute to hepatic mass. If there is concurrent necrosis and inflammation, the degree of fibroplasia will be greater. These nodular atrophic livers are also characterized by bile duct hyperplasia, as oval cells and cholangioles are also able to respond to the mitogenic stimuli. If the liver eventually reaches the mass required, some of these induced populations can shrink by apoptosis or redifferentiation into more normal hepatocytes and ducts.

Compensatory liver atrophy, for example during cachexia, results in a discolored smaller firmer liver, whereas *acute atrophy* arising from diffuse cell death results in symmetrical flaccidity. In these conditions, the organ usually maintains its original shape. However, in chronic atrophy arising from hepatocellular loss or impaired regeneration, the organ becomes smaller and firmer as hepatocytes are lost from the condensing stroma. *Under a prevailing stimulus to regenerate, some altered hepatocytes escape inhibition and flourish as nodules*, resulting in a multinodular atrophic liver with most of the gross features of postnecrotic cirrhosis. Experimentally, various toxic insults that inhibit normal hepatocellular regeneration eventually cause liver atrophy with nodules. These nodules are composed of hepatocytes that more efficiently detoxify, excrete, and otherwise resist chemical insults, for example by excluding iron. However, hepatotoxins such as aflatoxin and pyrrolizidine alkaloids that inhibit proliferation also cause necrosis, so postnecrotic scarring and atrophy can be concurrent. In these conditions, some of the nodules originate from atypically differentiated cells generated by mutagenic insults, and some are clusters of regenerating normal hepatocytes.

Some of the common foci of atypical hepatocytes and hyperplastic nodules that develop spontaneously in canine livers may also have a survival advantage in the face of necrosis or atrophy, and give rise to the larger nodules that flourish in atrophic livers. Livers that are small and nodular (Fig. 2.35A, B), but lack the postnecrotic fibrovascular bridging characteristic of cirrhosis, can be reliably described as **hepatic atrophy with nodules**, pending further qualification according to necroinflammatory, mitoinhibitory, or combined pathogenesis. The nodular livers of some dogs presented with hepatocutaneous syndrome may be one example of this process (see section on Hepatocutaneous syndrome, below).

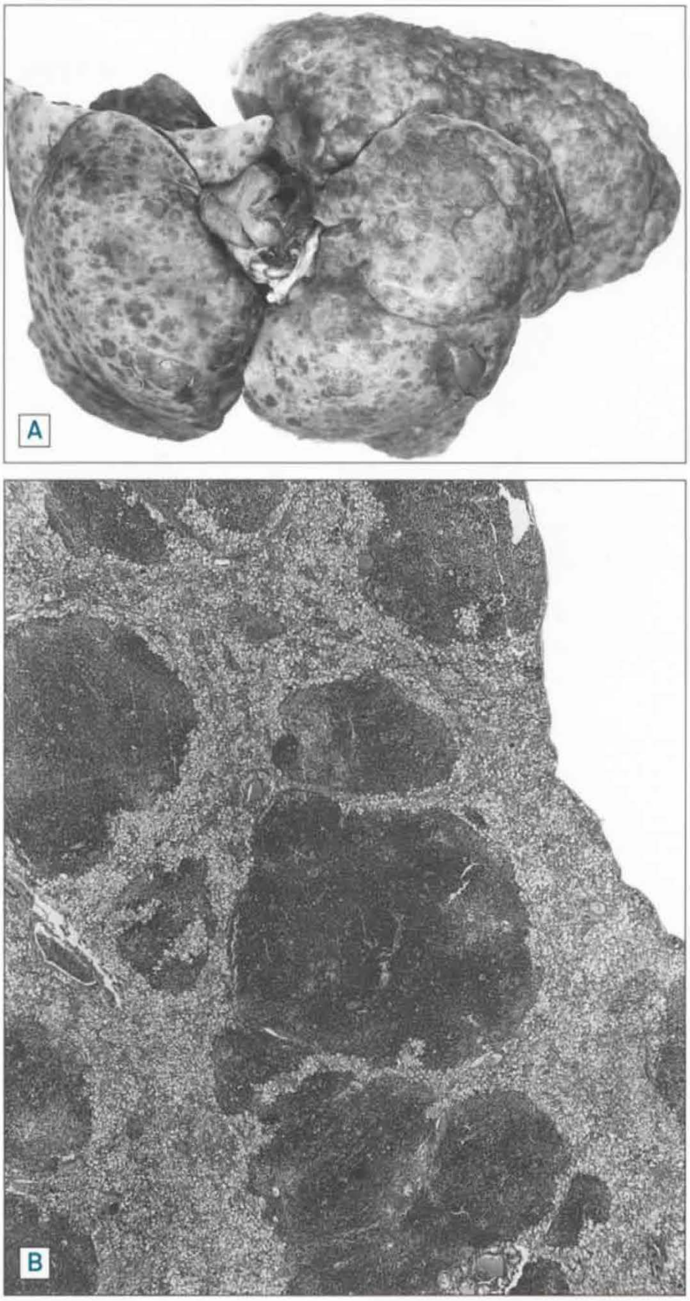

Figure 2.35 **A. Fatty liver** with nodules in a dog. **B.** Histology of **(A)** demonstrating **diffuse lipidosis with nonfatty nodules** in a dog.

Bile duct hyperplasia

Biliary hyperplasia is a characteristic reaction of the liver to particular types of insult, but much has still to be learned regarding the proliferative potential of these structures and the metabolic stimuli that provoke them. Ductular proliferation, with the formation of new, irregular, and tortuous channels in the portal and periportal region, is commonly associated with *bile duct obstructions* (Fig. 2.36). It may also develop secondary to *local portal inflammation and fibrosis*. In some situations, proliferation of ducts is a byproduct of sustained ineffective stimulus for the liver to regenerate (see above).

Bile duct proliferation can occur quite independently of changes in the parenchyma, particularly when an irritant stimulus is centered on the triads. Such pure bile duct proliferation may be a typical response to toxins, such as α-naphthylisothiocyanate in experimental models, or to physical biliary obstruction before infection complicates the picture. Injury to bile duct epithelium rather than hepatocytes is seen with paraquat intoxication and with exposure to the mycotoxin sporidesmin. There is also evidence for heterogeneity in the response of small and large cholangiocytes to different forms of hepatic injury or toxins. When the insults are removed the excess of bile ducts may disappear completely. The most extravagant expression of hyperplasia in the large ducts occurs in hepatic coccidiosis and some forms of hepatic distomiasis.

The originating cells of bile duct hyperplasia are thought to be *the hepatic bipolar stem cells, or oval cells*. Studies on isolated cells suggest that these intercalated cells are pluripotent and may differentiate into hepatocytes or cholangiolar epithelium. In experimental carcinogenesis or spontaneous hepatic disease in animals, cholangiolar

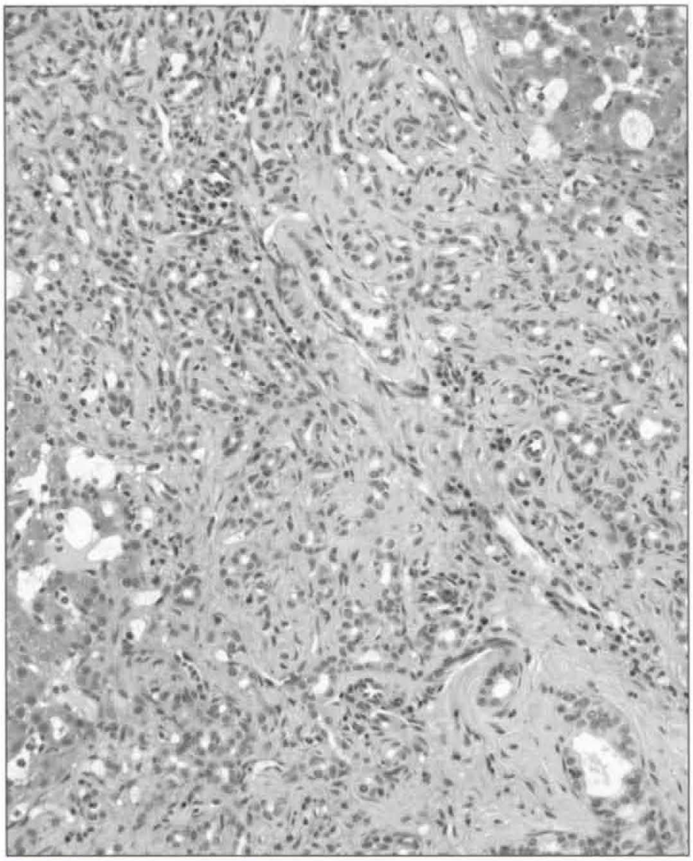

Figure 2.36 Portal fibrosis and bile duct hyperplasia secondary to bile duct obstruction in a horse.

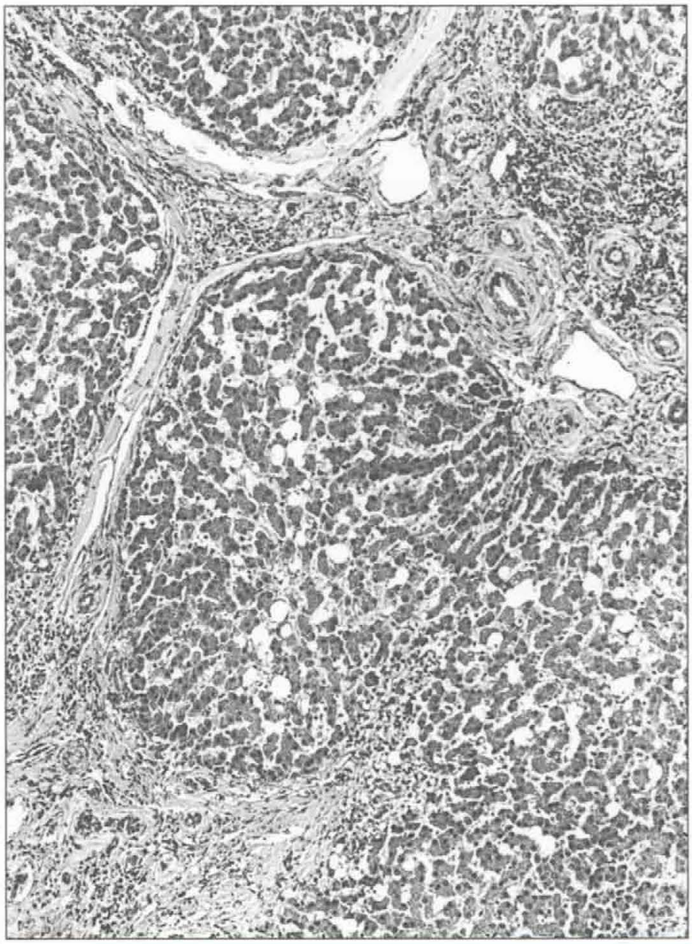

Figure 2.37 Biliary fibrosis secondary to chronic cholangitis in a dog.

hyperplasia may be an attempt to regenerate parenchyma when the parenchymal cells themselves have lost this capacity. Illustrative examples from natural disease are provided by the toxicoses of phomopsin, pyrrolizidine alkaloids, and aflatoxin, and by equine serum hepatitis and ovine white-liver disease.

Hepatic fibrosis

Fibrosis, the collagenous repair stage of necroinflammatory liver diseases, is a complicated spectrum of reactions that increase the deposition of extracellular matrix in the different portal, central, and perisinusoidal compartments, according to the distribution of the injury. The normal liver contains conventional connective tissue containing fibrillar collagen types I and III, predominantly within the connective tissue surrounding portal tracts and around terminal hepatic veins. Type IV collagen, mainly expressed by stellate cells, forms a delicate interstitial reticulin framework in the perisinusoidal space of Disse, between hepatocytes and sinusoidal endothelial cells. In diffuse interstitial hepatic fibrosis, accumulating types I and III collagen and other components of the extracellular matrix, including proteoglycans, fibronectin, and hyaluronan, are increased in the space of Disse. This increase in extracellular matrix reflects both increased expression of extracellular matrix components and reduced activity of matrix metalloproteases. On type I collagen, sinusoidal endothelia tend to lose fenestrae. This converts hepatic sinusoids from fenestrated endothelial channels that freely exchange proteins and other solutes between plasma and hepatocytes, to *higher-resistance, faster-flow tubular channels with limited solute exchange*. These changes, termed **capillarization** of sinusoids, are a common local response to liver injury, but must be extensive before they compromise the overall functional performance of the liver.

The major source of interstitial collagen production is the fat-storing perisinusoidal hepatic stellate cells. After some forms of liver injury, these cells proliferate and become activated, losing vitamin A storage and undergoing a major phenotypic transformation into smooth-muscle actin-expressing myofibroblast-like cells. The stimuli for this activation may include inflammation with release of proinflammatory cytokines such as tumor necrosis factor and interleukin-1, release of transforming growth factor-β and reactive oxygen species from injured hepatocytes and Kupffer cells, disruption of the extracellular matrix or direct stimulation of stellate cells by toxins. Once activated, hepatic stellate cells continue to produce a number of cytokines and growth factors capable of paracrine and autocrine stimulation, as well as tissue inhibitors of metalloproteinases, that perpetuate the process of fibrosis.

Hepatic fibrosis is potentially reversible. If the underlying insult is effectively treated or stopped, apoptosis of hepatic stellate cells and reduced expression of metalloproteinase inhibitors slow the production of extracellular matrix and allow degradation of immature collagen by matrix metalloproteinases to proceed. The balance is tipped in favor of progressive fibrosis when the insult continues to act, and

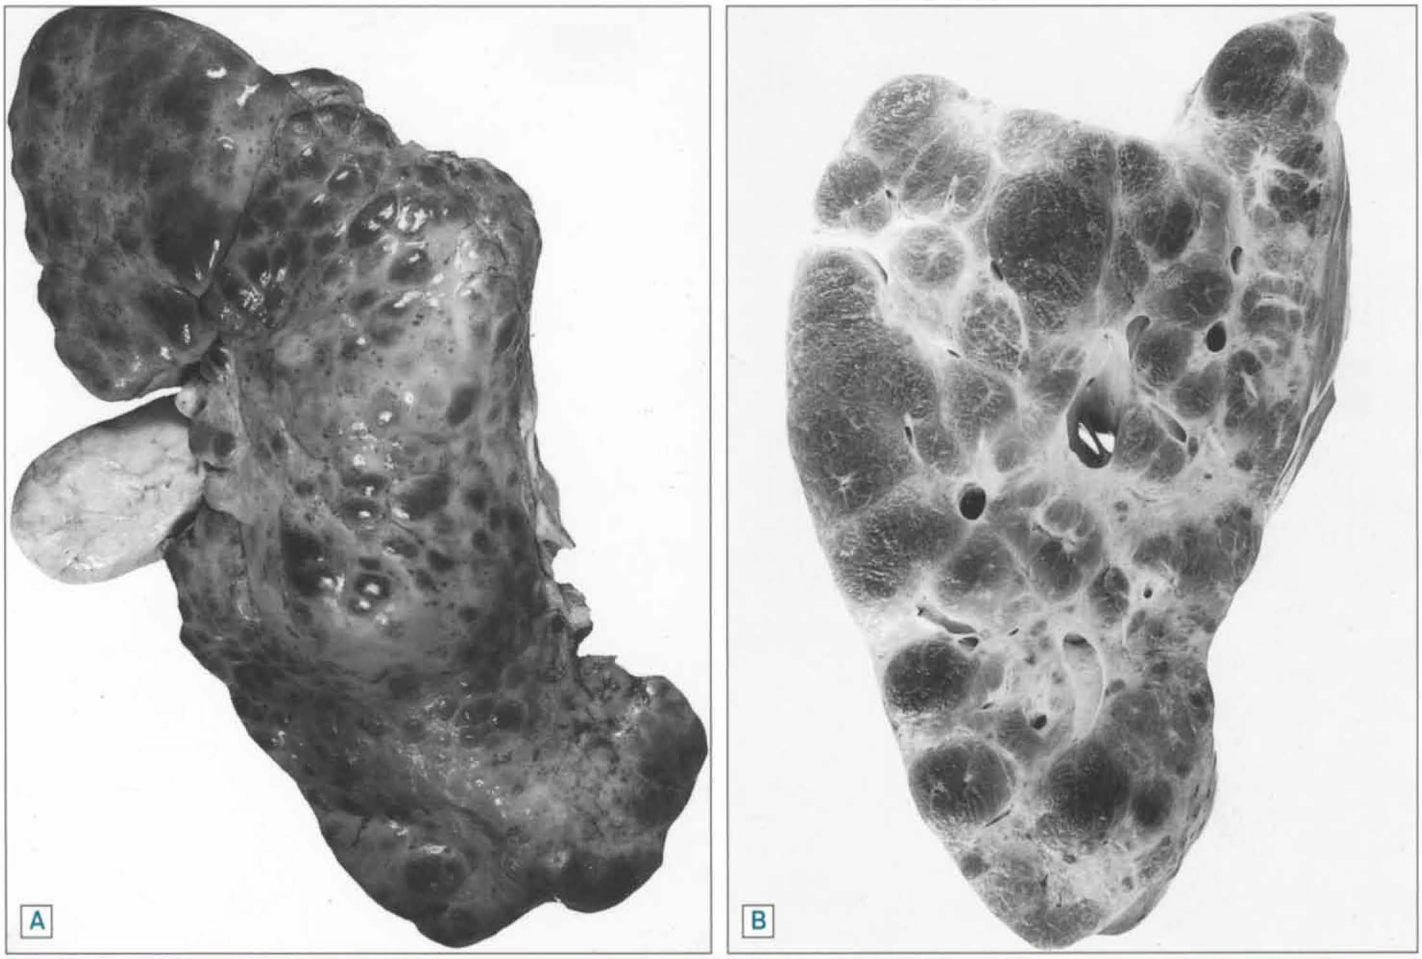

Figure 2.38 Postnecrotic scarring in an ox. **A.** Capsular surface. **B.** Cut surface.

collagen maturation and cross-linking potentially reduce its susceptibility to enzymatic degradation, or when the initial damage is so severe that the scar that results is extensive enough to exacerbate damage to the parenchyma by progressive sclerosis that impedes circulation.

The *distribution of fibrosis* in the liver reflects the pathogenesis of the necroinflammatory disease responsible:

- In the event of *inflammation in the portal triads*, the fibrosis remains largely confined to these areas and is termed **biliary fibrosis** (Fig. 2.37).
- **Postnecrotic scarring** *occurs after massive necrosis*, where large areas of parenchyma are destroyed. The reticulin network collapses and condenses, and portal areas converge, resulting in broad, irregular bands of scar tissue with variable irregular areas of parenchymal regeneration interspersed (Fig. 2.38A, B).
- **Diffuse hepatic fibrosis** is the outcome of *chronic parenchymal injury* such as prolonged inflammation or multiple episodes of zonal necrosis. The fibrosis throughout the lobules bridges connective tissue tracts in portal areas and hepatic venules to produce pseudolobulation, in which small areas of parenchyma are separated by a pattern of fibrosis on the scale of true lobules. This pattern of fibrosis can lead to capillarization of sinusoids, or intrahepatic bypass of portal and arterial blood, both of which can reduce the influences of portal growth factors on liver regeneration. These and accompanying malnutrition and hypoxia are important in the genesis of the hepatocellular atrophy that is almost always concomitant with diffuse hepatic fibrosis.
- Postnecrotic fibrosis that develops around hepatic venules is termed **periacinar fibrosis**. This is the most common pattern *following zonal necrosis in hypoxic and toxic injury*. Good examples are seen in animals with prolonged passive venous congestion of the liver (Fig. 2.39A, B), especially when this is due to extracardiac sources of increased venous pressure, rather than to congestive heart failure. Otherwise, this pattern of fibrosis is a response to toxic injury; poisoning by pyrrolizidine alkaloids may cause it in ruminants, and extraordinary development of periacinar fibrosis may follow accidental exposure to nitrosamines in several species.

Fibrosis as a postnecroinflammatory response is mechanistically distinct from simple condensation of stromal elements within atrophic segments of the liver, although often the two processes are concurrent.

Cirrhosis

The term cirrhosis is most correctly used for the end-stage of diffuse hepatic disease characterized by nodular regeneration with fibrovascular bridging scars in which there are intrahepatic portal-hepatic vascular shunts. Cirrhosis involves disruption of the architecture of the entire liver, a reflection

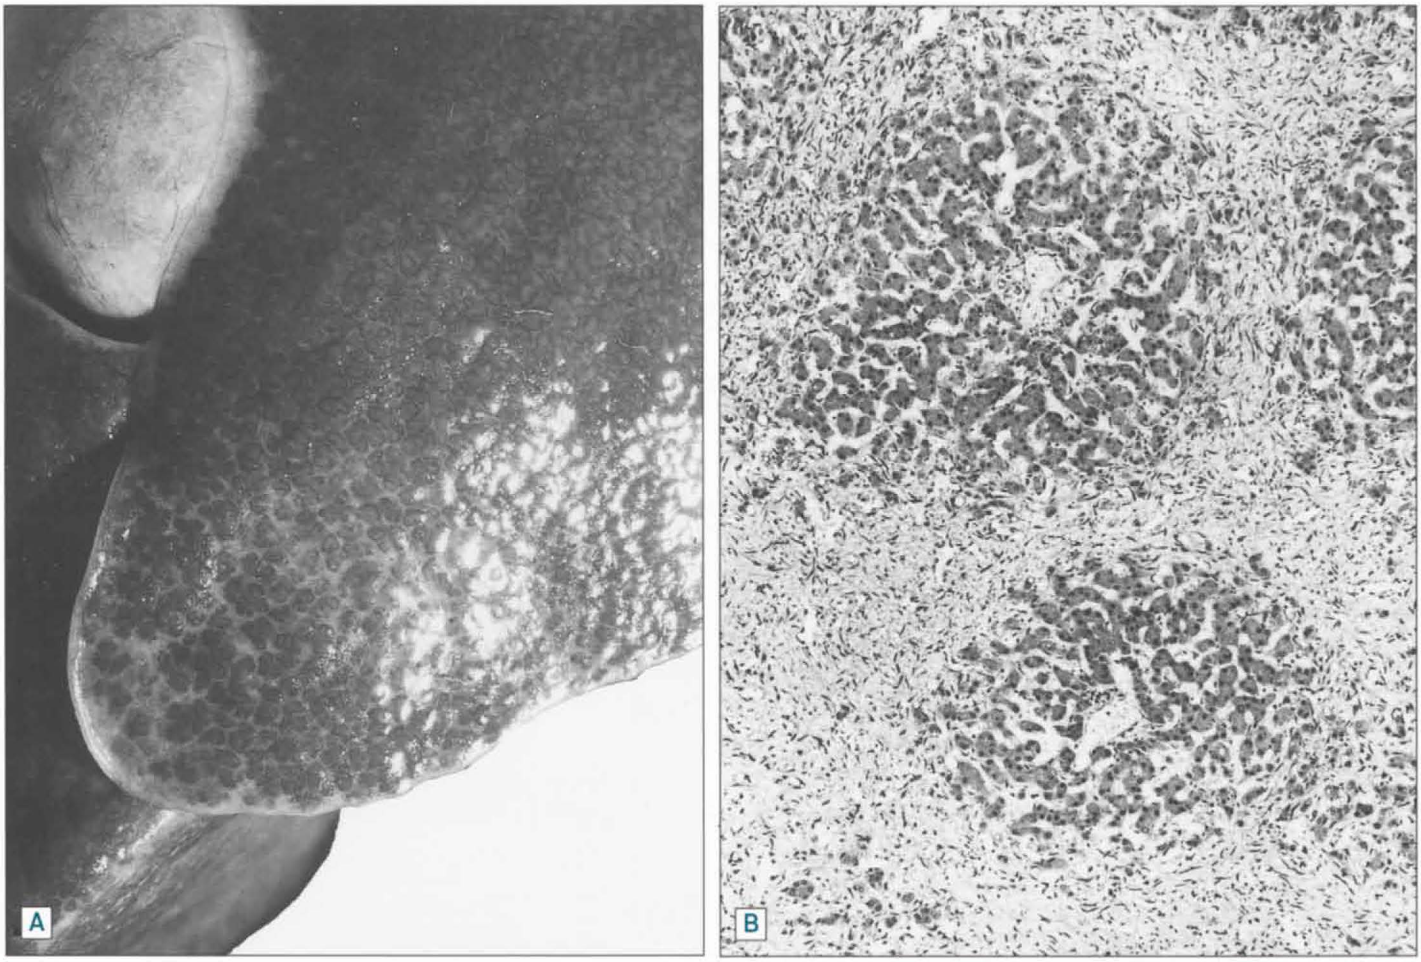

Figure 2.39 A. Periacinar fibrosis (cardiac fibrosis), most severe at the periphery of the lobe in chronic passive congestion in a dog with chronic heartworm disease. **B.** Section of (**A**).

of diffuse parenchymal injury, and subsequent fibrosis. *Note that not all nodular livers are cirrhotic* (see section on Hepatocellular replication, above). Clinically, *cirrhosis results in hepatic insufficiency*, mainly in the form of ascites and hypoproteinemia rather than excretory dysfunction and icterus, although in advanced cases all manifestations of fatal liver failure can occur. The *hallmarks of cirrhosis* are:

1. *Bridging fibrous septa*, ranging from delicate bands to broad scars that replace multiple adjacent lobules. These fibrous septa contain vascular channels, originating from sinusoids in collapsed parenchyma or angiogenesis that allow a considerable portion of blood to bypass hepatocytes. These microvascular channels in fibrous septa resist flow more than normal sinusoids and contribute to portal hypertension.
2. *Impaired exchange* between hepatocytes and sinusoidal blood, due to the increase in perisinusoidal extracellular matrix.
3. *Parenchymal nodules*, created by the regenerative attempts of entrapped hepatocytes, and varying in size from less than 3 mm in diameter (micronodular) to several centimeters in diameter (macronodular). These nodules are composed of trabeculae that are typically two or more cells thick, with relative reduction of sinusoidal space. Some expanding nodules may compress the vessels within fibrous septa, contributing to portal hypertension.
4. *Ongoing damage and reorganization* of the hepatic connective tissue, sometimes with areas of portal and arterial thrombosis and segmental ischemia.

Cirrhosis is usually the end-result of several pathogenetic processes, namely cell death (necrosis or apoptosis) and active inflammation with chronic fibrosis. Cirrhosis is not a synonym for chronic hepatic fibrosis, although some insults that cause chronic diffuse fibrosis in the liver can lead to cirrhosis. There is emerging evidence to suggest that hepatic fibrosis is potentially reversible, whereas the vascular changes in cirrhosis are generally regarded as irreversible. The nodular pattern of regeneration in cirrhosis is due to expanding islands of surviving parenchyma entrapped between bands of scar tissue. At the point of liver failure, these regenerative attempts are insufficient to restore function, but the reasons for this are poorly understood. Plausible contributors to this impairment are: altered circulation through the bridging scar tissue; portal hypertension and shunting; deposition of extracellular matrix in the perisinusoidal space; reduced supply of portal growth factors; inhibition of proliferation of extracellular matrix; and toxic inhibition of hepatocellular proliferation. The characteristic fibrovascular septa that bridge portal and central vascular tracts are readily observed in liver sections, but the portal-hepatic shunting therein can be difficult to identify. Clinical evidence for portosystemic shunting, such as impaired ammonia or bile acid clearance, can reflect acquired portocaval shunts that often develop in chronic hepatic fibrosis.

Acquired portosystemic shunting

Any chronic liver disease that causes sufficient fibrosis or atrophy to restrict portal blood flow significantly has the potential to cause the development of collateral portosystemic shunts. These are described below in the section on Vascular factors in hepatic injury and circulatory disorders.

HEPATIC DYSFUNCTION

Hepatic failure is a syndrome that results from inadequate hepatic function. This may be the result of sudden, massive hepatic destruction, or, more frequently, the end-point of progressive liver damage. Failure can be manifest as inadequacy of one or more of the major functions of the liver, especially energy metabolism, detoxification and excretion, bile production, and protein secretion. Liver alterations are often recognized by serum biochemistry, imaging, or liver biopsy, but severe clinical dysfunction or failure is uncommon. The liver is an organ with very large functional capacity and regenerative potential, and many of the plasma proteins produced by the liver are supplied in abundance, so many insults do not cause clinically significant liver dysfunction. Signs of insufficiency do not develop until the reserves in production, supply, and recovery are exhausted, by which time the lesions may be advanced and irreversible. *The central role of the liver in many systemic functions means that liver disease can be manifest as lesions or dysfunctions elsewhere, for example in the brain, skin, blood, and gut.* Also, disease that selectively affects the parenchymal, circulatory, or ductular components can present different clinical syndromes.

Cholestasis and jaundice

- **Cholestasis** is a general term for impedance of bile output from the liver.
- **Jaundice (icterus)** is the discoloration of tissues and body fluids by an excess of bile pigments. *Jaundice can have prehepatic or cholestatic origins.*
- **Prehepatic jaundice** is usually related to overproduction of bilirubin from heme catabolism in hemolytic disease.
- **Cholestatic jaundice** can be hepatic or posthepatic:
  - In *hepatic jaundice*, there may be impaired uptake, metabolism, secretion, and transport of bile pigments within the liver.
  - In *posthepatic jaundice*, cholestasis is related to obstruction of bile flow at the level of the major bile ducts or gallbladder.

Hepatic causes of jaundice can be conveniently subdivided into: (1) failure of hepatocytes to take up or conjugate bilirubin; (2) impaired excretion and transport of conjugated bilirubin in canaliculi or ducts within the liver; and (3) impaired function of hepatocellular adenosine triphosphate-binding cassette transporters and aquaporins that drive the osmotic flow of bile. The bile secretion pathway has multiple steps that can be a target of a particular cholestatic mechanism. These include impaired uptake of unconjugated bilirubin, reduced production of conjugated bilirubin, slow canalicular transport, leakage from the duct system, and physical obstructions at various levels within and beyond the liver. However, the injurious effects of cholestasis mean that it is common for these prehepatic, hepatic, and posthepatic causes to be combined to various degrees in any case of jaundice. In hemolytic disease, for example, the large amount of bilirubin presented to the liver for excretion may overload both the hepatocellular bile uptake and bilirubin conjugation mechanisms, as well as the intracellular and canalicular transport process. In addition, the anemia usually associated with severe hemolytic disease will compromise hepatocellular function and further hamper bilirubin excretion. Hepatocellular accumulation of bile salts in obstructive jaundice interferes with bile conjugation and transport by the smooth endoplasmic reticulum. For these reasons, *the ratio of conjugated to unconjugated bilirubin in hyperbilirubinemia is not a reliable indicator of pathogenesis in most cases of jaundice.*

Bilirubin is conjugated by uridine diphosphate-glucuronyl transferase in the endoplasmic reticulum of hepatocytes. From there it is transported into the bile by the ATP-dependent canalicular multispecific organic anion transporter (cMOAT), a broad-spectrum transporter of many conjugates and bile salts. Hepatocellular membrane damage or ATP depletion reduces this output. Experimentally, there is a direct relationship between bile flow and the secretion of bile salts, glutathione, and bicarbonate by various energy-dependent transporters. Bile salts undergo enterohepatic recycling, involving apical bile salt transport in enterocytes, hepatic bile salt transport at the sinusoidal pole, and bile salt export pumps at the canaliculi. Canaliculi also express various other transporters, including P-glycoprotein (multidrug resistance protein 1 or mdr1) and cMOAT.

Severe diffuse liver necrosis obviously impairs bilirubin conjugation at various levels, but *the severity of jaundice depends on the amount of liver affected, the chronicity, the supply of heme for catabolism, and nonhepatic routes of bilirubin excretion.* Focal liver injury can have substantial local cholestasis but jaundice does not occur because bilirubin can be cleared by unaffected parts of the liver. Similarly, segmental duct obstructions that spare some parts of the liver can lead to cholestasis but not jaundice. Rarely, cholestasis and its indicators can occur in the absence of primary hepatocellular damage and other signs of liver failure. This can occur in toxicity by *Lantana camara* in ruminants and as an idiosyncratic reaction to some drugs.

Intrahepatic cholestasis can also occur through disruption of the structural integrity of the canaliculi, as discussed later for *L. camara* toxicity. Poisons such as phalloidin and cytochalasin that disrupt the polymerization cycle of pericanalicular actin microfilaments are cholestatic because these contractile filaments are required for propelling bile along the canaliculi. Some of the enzymes involved in bile production, alkaline phosphatase and γ-glutamyl transpeptidase, cMOAT, and P-glycoprotein are inducible under the regulation of various nuclear receptors. Cholestasis is a common effect of sepsis, and lipopolysaccharide reduces expression of cMOAT and other transporters. Bile flow also slows during anorexia by mechanisms that are not yet clear. In cats with prolonged anorexia, bile pigments can be observed as canalicular casts in liver sections; these likely reflect secretion of conjugated bilirubin without osmotic flow.

Some of the various transporters and conjugating enzymes involved in bilirubin excretion can be genetically defective. *Congenital hyperbilirubinemia in mutant Southdown sheep* is due to impaired hepatic uptake of unconjugated bilirubin. These animals have few liver lesions, but eventually develop chronic renal disease, the reason for which is not clear. Unconjugated bilirubin levels in the plasma are consistently elevated, but sufficient excretion takes place to prevent them from becoming icteric. They become photosensitized, indicating that excretion of phylloerythrin is less efficient than that of bilirubin.

Hyperbilirubinemia in mutant Corriedale sheep is a defect in excretion of conjugated bilirubin similar to congenital defects in cMOAT in other species. There is also elevation of plasma bilirubin (just over half of which is conjugated), but there is no obvious jaundice. Nevertheless, phylloerythrin excretion in these Corriedales is also sufficiently impaired to produce photosensitization. There is impaired excretion of other conjugated metabolites, and there is pigmentation of the liver by polymerized residues of retained catecholamine metabolites. This pigment, resembling lipofuscin, accumulates in lysosomes in the pericanalicular cytoplasm.

Extrahepatic biliary obstruction initially causes increased pressure in bile ducts with dilation and stasis of content in the smaller radicles in the portal triads. Shortly, however, the parenchymal changes are the same as in intrahepatic cholestasis. Brown bile pigment is present in canaliculi and hepatocyte cytoplasm. The canaliculi are distended and sometimes loculated. The bile plugs are homogeneous. In the hepatocyte cytoplasm, initially in periacinar zones and later in all zones, the pigment is present in large, irregular lysosomes. In long-standing cholestasis, such as may occur with extrahepatic biliary obstruction, cholangioles become hyperplastic and some hepatocytes become hydropic with a reticulated appearance to the cytoplasm and are coarsely impregnated with pigment. Foci of parenchymal necrosis release small lakes of bile that can become surrounded by macrophages and giant cells.

The recognition of jaundice at necropsy sometimes involves differentiation of bile staining of tissues from the yellow staining caused by accumulation of carotenoid pigments. These latter are limited to fat depots and are to be expected in certain species such as horses; sometimes there are breed influences, as seen in the yellow fat of Channel Island breeds of dairy cattle. The yellow discoloration of fat depots of older cats is less well understood; in animals fed ox liver, carotenoids may again be responsible; in others there may be some contribution by ceroid-type pigments. Distinction of the fatty pigments from bile depends on the absence of the former from pale, nonfatty tissues such as periosteum and dermal collagen.

Photosensitization

Photosensitization is the term applied to inflammation of skin (usually unpigmented) due to the action of ultraviolet light of wavelengths 290–400 nm on photodynamic compounds that have become bound to dermal cells. These compounds may have been deposited unchanged in the skin after ingestion, when the normal liver is incapable of excreting the native compound. This is known as **primary photosensitization** and is seen, for example, after ingestion of hypericin in St. John's wort (*Hypericum perforatum*). Photodynamic agents may also be produced by aberrant endogenous metabolism. This can occur, for example, in congenital erythropoietic protoporphyria due to ferrochelatase deficiency in Limousin and Blonde d'Aquitaine calves.

Hepatogenous photosensitization is an almost invariable accompaniment of cholestasis of more than a few days' duration in herbivores that are kept in sunlight and that have been eating green feed. Phylloerythrins are green photoactive catabolites of plant porphyrins (mainly chlorophyll) that are generated by the alimentary microflora of herbivores. Some phylloerythrin is absorbed and normally excreted in the bile by the transporters that eliminate bilirubin. Cholestasis in herbivores can increase retention of phylloerythrin in the blood, and it can result in photosensitive dermatitis of unpigmented areas of skin exposed to sunlight for several days. It is possible, however, for mild photosensitization to appear in the absence of gross or microscopic evidence of cholestasis in animals grazing alfalfa, *Paspalum*, pangola, or *Panicum* grasses; however, it is unclear if these are related to phylloerythrin or other photoactive products of these forages. Absence of serum biochemical evidence for cholestasis or liver damage is used to differentiate primary from secondary photosensitization in these circumstances.

If no hepatic changes can be discerned in photosensitized animals, the possibility of primary photosensitization must be considered, but hepatogenous photosensitization cannot be excluded unless adequate liver function tests are performed.

Hepatic encephalopathy

The neurologic manifestations of hepatic failure are variable and nonspecific; they range from dullness, through complete unawareness and compulsive aimless movement, to mania and generalized convulsions. There is considerable variation in the clinical signs of hepatic encephalopathy between different species. Sheep rarely show more than dullness and central blindness, with perhaps some compulsive chewing movements and tremor. The picture in cattle is similar, but mania and aggression may also be seen, while frenzy is more often recorded in horses. The closer clinical observation accorded to cats and dogs may reveal more subtle behavioral changes, and inappetance and vomiting are commonly reported in carnivores with portosystemic shunts. *In animals with acute hepatic disease, hepatic encephalopathy is a serious sign usually indicating imminent death.* However, in animals with portosystemic shunting or deficiency of a urea cycle enzyme, neurologic signs can be intermittent for many months, and may disappear after appropriate dietary modification.

Ammonia toxicity is responsible for the major part of the clinical signs and the brain lesions. The ammonia is largely of dietary origin, derived from protein and urea by microflora in the large bowel and from hepatic deamination of amino acids. Ammonia is normally removed in the first pass of portal blood through the liver, wherein it is incorporated with carbon dioxide into carbamoyl phosphate that enters the urea cycle. In shunting or hepatic failure, ammonia that bypasses this outcome accumulates in the general circulation and crosses the blood–brain barrier, leading to encephalopathy. Astrocytes are the site of ammonia detoxification in the brain, and eliminate ammonia by the synthesis of glutamine through amidation of glutamate by the enzyme glutamine synthetase. Elevated blood ammonia is postulated to increase the accumulation of glutamine in astrocytes, resulting in osmotic stress and astrocyte swelling, the consequences of which include altered gene expression, changes in multiple neurotransmitter systems, and brain edema. In addition, ammonia can be directly neurotoxic, altering neurotransmission, and potentially contributing to cerebral energy failure through inhibition of α-ketoglutarate dehydrogenase, a rate-limiting enzyme in the tricarboxylic acid cycle. Numerous studies have also implicated alterations in inhibitory and excitatory neurotransmitters, including γ-aminobutyric acid, endogenous benzodiazepines, and serotonin, as well as their receptors. While infusion of ammonia or hyperammonemia due to deficiency of urea cycle enzymes reproduces similar neurologic signs and vacuolar lesions, other noxious substances in the alimentary tract are also believed to contribute to hepatic encephalopathy resulting from liver failure. These include *variably toxic amines, captans, thiols, and short-chain fatty acids* that are normally removed from the portal blood in one passage through the liver after production in the large bowel. In cases of complete liver failure, hypoglycemic convulsions may result from failure of glucose synthesis.

The microscopic lesions of hepatic encephalopathy are subtle and variable, likely because necropsy examinations of the brain are performed at various time points of chronicity and clinical severity. There are also significant differences in the microscopic lesions between species. *The hallmark of hepatic encephalopathy is Alzheimer type II astrocytosis, in which astrocytes are enlarged with swollen nuclei, margination of chromatin and prominent nucleoli.* Other common changes are microcavitation or spongiosis of myelinated tracts of the cerebrum (internal capsule), thalamus, hypothalamus, and cerebellum, although this is not a consistent finding in cats, ruminants, or horses (see Vol. 1, Nervous system). These changes can be observed best in animals with chronic liver disease and portosystemic shunts; in animals with acute liver failure, the brain lesions can be minimal. In addition, similar changes in the brain can be observed with renal disease, including the formation of Alzheimer type II cells.

Hemorrhage and liver failure

Hemorrhagic diathesis characterized by widespread ecchymoses and petechiae can occur when the liver is the site of rapid consumption of plasma-clotting factors. The liver is the source of plasma proteins involved in the clotting cascade, but these are normally supplied in substantial excess, and are further inducible as part of the acute-phase response to inflammation. Thus, *coagulopathy with hemorrhage is most likely to occur when there is acute liver necrosis*, for example, in acute canine hepatitis or acetaminophen toxicity. Under these conditions, there is significant intrahepatic consumption of clotting factors at sites of endothelial necrosis in the damaged liver. While the damaged liver also fails to resupply the clotting factors, this is probably a minor contributing influence. *In more chronic liver diseases with hypoproteinemia, coagulation tests may be prolonged but hemorrhagic diathesis is unlikely*, unless there is an additional demand for hemostasis, for example during the trauma of surgery. Consumption of clotting factors can also occur in septic diseases that affect the liver and other tissues.

Nephropathy

Acute liver failure may be accompanied by oliguria and biochemical indications of renal failure. The kidneys are large, moist, and stained by bile pigments that are present histologically in tubular epithelium and luminal casts. The renal component is referred to as **biliary nephrosis**. The mechanisms are not known but may represent a perfusion deficit with shunting of blood from cortex to medulla. **Hepatorenal syndrome** is a complication of advanced cirrhosis in humans, characterized by renal failure in which there are no intrinsic renal morphologic or functional causes. The pathogenesis of hepatorenal syndrome is related to *deterioration in effective arterial blood volume due to splanchnic arterial vasodilation and reduced venous return and cardiac output.* Intense compensatory vasoconstriction of the renal circulation results in decreased glomerular filtration and resultant renal failure.

Edema and ascites

Ascites (retention of excess low-protein peritoneal fluid) is a feature of chronic liver failure, but is more frequently associated with systemic venous congestion (e.g., right-side heart failure) or hypoproteinemia secondary to protein-losing renal or alimentary tract conditions. Retention of peritoneal fluid can also sometimes result from mechanical obstructions to mesenteric and peritoneal lymphatics by inflammatory or neoplastic lesions. Peritoneal fluids with a higher protein and cell content that accumulate in various abdominal inflammatory conditions are considered exudative inflammatory conditions (see section on peritonitis, in Vol. 2, Alimentary system).

Reduced synthesis of albumin and globulins by the failing liver can reduce vascular oncotic pressure, but edema resulting from this mechanism is generalized. The pathogenesis of ascites in the absence of systemic edema in chronic liver failure is more complex. *It is likely that ascites in advanced liver disease is influenced by both mechanical and dynamic influences on blood flow through a damaged liver.* For example, fibrosis and nodular expansion can impede blood flow. There are also dynamic influences of stellate cell contraction and hepatic vein smooth muscle that affect portal venous pressure. Ascites is often observed in severe portal hypertension, for example in arterioportal fistulae, but the increase in pressure per se might not be directly responsible for fluid retention. In some experimental models, portal hypertension induced by portal stricture does not cause ascites, and clinical portal hypertension is not necessarily associated with ascites. Also, passive venous congestion of the spleen and viscera are not obvious features of portal hypertension. Lymphatic drainage through the mesenteric lymph nodes and thoracic duct remains available for removal of peritoneal fluids in most examples of liver disease with ascites. These various findings suggest that *ascites might result from other hemodynamic dysfunctions that affect splanchnic arterial blood* *flow.* Various factors that regulate splanchnic blood flow, including histamine, nitric oxide, endothelins, atrial natriuretic peptide, calcitonin gene-regulated peptide, tumor necrosis factor-α, substance P, and vasoactive intestinal peptide are produced locally in the splanchnic circulation and are normally cleared by the liver. Increased generation or impaired clearance by a failing liver could contribute to increases in splanchnic arteriolar blood flow, increased hydrostatic pressure in the splanchnic capillaries, overproduction of splanchnic lymph, increased portal pressure, sodium retention, and increased cardiac output. Also, some vasoactive mediators induce contraction of stellate cells and intrahepatic vascular smooth muscle, so impaired clearance might dynamically affect hepatic perfusion. Others could restrict venous outflow through established portosystemic collateral veins. In humans, there is evidence that autonomic regulation of splanchnic blood flow is also dysregulated in patients with ascites.

Hypoglobulinemias

The liver is a major part of the innate immune system, clearing microorganisms and immune complexes from the circulation, and supplying various plasma proteins that are important in host defense, including plasma antiproteinases that limit activity of some microbial toxins or endogenous proteinases activated during coagulation, complement activation, inflammation, and tissue repair. The liver also produces various effector molecules of the innate immune system, including complement proteins, antimicrobial lectins, and mineral transport proteins that restrict iron and copper from pathogens. In spite of the importance of this spectrum of innate immune functions, *increased susceptibility to infection and inflammatory disease is not generally recognized as a sequel to liver failure.*

Hepatocutaneous syndrome

An *idiopathic vacuolar hepatopathy with parenchymal collapse and nodular regeneration* has been reported in dogs and cats that have been presented clinically with **superficial necrolytic dermatitis**. Some cases have been considered under the clinical term "*hepatocutaneous syndrome.*" The skin disease resembles necrolytic migratory erythema in humans, a well-defined paraneoplastic syndrome typically associated with hyperglucagonemia secondary to glucagon-secreting pancreatic neoplasia, but also reported in individuals with hepatitis, cirrhosis, celiac disease, chronic malabsorption, and inflammatory bowel disease. *In dogs, superficial necrolytic dermatitis is most commonly associated with liver disease*, including severe vacuolar hepatopathy, idiopathic hepatocellular collapse, and hepatopathy secondary to anticonvulsant drug administration, and more rarely with pancreatic adenocarcinoma and gastric carcinoma.

Clinical presentation is typically because of the dermatitis; skin lesions include erythema, crusting, exudation, ulceration, and alopecia, involving footpads, periocular, perioral, anogenital regions, and pressure points. The dermatologic lesions are described more fully in Vol. 1, Skin and appendages. Affected dogs have depressed plasma amino acid concentrations, inconsistent elevations of plasma glucagon levels, and may also become diabetic. The liver of affected dogs is usually grossly nodular, resembling cirrhosis (Fig. 2.40); however, histologically, there is typically moderate to severe vacuolation of hepatocytes, with parenchymal collapse accompanied by nodular regeneration. Inflammation, necrosis, and fibrosis are not usually prominent. Although some studies report fibrosis typical of cirrhosis, more characteristically there is a network of reticulin and fine collagen fibers representing the remnants of collapsed hepatic lobules, with proliferation of bile ductules. The vacuolated hepatocytes stain with oil red O for lipids. *The hepatic lesions have been suggested to support an underlying metabolic, hormonal, or toxic etiology.* In humans, persistent hyperglucagonemia stimulates prolonged gluconeogenesis, resulting in secondary hypoaminoacidemia. Although hepatic insufficiency can increase glucagon levels in animal models, in dogs, the link between liver disease and hypoaminoacidemia remains unclear, although a hypermetabolic state with exaggerated amino acid catabolism has been suggested. Other biologically active molecules that are normally cleared by the normal liver or generated by a damaged liver should also be considered.

POSTMORTEM AND AGONAL CHANGES IN LIVER

The liver, rich in nutrients for bacteria and freely exposed to agonal invaders from the intestine, *undergoes postmortem decomposition very rapidly*. Gas bubbles generated by anaerobic saprophytes form first in the hepatic blood vessels, but soon suffuse large portions of the organ. The vessels and adjacent parenchyma are stained by hemoglobin. The substance of the organ becomes soft and clay-like, and the formation of putrefactive gases may make it foamy. On the capsular surface, irregular, pale foci are visible; they resemble infarcts or fatty areas but can be observed to increase in size and, microscopically, are without cellular reaction. Bacilli are present in large numbers in such foci. Green-black pigmentation of the capsule and superficial parenchyma occurs where the liver is in contact with gut. The lobes surrounding the gallbladder are stained brown with bile.

There is much microscopic structural change in the liver approaching and immediately following death. In general, the confusing autolytic changes mainly affect the regions around the hepatic venules. Indeed, cytologic criteria of necrosis in periacinar necrosis are more reliably found in animals that have been allowed to die or that are killed in extremis. Shrinkage of liver cells and disappearance of many with widening of periacinar sinusoids are seen after death with hepatic congestion. *Dissociation of liver cells* may be complete, with every cell in every cord separated and free from adjacent cells so architectural patterns are lost. The early expression of this change affects periacinar cells, which become detached, rounded in contour, condensed, and hyperchromatic. The dissociation is particularly seen in feline panleukopenia and leptospirosis, but it is related somewhat to postmortem change.

VASCULAR FACTORS IN HEPATIC INJURY AND CIRCULATORY DISORDERS

Hepatic artery

The hepatic artery brings approximately one-third of the afferent hepatic blood supply; this enters a peribiliary capillary plexus in the portal triads, before anastomosis with the portal veins and entry into the sinusoids. Anomalous origin of the arterial supply is common. Hepatic arterial occlusions occur rather commonly in animals but usually involve small intrahepatic branches and are of little consequence. Large segments of the liver may be necrotic in cats as a result of thrombosis of the aorta and hepatic artery. Verminous arteritis may occlude the hepatic artery in horses. The extent of necrosis depends on how completely the obstruction excludes collateral circulation and also on the oxygen tension of the portal blood. Ischemic areas of liver can be sequestered, but in some instances bacteria such as clostridia and other anaerobes can flourish and release potent toxins with systemic effects.

Portal vein

The portal vein drains the splanchnic viscera and normally contributes two-thirds of hepatic blood flow. Portal blood flow in some animals is streamlined, such that blood from the stomach and duodenum flows preferentially to the left lobes, whereas blood from the jejunum and ileum flows to the right lobes. Streamlining may account for the different regional distributions sometimes observed with metastatic tumors and infections. The umbilical vein usually delivers to the left lobe, so hematogenous umbilical infections tend to localize in the left lobe.

The liver cannot regulate portal venous flow, so hepatic blood flow is largely dependent on the portal venous supply balanced by arterial supply controlled by the sympathetic nervous system. If portal blood flow increases, the hepatic arterial supply is reduced, or vice versa. Hepatic blood thus flows evenly through the sinusoids under a very-low-pressure gradient. The liver can receive approximately 25% of the cardiac output, event though it represents about 2.5% of body mass. Approximately 25% of the weight of the liver in situ is blood. Reduction in the volume of hepatic flow leads to atrophy of deprived segments of liver.

Obstruction of the portal vein, if sudden and complete, produces a condition akin to strangulation of the gut, and death occurs quickly without significant hepatic change. Obstruction of a large branch of the portal vein in cattle, sheep, and cats leads to acute ischemia of a wedge of tissue in which necrosis may be zonal or massive. Obstruction to many small portal radicles is common, with necrosis of many acini. It is evident that if a collateral supply develops and oxygenation remains adequate, obstruction of portal radicles will have no immediate effect on the hepatic parenchyma, save perhaps to make it more sensitive to toxic injury. There is, however, a long-term effect, probably nutritional. The parenchyma in the affected lobe, deprived of hepatotrophic factors, loses much of its regenerative power and atrophies fairly rapidly, allowing condensation and scarification of the stromal tissues.

Acute increase in pressure in the portal vein may occur in any severe episode of widespread acute hepatic necrosis; the cause appears to be simple obstruction of the sinusoidal flow by thrombosis and actual sinusoidal disruption. In such animals there is severe acute congestion of the liver, slight ascites, free fibrin accumulations in the abdomen (not the firm capsular adhesions seen in passive congestion), and distended portal lymphatics.

Obstruction of the extrahepatic portal vein is quite uncommon. External compression may occur due to adjacent abscesses or neoplasms. **Portal vein thrombosis** may be caused by damage to the portal vein by local inflammatory processes, or be associated with states of hypercoagulability or retrograde intravascular growth of hepatic neoplasms. In dogs, thrombosis of the portal vein has been associated with distant neoplasia, immune-mediated hemolytic anemia, protein-losing nephropathy and enteropathy, pancreatitis, peritonitis, and corticosteroid administration. Portal vein obstructions of slow development are expected to lead to portal hypertension and its consequences. Atresia of the portal vein can be demonstrated in some cases of extrahepatic congenital portosystemic shunting, but this is not associated with portal hypertension. Primary hypoplasia of the portal vein is discussed in the section on Developmental anomalies, above.

Obstruction to intrahepatic portal vessels is a consequence of progressive fibrosing lesions of primary hepatic disease centered on the portal triads. The small portal vessels may be obliterated in the proliferative portal lesions and new connections may be established, including small functional arteriovenous communications. Regenerative hepatic nodules and neoplasms may deform and compress portal vessels in some locations.

Portal hypertension is caused by sustained impedance to portal flow anywhere along the path from the portal vein to the right heart.

- **Prehepatic** portal hypertension is associated with occlusion of the portal vein by thrombi, stenosis, extraluminal compression, or as a result of congenital portal vein hypoplasia.
- **Intrahepatic** sites of increased vascular resistance may be further divided into:
  - *presinusoidal* (including intrahepatic portal vein hypoplasia, intrahepatic arterioportal fistulae, periportal neoplastic or inflammatory infiltrates, and periportal fibrosis);
  - *sinusoidal* (cirrhosis or long-term inflammatory disease with fibrosis and capillarization perisinusoidal, neoplastic infiltrations); and
  - *postsinusoidal* (perivenular fibrosis, veno-occlusive disease).
- **Posthepatic** hypertension is associated with increased resistance to blood flow in the major hepatic veins, caudal vena cava or right heart, and includes obstruction of the hepatic veins, neoplastic occlusion (e.g., pheochromocytoma or aortic body tumors), and kinking of the caudal vena cava, associated with abdominal trauma. The complications of portal hypertension include acquired portosystemic shunts, congestive splenomegaly, and ascites.

Efferent hepatic vessels

Efferent flow begins in the sinusoids and passes through terminal hepatic venules and larger hepatic veins to the vena cava. In the sinusoidal network, flow is interconnected in many directions. However, in normal conditions lobule outflow is closely matched to inflow. In dogs, hepatic veins have substantial smooth-muscle sphincters that regulate outflow, but these are less obvious in other species. Splanchnic engorgement during anesthesia and anaphylaxis is an indication that these smooth muscles control canine hepatic outflow in a dynamic manner. There are likely to be important differences in the structure and function of outflow veins in humans due to the postural influences on hepatic venous pressure.

The amount and arrangement of conventional connective tissue around the terminal hepatic veins and larger hepatic veins influence the patterns of fibrosis observed in various patterns of periacinar injury. Hypoxia from anemia, heart failure, or shock can cause periacinar necrosis, as can many toxic agents that are preferentially injurious to zone 3 hepatocytes. Necrosis at this level elicits a tissue repair response involving the fibrous connective tissue along the terminal hepatic venules. Tissue fibrosis can increase the resistance of the hepatic parenchyma and slow local outflow. This can redirect sinusoidal blood to alternative less-affected venules, unless the necrosis is extensive. Within the sinusoids, flow may become quicker in sinusoids that are capillarized by the deposition of extracellular matrix in the perisinusoidal space, but the net flow of blood through such fibrotic liver is reduced. **Hepatic veno-occlusive disease** *is the obliteration of small intrahepatic veins associated with damage to the sinusoidal endothelium, accumulation of red cells and fibrin in the subintimal space, and subsequent subendothelial fibrosis.* This pattern of postnecrotic fibrosis can contribute to the development of portal hypertension. Veno-occlusive disease is a feature of pyrrolizidine toxicosis in humans ingesting these alkaloids in so-called bush tea. In domestic animals, occlusive changes in terminal venules are notable in poisoning by ragwort (*Senecio jacobea*) in cattle and also in dogs treated experimentally with the pyrrolizidine alkaloid monocrotaline. Veno-occlusive disease has also been reported as a consequence of prolonged chemotherapy, radiotherapy, and bone marrow transplantation in humans, and similarly in dogs treated with irradiation or busulphan. Idiopathic veno-occlusive disease with perivenular fibrosis around central and sublobular veins, causing Budd–Chiari-like syndrome (see below), has also been reported as a rare occurrence in the dog and cat. Total or subtotal obliteration of central hepatic or sublobular veins by subintimal accumulation of collagen and fibrous tissue has also been reported in captive snow leopards and cheetahs.

Obstruction at the level of the large hepatic veins can occasionally occur due to suppurative phlebitis, hepatic abscesses, neoplasms, or other physical obstacles that impinge on the hepatic veins. Similar space-occupying lesions in or around the vena cava in the diaphragm or mediastinum can also affect hepatic outflow, along with systemic venous return. However, *by far the most common cause of diffuse hepatic congestion is cardiac failure.*

Passive venous congestion of the liver denotes elevation of pressure in the hepatic veins and venules relative to the pressure in the portal venules. This may be due to congestive heart failure as a result of congenital or acquired cardiac disease or pericardial disease, or, much less frequently, to partial obstruction of the larger hepatic veins or caudal vena cava by abscess, neoplasm, thrombus, or severe heartworm disease (dirofilariasis). Passive congestion is also seen when part of the liver is incarcerated as a result of diaphragmatic hernia, or when a lobe is subjected to chronic partial torsion.
